Adaptation within natural systems has been considered a possibility only recently; it results in part from considerations of coastal resilience. An example is provided by coral reefs. Applying the two types of adaptation discussed in Box 6-5, Pittock (1999) suggests that “autonomous adaptation” is what reefs would do by themselves, whereas “planned adaptation” involves conscious human interference to assist in the persistence of some desirable characteristics of the coral reef system. The first type of adaptation may involve more rapid growth of coral, changes in species composition, or evolution of particular species in response to changed temperatures or other conditions. Planned adaptation might involve “seeding” of particular reefs with species adapted to higher temperatures or attempts to limit increased sediment, pollutant, or freshwater flow onto reefs. For reef communities that presently are under stress and are likely to be particularly vulnerable to climate change, the design of managed (or planned) adaptation should involve an evaluation of the extent of autonomous adaptation that can be expected given the current and probable future status of the reef system.

Box 6-6. Adaptation through Managed Retreat

Managed retreat generally is designed to avoid hazards and prevent ecosystems from being squeezed between development and the advancing sea. The most common mechanisms for managed retreat are *setbacks* that require new development to be a minimum distance from the shore, *density restrictions* that limit development, and *rolling easement* policies that allow development on the condition that it be removed to enable wetlands to migrate landward (Titus, 1998). These strategies may all become elements of an integrated coastal management policy. Setback could be considered a managed retreat strategy, particularly in cases in which the setback line is shifted inland as the shoreline recedes. Other measures of managed retreat can include conditional phased-out development, withdrawal of government subsidies, and denial of flood insurance.

Examples of managed retreat and related measures as adaptation to sea-level rise include the following:

- **Canada:** New Brunswick completed remapping of the entire coast of the province to delineate the landward limit of coastal features. Setback for new development is defined from this limit. Some other provinces have adopted a variety of setback policies, based on estimates of future coastal retreat.
- **Barbados:** A national statute establishes a minimum building setback along sandy coasts of 30 m from mean high-water mark; along coastal cliffs the setback is 10 m from the undercut portion of the cliff.
- **Aruba and Antigua:** Setback established at 50 m inland from high-water mark.
- **Sri Lanka:** Setback areas and *no-build zones* identified in Coastal Zone Management Plan. Minimum setbacks of 60 m from line of mean sea level are regarded as good planning practice.
- **United Kingdom:** House of Commons in 1998 endorsed the concept of *managed realignment* as the preferred long-term strategy for coastal defense in some areas.
- **United States:** The states of Maine, Massachusetts, Rhode Island, and South Carolina have implemented various forms of *rolling easement* policies to ensure that wetlands and beaches can migrate inland as sea level rises.
- **Australia:** Several states have coastal setback and minimum elevation policies, including those to accommodate potential sea-level rise and storm surge. In South Australia, setbacks take into account the 100-year erosional trend plus the effect of a 0.3-m sea-level rise to 2050. Building sites should be above storm-surge flood level for the 100-year return interval.

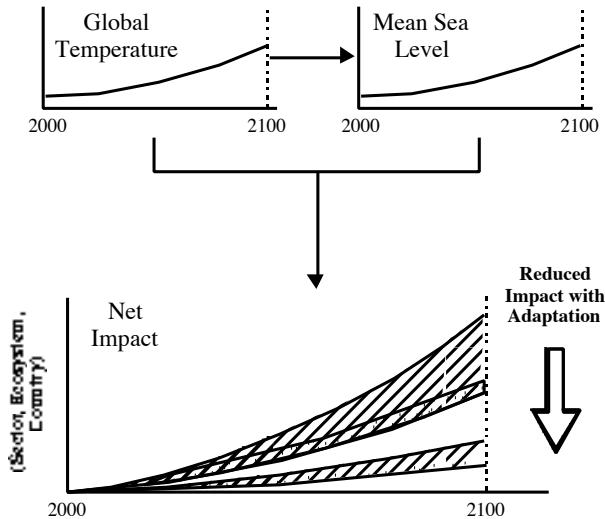

Figure 6-1: The role of adaptation in reducing potential impacts in the coastal zone from global temperature increase and sea-level rise to the year 2100. The bottom panel is a schematic that shows the increasing cost or loss to an economic sector, ecosystem, or country. The area shown by cross-hatch indicates the range of possible impacts and how net impact can be reduced with adaptation. Stipple within the cross-hatched areas indicates the importance of sector, ecosystem, or country resilience as a component of net impact.

Some adaptation measures handle uncertainty better than others. For example, beach nourishment can be implemented as relative sea level rises and therefore is more flexible than a dike or seawall; expansion of the latter may require removal or addition of structures. Any move from “hard” (e.g., seawall) to “soft” (e.g., beach nourishment) shore protection measures must be accompanied, however, by a much better understanding of coastal processes that prevail in the area (Leafe *et al.*, 1998). Rolling easements are more robust than setbacks (Titus, 1998) but may be impractical for market or cultural reasons. Maddrell (1996) found that over time scales of 35 and 100 years, managed coastal retreat is the most cost-effective adaptation option in reducing flood risks and protection costs for nuclear power facilities on the shingle foreland at Dungeness, UK. Flood insurance can discourage a flexible response if rates are kept artificially low or fixed at the time of initial construction, as they are in the United States (Crowell *et al.*, 1999).

Reevaluations of the efficacy of hard shore protection schemes as a long-term response to climate change and sea-level rise are increasingly being undertaken. Chao and Hobbs (1997) have considered the role of decision analysis of shore protection under climate change uncertainty; Pope (1997) has suggested several ways of responding to coastal erosion and flooding that have relevance in the context of climate change. Documented changes in tidal characteristics as a result of the construction of sea dikes and seawalls also have implications for shore protection in the face of rising sea level. Several alternatives to seawalls

have been suggested as adaptation measures to reduce coastal erosion and saltwater intrusion from rising sea levels in Shanghai, including improving drainage quality and channel capacity, increasing pumping facilities to reduce the water table, constructing a barrier across the mouth of the river, and developing new crops that are tolerant of a higher groundwater table (Chen and Zong, 1999).

It also should be noted, however, that Doornkamp (1998) has argued that in some situations past management decisions about human activities in the coastal zone (including flood defenses, occupancy of flood-prone lands, extraction of groundwater and natural gas) have had an impact on relative land and sea levels and have done more to increase the risk of coastal flooding than damage that can be assigned to global warming to date.

6.6.4. Adaptation in Marine Ecosystems

Adaptation of the fishing industry to climate change is closely connected with investigations of the consequences of the effect of climatic anomalies and climate change scenarios. Because the effects of changes in climate factors will have different consequences for various species, development of special measures aimed at adaptation of the fish industry is regional in character and falls into the category of important socioeconomic problems.

Possible adverse effects of climate change can be aggravated by an inadequate utilization of fish reserves. For example, if a fish stock decreases as a result of the combined effect of climate change and overfishing, and the commercial catch remains high, species abundance may decrease dramatically and the commercial catch may become unprofitable. In such circumstances, some measures may need to be taken to protect fish reserves, such as the precautionary measures suggested by O’Brien *et al.* (2000) to give the North Sea cod fishery a chance to rebuild. Several sustainability indicators of marine capture species are discussed in Garcia and Staples (2000). Aquaculture also can be regarded as an adaptation; though to be an ecologically sustainable industry, it must emphasize an integrated approach to management (Carvalho and Clarke, 1998). Another adaptation is fish stock enhancement through ocean ranching (see Section 6.3.6).

Fish reserves rank among the most important economic resources in many countries. Approximately 95% of the world catch falls within the 200-mile economic zones of maritime states. Environmental impacts in those zones as a consequence of climate change could affect the catch volume and national economies. It should be noted that gains and losses at different levels of social organization can occur not only as a consequence of climate change but also as a result of human society’s responses to this change. In some regions, for instance, special measures may be taken to promote adaptation and to reduce the negative consequences of climate change—which adds another dimension to fish management.

Adaptation measures that are relevant to the fishing industry may include the following:

- Establishment of national and international fishery management institutions that will be able to manage expected changes
- Expansion of aquaculture as a way of meeting increasing demand for seafoods of an increasing world population
- Support for innovative research and integrated management of fisheries within coastal and open marine ecosystems
- Improvement and development of an integrated monitoring system in the most productive areas, aimed at obtaining systematic information on hydrophysical, hydrochemical, and hydrobiological processes
- Organization of data banks on the results of integrated ecological monitoring to identify anthropogenic changes, including climate change, and predict fish productivity
- Modification and improvement of the technology of the fishing industry and management of the fish trade as required to adapt to climate change
- Organization of marine biosphere reserves and protected areas for the habitat of marine mammals
- Use of emerging predictive information related to natural climate variability (e.g., ENSO) to support fishery management and planning.

Adoption of some adaptation options to the potential impacts of climate change is not a panacea, however. Fish often are transboundary resources in that they may cross international and state boundaries in their oceanic migrations. In the case of Pacific salmon, for instance, problems have arisen in the agreement between the United States and Canada that are attributable in part to the effects of large-scale climate fluctuations (see Box 6-1). Miller (2000) suggests that the Pacific salmon case demonstrates that it may not be a simple matter for the fishing industry or governments to respond effectively to climate change. She concludes that adaptation is difficult when a resource is exploited by multiple competing users who possess incomplete information about the resource. If their incentives to cooperate are disrupted by the impacts of climate variation, dysfunctional breakdown in management rather than efficient adaptation may occur (Miller, 2000).

6.7. Synthesis and Integration

This chapter is concerned with two closely related but geographically different environments. The oceans—which cover more than 70% of the Earth's surface—are open, expansive, and spatially continuous. By contrast, coastal zones are long, narrow, and discontinuous. As a result, climate change impacts on marine ecosystems may be accommodated more readily in the open ocean (e.g., by migration) than in coastal regions, where mobility is restricted, there are more environmental constraints, and human impacts may be more severe.

The potential biological and physical impacts of climate change and sea-level rise vary considerably between the oceans and coastal regions. The least vulnerable coastal and marine ecosystems have low exposure or high resilience to the impacts. Similarly, coastal communities and marine-based economic sectors that have low exposure or high adaptive capacity will be least affected. Countries, communities, and individuals in the higher range of economic well-being have access to technology, insurance, construction capital, transportation, communication, social support systems, and other assets that enhance their adaptive capacity. Those that do not have access have limited adaptive capacity. Unequal access to adaptation options, therefore unequal vulnerability, are attributable largely to different socioeconomic conditions. Poor adaptation or “maladaptation” also may lead to increased impacts and vulnerability in the future, with implications for intergenerational equity. These concepts are summarized in Figure 6-2.

Whereas the estimated costs of sea-level rise and other climate-related impacts in developed countries typically are limited to

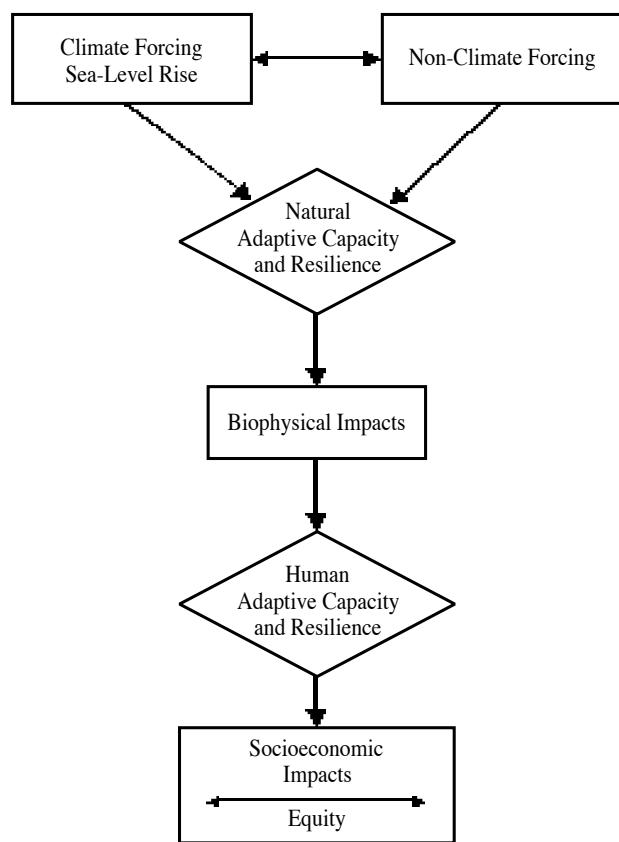

Figure 6-2: The role of natural and human adaptive capacity and resilience on the socioeconomic impacts of climate change following climate forcing, sea-level rise, and nonclimate forcing. The equity arrow in the bottom box indicates that impacts will not be uniform and that there will be wide inequalities, depending on socioeconomic conditions.

property losses, the reported outcomes of coastal floods in developing countries often include disease and loss of life. Vulnerability assessments in the developing world often do not consider the costs of business interruptions and failures, social disruption and dislocation, health care, evacuation, or relocation. A full accounting of the economic costs associated with lost, diminished, or disrupted lives would require estimates of the economic productivity losses they represent. Because this level of cost accounting is rare in developing countries, inequities may be significantly underestimated.

Turner *et al.* (1996) note that coastal zones are under increasing stress because of an interrelated set of planning failures, including information, economic market, and policy intervention failures. Moreover, moves toward integrated coastal management are urgently required to guide the co-evolution of natural and human systems. Acknowledging that forecasts of sea-level rise have been scaled down, they note that (1) much uncertainty remains over, for example, combined storm-surge and other events; and (2) within the socioeconomic analyses of the problem, resource valuations have been only partial at best and have failed to incorporate sensitivity analysis in terms of the discount rates utilized. They suggest that these factors would indicate an underestimation of potential damage costs and conclude that a precautionary approach is justified, based on the need to act ahead of adequate information acquisition and use economically efficient resource pricing and proactive coastal planning.

More recently, Turner *et al.* (1998) have aimed to elicit the main forces influencing the development of coastal areas and the means available to assess present use and manage future exploitation of the coastal zone. Their way of analyzing coastal change and resource management is through the pressure-state-impact-responses (P-S-I-R) conceptual framework. They analyze a variety of pressures and trends (including climate change, population changes, port development, marine aggregate extraction, and pollution). In the P-S-I-R framework, all of these factors are examined in the context of sustainable use of coastal resources and on the basis of an interdisciplinary ecological economics approach.

Several changes that might be expected to accelerate with global warming in the future already are detected in some regions and systems. Examples include global sea-level rise, increases in SST, and regional decreases in sea-ice cover. Impacts associated with these changes have included shoreline erosion, wetland loss, seawater intrusion into freshwater lenses, and some impacts on coral reefs. These impacts provide contemporary analogs for potential impacts in the future, recognizing that future changes and impacts may be of greater magnitude than those experienced so far and that changes and impacts may become more geographically widespread, including expansion into new areas that have not experienced such conditions previously. The contemporary environment gives us some insights into potential ecosystem impacts, some idea of costs, and some experience with potentially useful adaptation strategies.

We have found very few studies that indicate benefits of climate change and sea-level rise in coastal and marine systems. Recent studies, however, point to possible economic benefits from adaptation measures. Such benefits are likely to be restricted, particularly in the areas most at risk—including a large number of developing countries. Furthermore, the extent of impacts in those regions and the range of potentially effective adaptation measures remain poorly defined. Although there is growing acceptance of the need for integrated management strategies, progress has been slow in implementing these concepts in many jurisdictions. Part of the reason is limited development of understanding and tools for integrated assessment and management needs, involving various levels and aspects of integration, each of which may be difficult to implement. For instance, integration between the different disciplines involved in coastal and marine impact and adaptation analysis has been identified as a key issue by Capobianco *et al.* (1999). This and other integration needs are summarized in Box 6-7.

Some progress has been made since the SAR in developing and refining methodologies for assessing impacts of sea-level rise. Environments under particular threat include deltas, low coastal plains, coastal barriers, heavily utilized seas, tropical reefs and mangroves, and high-latitude coasts where impacts from warming may occur sooner or more rapidly.

Some topic areas rarely have been addressed, however. For instance, only a few case studies attempt to integrate potential impacts of sea-level rise and increased precipitation and runoff in coastal watersheds in assessing coastal vulnerability. Techniques for similar integration between biophysical and socioeconomic impacts are developing slowly, while human development and population growth in many regions have increased socioeconomic vulnerability and decreased the resilience of coastal ecosystems. Few studies provide details or any quantitative measures. We believe that integrated assessment and management of open marine and coastal ecosystems and a better understanding of their interaction with human development could lead to improvements in the quality of sustainable development strategies.

Global climate change will affect the biogeophysical characteristics of the oceans and coasts, modifying their ecological structure and affecting their ability to sustain coastal residents and communities. Impacts in the coastal zone will reflect local geological, ecological, and socioeconomic conditions within a broader regional or global context. Shorelines are inherently dynamic, responding to short- and long-term variability and trends in sea level, wave energy, sediment supply, and other forcing. Coastal communities—particularly on low-lying deltas, atolls, and reef islands—face threats of inundation, increased flooding, and saltwater intrusion, with impacts on health and safety, water supply, artisanal fisheries, agriculture, aquaculture, property, transportation links, and other infrastructure. In some coastal areas, particularly in developed nations, a shift in emphasis toward managed retreat appears to have gained momentum. Enhancement of biophysical and socioeconomic resilience in coastal regions increasingly is regarded as a cost-effective and

Box 6-7 Integration for Assessment and Management of Marine and Coastal Systems

Integration of marine, terrestrial, and coastal processes and a better understanding of their interactions with human development could lead to substantial improvements in the quality of adaptation strategies. Integration must take place in several areas, including the following:

- **Subject/topic-area integration** (e.g., climate-change related stresses plus non-climate stresses; biophysical and socioeconomic susceptibility, resilience, vulnerability, impacts)
- **Geographical/spatial integration** (e.g., linkages between terrestrial, coastal, and oceanic systems and feedbacks; global, regional, local scales)
- **Methodological integration** (e.g., integrating physical, social, and economic models)
- **Integrated implications** (e.g., for sustainable development, intergenerational equity and ethics)
- **Integration of science, impacts, and policy.**

Estuaries as an example of the need for integration

Changes in salinity, temperature, sea level, tides, and freshwater inflows to estuaries are considered likely consequences of climate change on estuarine systems. Estuaries are among the world's most-stressed ecosystems because of their close proximity to areas of population growth and development. Understanding of regional differences in the physical drivers that will cause changes in estuarine ecosystems and their ecological functions is limited. Uncertainty also exists regarding changes to dissolved carbon, nutrient delivery and pollutant loading, and their interactions. For example, intensive forestry and agriculture that may be implemented as some regions adapt to climatic change could increase the transport of nutrients such as nitrogen and phosphorus to estuaries. Linkage of hydrological models for surface waters with ocean-atmosphere models is needed to integrate marine and terrestrial ecosystem change. Estuaries illustrate the need for vertical integration among the foregoing subject areas and issues, spatial scales, and methodological approaches, with implications for habitation and use of coastal environments and ecosystems.

desirable adaptive strategy. Growing recognition of the role of the climate-ocean system in the management of fish stocks is leading to new adaptive strategies that are based on determination of acceptable removable percentages in relation to climate change and stock resilience.

Vulnerability to climate change and sea-level rise has been documented for a variety of coastal settings via common methodologies developed in the early 1990s; these assessments have confirmed the spatial and temporal variability of coastal vulnerability at national and regional levels. New conceptual frameworks include biophysical and socioeconomic impacts and highlight adaptation and resilience as components of vulnerability. Recent advances include models to evaluate economic costs and benefits that incorporate market and nonmarket values. Sustainable approaches to integrated coastal management can now include new financial accounting approaches that include ecological services and traditional cultural values. Nevertheless, adaptive choices will be conditioned by policy criteria and development objectives, requiring researchers and policymakers to work toward a commonly acceptable framework for adaptation.

EXECUTIVE SUMMARY

Climate change will affect human settlements against a very dynamic background of other environmental and socioeconomic factors. Human settlements are expected to be among the sectors that could be most easily adapted to climate change, given appropriate planning and foresight and appropriate technical, institutional, and political capacity. This chapter covers the same general topic areas as Chapters 11 and 12 of the Second Assessment Report (SAR); however, this chapter analyzes a wider variety of settlement types, provides a specific assessment of uncertainty and confidence in findings and adaptive capacity in human settlements, and places much of the discussion in a context of development, sustainability, and equity (DSE) (see Munasinghe, 2000). Energy and industry are treated as part of settlements. Figure 7-1 characterizes the conclusions of this chapter on two dimensions: scientific support (evidence available in the literature to support the finding) and consensus in that literature. Both scales are described more fully in Box 1-1 of Chapter 1 and in Moss and Schneider (2000).

Major Effects on Human Settlements

Infrastructure would have increased vulnerability to urban flooding and landslides (established but incomplete). Detailed

modeling of rainfall event frequency and intensity in the context of global warming has been linked to increased intensity and frequency of urban flooding, with considerable damage to infrastructure (see Chapters 4, 8, and 10–15). Although not definitive for any part of the world, the model-based analysis is plausible and demonstrates that flooding could be an increased threat for riverine settlements under climate change. More predictable is loss of snow pack in many regions, combined with more winter flooding. Landslides are a current threat in many hilly areas and could be more so with more intense rainfall events.

Tropical cyclones would be more destructive under climate change (established but incomplete). Close behind floods and landslides are tropical cyclones (hurricanes or typhoons), which could have higher peak intensity in a warmer world with warmer oceans (see Chapters 3 and 8, and TAR WGI Chapter 10). Tropical cyclones combine the effects of heavy rainfall, high winds, storm surge, and sea-level rise in coastal areas and can be disruptive far inland but are not as universally distributed as floods and landslides.

Water supplies for human settlements would be vulnerable to increased warming, dryness, and flooding (established but

Figure 7-1: Human settlements impacts, categorized by state of scientific knowledge.

(incomplete). There is reasonable consensus among experts that settlements in regions of the world that already are water-deficient (e.g., much of north Africa, the Middle East, southwest Asia, portions of western North America, and some Pacific islands) would face still higher demands for water with a warmer climate, with no obvious low-cost ways in which to obtain increased physical supplies. Observations on current water supply balances tend to back up this conclusion (see Chapters 4 and 10–13). However, theory and model output, though consistent with this view, are too weak quantitatively to offer much support, especially for urban areas. Repeated flooding also could create water quality problems in other areas.

Fire danger in settlements could increase with climate change (speculative for resource-dependent settlements; established but incomplete for infrastructure). Examples include forested and wildland/urban fringes in boreal regions (e.g., Canada, Alaska, Russia) and in Mediterranean climates in both hemispheres (e.g., California, southern Spain and France, and Australia) that could be affected (see Chapters 11, 12, 13, and 15). Although general circulation model (GCM)-projected summer climate in many regions looks similar to the hot, dry “fire weather” in many warm years of recent memory and economic activity in forests sometimes is restricted to reduce fire danger, impacts on the resource base have not been demonstrated, research has not shown what future fuel loadings would be, and it is unclear whether future economic activity and settlement infrastructure would be more vulnerable to fire.

Hail and windstorm could cause more damage to settlements (speculative). Although there is potential for more (and more severe) extreme weather episodes in a warmer atmosphere, modeling and data have not demonstrated a higher incidence of storms or of more severe storms (see Chapters 3, 8, 12, and 15).

Agroindustry and artisanal fisheries are sensitive to and in many cases vulnerable to climate change (well-established overall; competing explanations in specific regions). This conclusion dates back to the First Assessment Report (FAR). Additional studies and analysis conducted in the past 10 years have modified the details of the conclusion but have not overturned it. As described in Chapter 5, agriculture itself is sensitive to climate change. In some cases, yields may be reduced by as much as several tens of percent as a result of hotter weather, greater evaporation, and lower precipitation in mid-continent growing regions in particular. However, other regions may benefit, with higher yields possible. Impacts on agricultural processors and suppliers would tend to follow the impacts on agriculture itself. Changes in ocean conditions from El Niño episodes have demonstrated that changes such as ocean warming have substantial impacts on the locations and types of species available for fisheries, especially artisanal fisheries, but other regions could benefit (see Chapters 5, 6, and 10–17).

Heat waves would have more serious effects on human health and productivity (competing explanations). The impact of heat waves is most severe on the weakest parts of the populations

(old, chronically ill, very young) that are not acclimated, but effects on future overall death rates are less clear (see Chapters 9, 11, 13, 14, and 15). Because anthropogenic warming is projected to be greater at night than during the day, it would deprive sufferers of nighttime relief. Projections for several temperate climates show increased risk of severe heat waves (Chapter 3). As the weather becomes very warm, economic productivity of unprotected and outdoor populations declines.

Sea-level rise increases the cost/vulnerability of infrastructure and coastal resource-based industry (well-established for infrastructure; established but incomplete for resources). Although the amount of sea-level rise to be expected as a result of global warming by any given date and in any given location is uncertain, some studies are beginning to discuss likely ranges and probability distributions (e.g., Titus and Narayanan, 1995). The sensitivity of human infrastructure in coastal zones to given levels of sea-level rise is backed by theory, model results, and data on current rates of increase. In addition, several industries—such as tourism and recreation (the principal industry in many island economies)—are dependent on coastal resources (see Chapters 6, 8, and 10–17). Effective types of adaptive responses also are known in some circumstances, but vulnerability with adaptation is difficult to assess because the capacity and will to respond are uncertain or in doubt in many instances.

Energy demand in some locations is sensitive, and parts of the supply system are vulnerable (well-established). Modeling, theory, data, and expert opinion all say that warming of 1–5°C would considerably reduce the amount of energy that would be needed to heat buildings at mid- and high latitudes and altitudes, whereas cooling energy use would increase (see Chapters 10–15 and 17). The net overall impact on energy use would depend on local circumstances. If temperature increases take place primarily at night and during winter months, heating demand would be smaller and the increase in demand for energy for cooling and irrigation would be somewhat smaller than otherwise. Future climate is expected to include more intense rainfall events (which would require more conservative water storage strategies to prevent flood damage), greater probability of water deficits (less hydroelectric production), and less precipitation falling as snow (less water available during warm months) (see Chapter 4). All three factors point to less (or, at least, less flexible) hydroelectric capacity at current powerhouses. Reduced flows in rivers and higher temperatures reduce the capabilities of thermal electric generation, and high temperatures may reduce transmission capabilities as well.

There will be increased air and water pollution impacts (competing explanations). Climate change could contribute to water pollution problems in human settlements through drought or flooding, although not by simple increases in flow (which offers more dilution for pollutants). If droughts and floods become more frequent (see Chapter 3), so would instances of poor water quality (see Chapters 4, 10–15, and 17). Air pollution could be exacerbated if climate change alters the stability of air sheds and permits greater buildup of

atmospheric pollutants (see Chapters 10–15). However, the outcomes remain largely theoretical, unsupported by data or modeling.

Infrastructure in permafrost regions is vulnerable to warming (well-established). Data from circumpolar regions and model results suggest that permafrost areas would see some melting of permafrost. Permafrost melting is a threat to infrastructure in these regions because of increased landslides and loss of foundation stability for structures, as well as increased damage from freeze-thaw cycles, among other impacts. In addition, melting permafrost is thought to be a source of methane (CH_4) and carbon dioxide (CO_2) gases (see Chapters 15 and 16).

Heat island effects could increase heat stress, increase summer energy demand, and reduce winter energy demand (competing explanations). As discussed in Chapters 3 and 9, heat waves may increase in frequency and severity in a warmer world, leading directly to increases in mortality among sensitive populations that are not acclimated. Heat island effects exacerbate the oppressive effects of heat waves by increasing temperatures experienced in the summer by up to several °C; at the same time, increased demand for air conditioning increases the demand for electricity and the severity of the heat island itself through thermal electric production. Winter energy use for heating would be reduced by the same phenomenon (see Chapters 11, 13, 14, and 15). Effects in specific regions are far less clear.

Other Observations

Local capacity is critical to successful adaptation (well-established). Adaptation means local tuning of settlements to a changing environment, not just warmer temperatures. Urban experts are unanimous that successful environmental adaptation cannot occur without locally based, technically and institutionally

competent, and politically supported leadership. Local adaptive capacity generally is strongly correlated with the wealth, human capital, and institutional strength of the settlement. In addition, capacity depends in part on the settlement's access to national resources. Attempts to impose environmental solutions on settlements from the international or national level frequently have been maladapted to local circumstances. The most effective sustainable solutions are strongly supported and often developed locally, with technical assistance and institutional support from higher level bodies (see Chapters 10, 11, 14, 17, and 18).

Nonclimate effects are likely to be more important than climate change (competing explanations). The effects of climate change would occur against a background of other socioeconomic and environmental change that is itself very uncertain and complex (see Chapter 3). Model results, the current rate of environmental change, and economic theory all suggest that climate would be a relatively small additional uncertainty for most human settlements. Climate change in isolation also is unlikely to be as important a factor for DSE effects as other aspects of development, such as economic and technological change. In combination with other stresses from other processes such as population growth, however, climate change is likely to exacerbate total stresses in a multi-stress context. Particularly important could be effects of climate change on equity because relatively advantaged parts of global and local societies are likely to have better coping capacities than less advantaged parts.

Managing growth to ensure that it is sustainable and equitably distributed currently is a greater problem for most countries than the impacts of climate change. However, some experts are not in agreement on this point for the future, pointing out that the economic models do not show climate feedback to the economy and that climate effects are so uncertain that they could well dominate in some regions, especially by the end of the 21st century.

7.1. Introduction and Purpose

Humans live in a wide variety of settlements, ranging from hunter-gatherer camps and villages of a handful of families to modern megacities and metropolitan regions of tens of millions of inhabitants. Settlement economic and social structure—and the components of infrastructure that support settlements: energy, water supply, transportation, drains, waste disposal, and so forth—have varying degrees of vulnerability to climate change and generally are evolving far more quickly than the natural environment. Settlements can be affected directly through changes in human health and infrastructure and indirectly through impacts on the environment, natural resources, and local industries such as tourism or agriculture. Furthermore, these effects on human settlements theoretically could lead to tertiary impacts such as altered land use, redistribution of population and activities to other regions, and altered trade patterns among regions, resulting in still further changes in natural resources and other activities. Tertiary effects, however, are largely speculative at the current state of knowledge. Some of these tertiary effects could be either positive or negative at the regional level.

7.1.1. Overview of the SAR

This chapter builds on Chapters 11 and 12 of the IPCC Second Assessment Report (IPCC, 1996), and on the findings in the *Special Report on Regional Impacts of Climate Change* (RICC) (IPCC, 1998). The SAR identifies the most vulnerable types of communities, many examples of which are documented in RICC. The SAR states that the most vulnerable communities are not only poorer coastal and agrarian communities in arid areas identified in the First Assessment Report in 1990; they also include a great variety of settlements, most of them informal or illegal and with a predominance of low-income residents, built on hazardous sites such as wetlands or steep hillsides in or around many urban areas in the developing world.

The SAR and RICC also identify two categories of climate-sensitive industries. Sectors with activities that are sensitive to climate include construction, transportation operations and infrastructure, energy transportation and transmission, offshore oil and gas, thermal power generation, water availability for industry, pollution control, coastal-sited industry, and tourism and recreation. Sectors in which economic activity is dependent on climate-sensitive resources are agroindustry, biomass, and other renewable energy.

The SAR notes that infrastructure typically is designed to tolerate a reasonable level of variability within the climate regime that existed when it was designed and built. However, climate change could affect both average conditions and the probability of extreme events.

This Third Assessment Report (TAR) confirms most of these conclusions. However, the analyses in the SAR and RICC are concerned mostly with identifying and documenting potential

effects. The TAR assesses their relative importance and the certainty/confidence of the conclusions reached.

Although literature published since the SAR was issued has not changed the catalog of potential impacts, much more has been learned about the quantitative details of many of the effects, which are being studied more systematically than was true 5–10 years ago. The results are becoming somewhat more quantitative, and it is becoming possible to assign confidence ratings to many of the effects for the first time. More also is known concerning adaptation options. It is now possible to describe many of the options more quantitatively and in the context of development, sustainability, and equity (see Munasinghe, 2000). Energy, industry, and infrastructure are treated as part of settlements in the TAR.

7.1.2. Overview of Types of Effects

Human settlements integrate many climate impacts initially felt in other sectors and differ from each other in geographic location, size, economic circumstances, and technical, political, institutional, and social capacities. Climate affects human settlements by one of three major pathways, which provides an organizational structure for the settlements effects discussion in this chapter:

- 1) Changes in productive capacity (e.g., in agriculture or fisheries) or changes in market demand for goods and services produced in settlements (including demand from those living nearby and from tourism). The importance of this impact depends on the range of economic alternatives. Rural settlements generally depend on one or two resources, whereas urban settlements usually (but not always) have a broader array of alternative resources. Impacts also depend on the adaptive capacity of the settlement, which in turn depends on socioeconomic factors such as the wealth, human capital, and institutional capability of the settlement.
- 2) Physical infrastructure or services may be directly affected (e.g., by flooding). Concentration of population and infrastructure in urban areas can mean higher numbers of persons and value of physical capital at risk, although there also are many economies of scale and proximity that help to assure well-managed infrastructure and provision of services such as fire protection and may help reduce risk. Smaller settlements (including villages and small urban centers) and many larger urban centers in Africa and much of Asia, Latin America, and the Caribbean often have less wealth, political power, and institutional capacity to reduce risks in this way.
- 3) Populations may be directly affected through extreme weather, changes in health status, or migration. Extreme weather episodes may lead to changes in deaths, injuries, or illness. Health status may improve as a result of less cold stress, for example, or deteriorate as a result of more heat stress and disease.

The discussion of impacts on human settlements, energy, and industry that follows begins with a discussion of nonclimate trends that affect settlements. The discussion then assesses potential impacts of climate change on three general types of settlements: resource-dependent settlements; riverine, coastal, and steplands settlements; and urban settlements. This discussion is followed by a discussion of impacts on the energy sector and industries that may be particularly affected by climate change and an assessment of potential impacts on infrastructure. The chapter next discusses management and adaptation issues and integration of impacts across sectors, and it closes with a review of science and information needs.

7.2. State of Knowledge Regarding Climate Change Impacts on Human Populations

The TAR differs from the two previous assessments in that the literature has begun to quantify several of the climate-related risks to human settlements that previously were identified only in qualitative terms. Additional attention and research has been devoted to adaptation mechanisms that provide resistance to climate-related impacts and ability to recover from them. Several economic and social trends that are specific to development and change in human settlements will interact with the effects of climate change in the future and may exacerbate or mitigate the effects of climate change alone.

7.2.1. Nonclimate Trends Affecting Vulnerability to Climate

Population growth: Except for parts of Europe and the Russian Federation, most regions are expected to experience population growth. Although *Special Report on Emission Scenarios* (SRES) marker scenarios in Chapter 3 do not span the entire realm of possibilities and have not been assigned probabilities, they do show that under plausible conditions, future regional population growth rates will range from modest (Europe and North America, where projected rates are just above or below replacement) to 3% or more (portions of Latin America and especially Africa).

Urbanization (proportion of population living in urban areas) is expected to continue, especially in the developing world. Close to half of the world's population now lives in urban areas, and the likely trend toward a more urban world means that the impacts of climate change on human settlements, if they occur, increasingly will affect urban populations. The most rapid urban growth rates are occurring in the developing world, where urban populations are estimated to be growing at 2.7% yr⁻¹, compared to 0.5% yr⁻¹ in more developed regions (UN, 2000). There also is a growing concentration of population in cities with more than 1 million inhabitants. The number of such cities worldwide grew from 80 in 1950 to more than 300 by 1990 and is expected to exceed 500 by 2010 (UNCHS, 1996; UN, 2000). Most cities with more than 1 million inhabitants are now in the developing world, although—as in more developed regions—they are heavily concentrated in its largest economies (UNCHS, 1996).

Cities also are reaching unprecedented sizes. However, the future world may be less dominated by “megacities” (cities of more than 10 million population) than previously predicted. Megacities are likely to be smaller than previously predicted and still contain a small proportion of the world's population—less than 4% in 1990, the last date for which there is census data for most nations (UNCHS, 1996; UN, 2000). Most of the world's urban population live in the 40,000–50,000 urban centers with fewer than 1 million inhabitants (UNCHS, 1996). In 1990, cities with more than 1 million inhabitants had just more than one-third of the world's urban population and just more than one-seventh of its total population (UN, 2000). Urban population increases were particularly sharp in the second half of the 20th century in some regions where urbanization had been held down by policy, such as China (Institute of Land Development and Regional Economy, State Planning Committee, 1998). Trends toward urbanization mean that the impacts of climate change on human settlements in most countries, if they occur, increasingly will affect urban populations, not rural or traditional settlements.

Poverty is becoming increasingly urbanized, as a growing proportion of the population suffering from absolute poverty lives in urban areas. In more developed regions and in much of Latin America (e.g., 36% in Latin America—ECLAC, 2000), poverty is concentrated in urban areas. In other regions, the number of rural poor still exceeds the number of urban poor, although the proportion of absolute poor living in urban areas is growing. In addition, the scale and depth of urban poverty frequently is underestimated, in part because official income-based poverty lines are set too low in relation to the cost of living (or the income needed to avoid deprivation) in most urban centers and in part because no provision is made to include housing conditions, access to services, assets, and aspects of social exclusion within most government poverty definitions (Satterthwaite 1997). Where it occurs, urban poverty reduces the capacity of urban populations to take action to adapt to climate change; poverty also may exacerbate many of its effects.

Market systems and privatization increasingly are being used to provide new infrastructure and maintain older systems (World Bank, 1994), giving government a smaller direct role in providing infrastructure for energy, environmental residuals, communications, and other key urban services. Governments that are trying to adapt settlements to climate change increasingly may have to work indirectly through markets and regulation of private providers to adapt buildings and infrastructure to climate change.

Energy systems are changing in some places, helping to determine which mechanisms are salient in human settlements impacts (Schipper and Meyers, 1992; Hall *et al.*, 1993; World Energy Council, 1993a):

- Use of biomass fuels for cooking and space heating in many developing countries remains significant, which has added to deforestation and environmental destruction

- in some places but not others (Leach and Mearns, 1989; Tiffen and Mortimore, 1992). Biomass growth may be stimulated by warming, if precipitation remains adequate, but may fall otherwise.
- The increase in natural gas use in Europe and North America (and nuclear power in France) over the past 2 decades has held down the rate of use of coal and oil and has reduced coal use by 20% in western Europe. Accelerated coal use is expected in developing Asia (EIA, 1998). Much of the increase is related to increasing electricity demand, which would be compounded by climate warming.
 - An increasing market share for electricity is occurring in new homes in all regions. Between 1995 and 2020, the world's annual consumption of electricity is projected to rise from 12 trillion to 23 trillion kWh. The greatest increases are expected in developing Asia and in Central and South America (EIA, 1998). Climate warming in these regions would increase the demand for space cooling, which is primarily fueled by electricity, at the same time that rapid electrification already is stretching capacity.
 - Air conditioning in the commercial sector already accounts for a greater proportion of final energy demand than in the residential sector in developed countries. Commercial sector energy use also is increasing as a percentage of the total in developing countries. Some of this is a result of computerization of commerce.

Transportation activity and associated energy consumption are growing very rapidly in nearly every region. Except for economies in transition, the amount of goods traveling by road increased between 1990 and 1996. The increases were 50% or more, and total paved roadways worldwide rose from 39 to 46% of the total (World Bank, 1999). In all Organisation for Economic Cooperation and Development (OECD) countries, car ownership continues to rise steadily, but much of the growth in vehicle ownership is expected in developing countries and transition economies—especially in east Asia and the Pacific, and especially in urban areas (World Resources Institute, 1996). This trend contributes to local air pollution (which can be exacerbated by warm weather episodes) and to greenhouse gas (GHG) emissions.

A poleward intensification of agricultural, forestry, and mining activities is occurring, resulting in increased population and intensified settlement patterns in Canada's mid-north, for example, and even in arctic areas. Climate change could profoundly affect settlements in these regions, if climate change is greater toward the poles (Cohen, 1997). For example, some arctic and subarctic activities such as mining depend on snow roads, which would have to be replaced with more conventional transport.

Impact of urban wealth: Many of the worst city-level problems—such as sanitation and water supply—have been addressed in high-income cities such as those in Europe and North America, but not in many developing world cities (WHO, 1992; Hardoy

et al., 2000; McGranahan and Satterthwaite, 2000). A wealthy city can more easily afford the public finance and administration required to regulate more perceptible forms of pollution than a poor one. However, although the ambient environment of high-income cities may be more benign in terms of health impacts of pollution, these cities exert a far greater toll on the regional and global environment (UNCHS, 1996).

7.2.2 Sensitivity and Vulnerability of Human Settlements to Direct and Indirect Impacts of Climate Change

This chapter highlights some of the key processes through which climate impacts could occur; individual regional chapters categorize settlements based on size, location, or complete coverage of the population.

As a result of research that has been done on settlements since the SAR and RICC, as well as additional interpretation of older research, it is becoming clearer where many of the key vulnerabilities of human settlements, energy, and industry occur, although it is still very difficult to provide more than qualitative guidance. Table 7-1 provides an overview of these vulnerabilities for the years between approximately 2050 and 2080; much of the available literature concentrates on the effects of climate change of a magnitude roughly corresponding to that time period. The table divides human settlements into general size categories and economic function in a hierarchy of settlements. The table emphasizes the most salient effects that appear to be characteristic of certain types of settlements and mechanisms that might make the settlements more or less sensitive to climate change.

Implications of climate change for development of settlements, energy, and industry are highly location-specific. For instance, as shown in Table 7-1, climate change is more likely to have important impacts on the development of settlements in resource-dependent regions or coastal or riverine locations. Most of the concerns are about possible negative impacts on development (e.g., on the comparative advantage of a settlement for economic growth compared with other locations), although impacts on some areas are likely to be positive. Impacts on sustainability depend very largely on how climate change interacts with other processes related to multiple stresses and opportunities—such as economic, demographic, and technological change—except in low-lying areas that may be subject to sea-level rise or polar regions whose physical conditions will be more directly affected by global warming. Equity effects are of considerable concern because the ability to cope with negative impacts or to take advantage of positive impacts is likely to be greater among advantaged groups than among disadvantaged groups, within regions and between regions. As a result, climate change has the potential to enlarge equity-related gaps in human settlements and systems.

In general, country studies that have been completed since the SAR was published have provided more specific regional details concerning sensitivities and vulnerabilities to climate

Table 7-1. Impacts of climate change on human settlements, by impact type and settlement type (impact mechanism). Typeface indicates source of rating: Bold indicates direct evidence or study; italics indicates direct inference from similar impacts; and plain text indicates logical conclusion from settlement type, but cannot be directly corroborated from a study or inferred from similar impacts. Impacts generally are based on 2xCO₂ scenarios or studies describing the impact of current weather events (analog) but have been placed in context of the IPCC transient scenarios for the mid- to late 21st century.

change (e.g., IPCC, 1998; see Chapters 10–17). Because of variability in settlements across the world, it is virtually impossible to create rankings of impacts that do not contain numerous exceptions. However, the impact ratings in Table 7-1 provide a framework that can be adapted to local circumstances. Table 7-1 shows the author team's judgments, based on the available literature, about the vulnerability of different types of settlement to various aspects of climate change. The horizontal axis differentiates vulnerability according to type of settlement, capacity to adapt, and the mechanism through which the settlement is affected by climate change. For example, the resource base of settlements that are economically dependent on activities such as agriculture, forestry, fishing, hunting and gathering, or tourism may be affected; housing and infrastructure may be affected in coastal areas, riverine floodplains, islands that are sensitive to flooding, steeplands that are sensitive to landslides, and urban/wildland boundaries that are sensitive to fires; and the health and productivity of urban populations may be affected directly through air pollution, heat waves, and heat island effects. The vertical axis identifies 12 different types of climate change impact in descending order of global importance. Vulnerabilities are rated as low, medium, or high magnitude as described in Box 7-1. The information in Table 7-1 generally is presented as a range, reflecting the diversity of settlements within each broad class. The final column shows the level of confidence that the author team assigns to each type of climate impact. Table 7-1 depicts vulnerabilities for the years between approximately 2050 and 2080. Much of the available human settlements literature is silent on the timing of impacts; the choice of the years 2050–2080 in Table 7-1 is based on the size of the impacts or amount of climate change addressed in the literature reviewed by the author team. Table 7-1 takes into account the number and type of settlements affected worldwide and the likely strength of these effects by mid-to-late 21st century, as well as the financial, technical, and institutional capacity of settlements to respond. Figure 7-2 provides confidence scores for the impacts on individual scales described more fully in Box 7-1 (see also Moss and Schneider, 2000).

The negative impacts in Table 7-1 generally would be less negative or even positive in some regions before 2050 but

greater than shown and becoming more negative in more regions after 2100. The table is not intended to show that only specific types of settlements would be harmed (or helped) in certain ways by certain changes; it is intended to show that settlements of certain types probably are likely to be affected by certain impact mechanisms and are likely to be particularly vulnerable to certain types of climate changes or conditions.

Many of the effects in Table 7-1 are quite likely for some communities in some places; other effects are extremely uncertain, controversial, or inapplicable. Key articles that underlie the ratings are provided as footnotes to Table 7-1.

Confidence in the main conclusions of this chapter in Table 7-1 is rated in Figure 7-2 from very high (5) to very low (1) in four dimensions: support from theory, support from model results, support from data or trends in the existing environment, and the degree of consensus in expert opinion. Although these ratings reflect the subjective judgments of the chapter's authors concerning the weight that can be given to each element that increases confidence in the findings, the figure is useful in depicting the dimensions of the underlying literature that are particularly strong or weak in support of the chapter's conclusions. Confidence levels vary widely:

- Results that are very high on all dimensions, as in the expected vulnerability of at least some coastal settlements to sea-level rise
- Results that are very strong on most dimensions, such as local capacity being very important in practice for successful adaptation to environmental problems (even though the theory has not really been applied to climate change)
- Results that are very high on one or two dimensions, such as human health effects, where theory and model results are strongly supportive of the conclusion, whereas data are weaker or ambiguous and experts are somewhat divided
- Results for which there is some evidence, but most of it is only modestly supportive; one or two modestly

Box 7-1. Development of Scales for Assessing Potential Vulnerability of Human Settlements to Effects of Climate Change and Confidence in the Certainty of Impacts

Climate affects the stability of resources that support human systems. One way to assess the potential impact of climate change on human systems is by using a qualitative scale that expresses the vulnerability of settlements to various kinds of climate effects (e.g., floods) in terms of how potentially disruptive these climate effects are expected to be for various types of human settlements (based on differences in their economic base, location, size, and adaptability). The definitions in the rating system below are derived from standard environmental impact assessment language and are intended to apply to local climate impacts. However, the scale may be used nationally if the nation is small and homogeneous or if most of the population lives in settlements of a certain type.

Magnitude Ratings (Size of Impacts)

- *Low*: Impacts of changed climate are not distinguishable from normal background variability in weather impacts or there is little noticeable effect.
- *Moderate*: Resources or sectors are affected noticeably, even substantially, but the effect is not destabilizing and recovery is rapid.
- *High*: Impacts are large and sometimes catastrophic. Resources or settlements are destabilized, with little hope for near-term recovery.

A semi-quantitative approach is used with a 5-point confidence scale to indicate the certainty of the effects of climate change. The author team subjectively rated confidence on the basis of the literature in four dimensions: consensus among experts (*consensus*), the extent to which underlying theory and data is developed (*theory*), the quality of model results (*model results*), and the consistency of observational evidence (*observations*). The scores were used to create a four-sided polygon, as shown in Figure 7-2 on the facing page. All four dimensions were weighted equally to determine the area of the polygon and an overall confidence score.

$$\text{Polygon Area} = 0.5 \cdot (\text{Theory} \cdot \text{Observations} + \text{Observations} \cdot \text{Model Results} + \text{Model Results} \cdot \text{Consensus} + \text{Consensus} \cdot \text{Theory})$$

The overall confidence score assigned was based on the area of the polygon. For example, to rate a 4 for “high confidence,” the polygon had to have an area between 16 and 25—the area of a polygon with ratings of greater than 4 but less than 5 on all four dimensions.

Confidence Rating (Certainty of Impacts)

- 1) *Very Low*: Impacts are extremely difficult to predict (confidence < 5%) (*Polygon Area* = 0–8).
- 2) *Low*: Impacts are regularly much greater or less than the median value (confidence < 33%) (*Polygon Area* = 8–18).
- 3) *Medium*: Impacts are regularly greater or less than the median value (confidence ≥ 33%) (*Polygon Area* = 18–32).
- 4) *High*: There is noticeable variation in the size of impacts (confidence ≥ 67%) (*Polygon Area* = 32–50).
- 5) *Very High*: There is little variation in impact among scenarios, within a settlement type (confidence = 95%) (*Polygon Area* = 50).

strong elements lead to the conclusion, but confidence is weak.

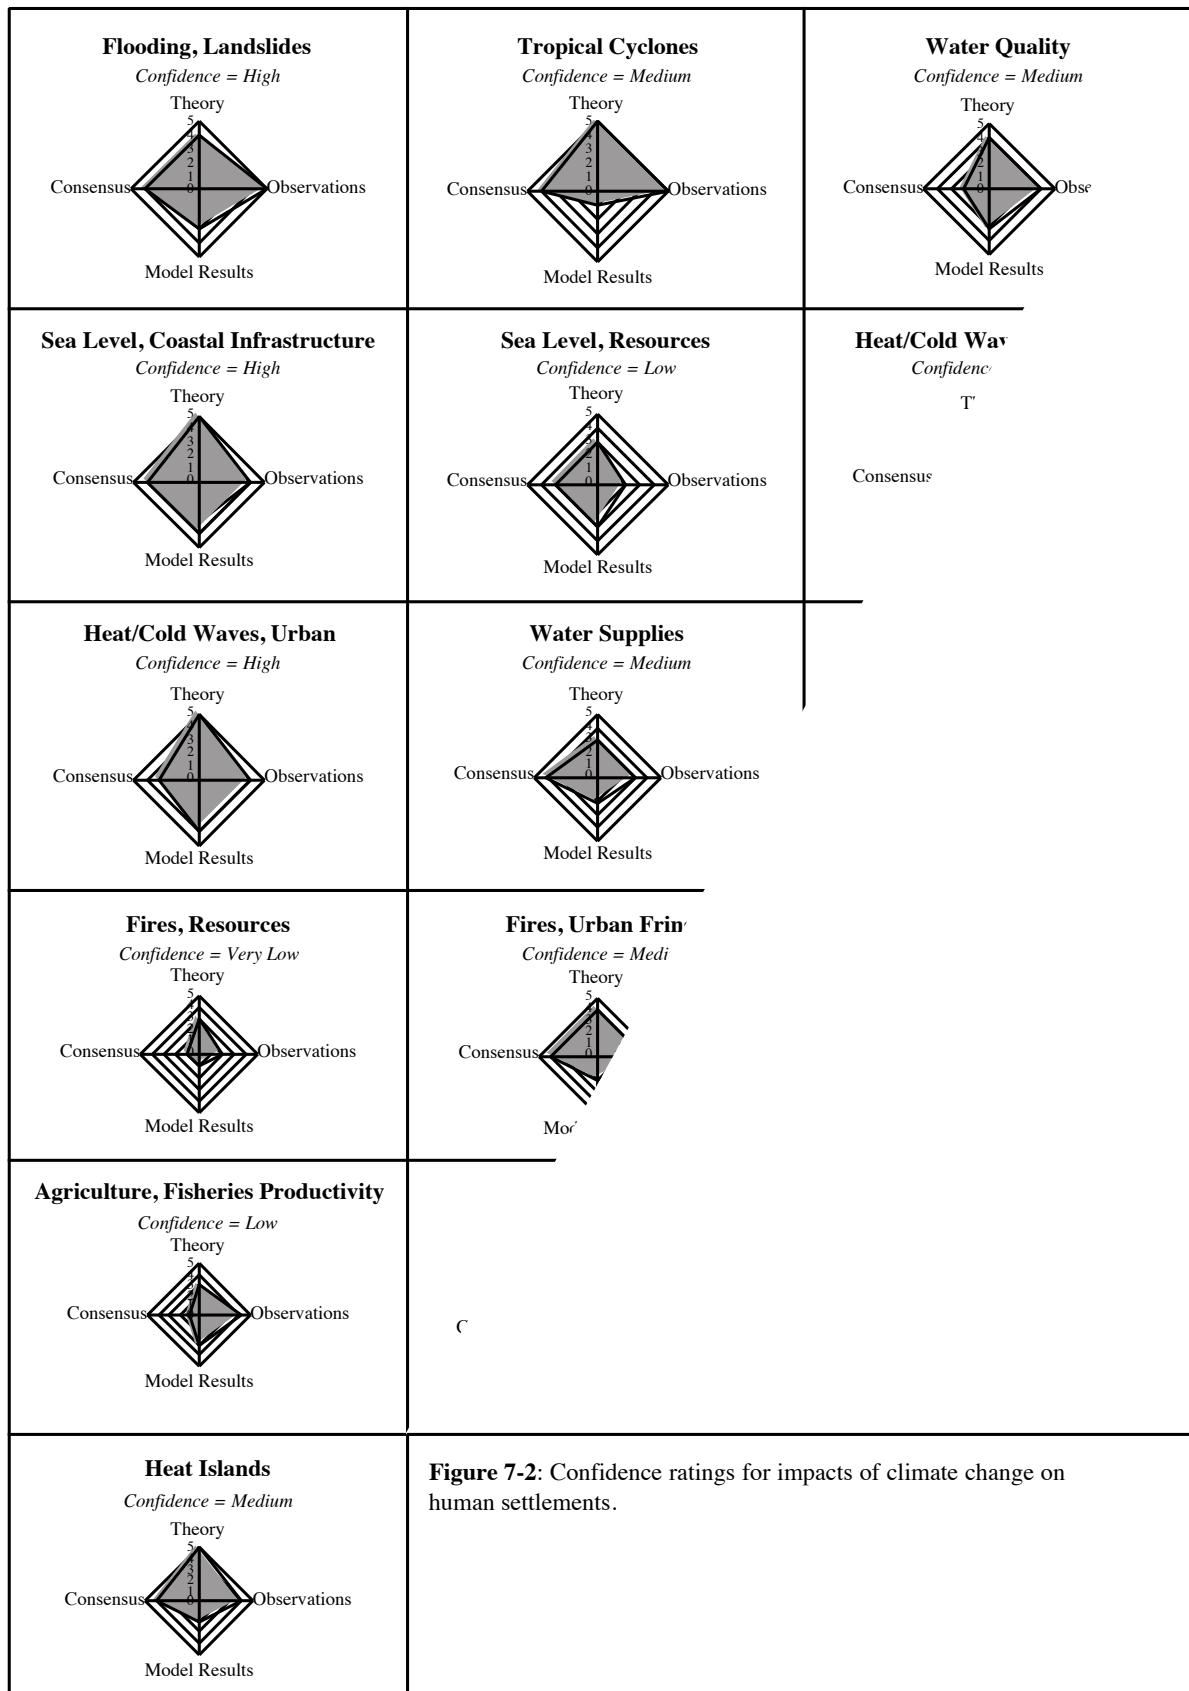

agricultural settlements, artisanal fishing communities, and the like. The issues are somewhat different in different locations, as indicated below.

7.2.2.1. Resource-Dependent Settlements

What makes resource-dependent settlements unique is the extent to which they are dependent on and tuned to the natural resources of the region and the extent to which they are vulnerable to changes in these natural resources. Resource dependency emphasizes the impact of climate change on the economic livelihood of inhabitants. An extreme form of resource-dependent settlements are settlements of traditional peoples, including hunter-gatherer communities, subsistence

7.2.2.1.2. Arid and semi-arid regions

Human societies have been developing by adaptation to the arid environment in desert regions for centuries. An example is the oasis water supply system called *karez*, *qanats*, or *foggaras*. For adaptation or mitigation, windbreaks are a powerful method to reduce the effects of the strong winds, dust storms, and sand dune movements (Du *et al.*, 1996; Maki *et al.*, 1997a,b). In addition, trees in windbreaks provide materials for

construction and firewood for people, keep a better hygienic environment in the settlements, and improve conditions for crops and livestock.

Social vulnerabilities in arid regions include low income among residents as a result of underdevelopment of industry in the oases, difficulty in telecommunication and transportation between oases, and growing human pressure on the limited land base, as illustrated by the scarcity of suitable irrigable land in oases in the Taklimakan Desert, northwest China (Yoshino, 1997c, 1998). On the northern rim of the Taklimakan desert, only 4–4.5% of the land is available for irrigation, and only about 2% on the south rim is available. Although these limit values vary from desert to desert because of the amount of available water, scarcity of suitable land is a vulnerable feature of settlements in all arid regions. In northern Africa, southwest Asia, and parts of the Middle East, there is a belt of entire countries that currently suffer from inadequate water supplies (see Chapter 4). Increasing temperatures and reduction in rainfall would further limit these settlements.

Climate change could reduce water availability in the semi-arid savanna ecosystem of tropical Africa, affecting farmers, herders, and tourist-industry workers, which in turn will impact human settlements. Conflict already occurs between herdsmen and farmers in this region, and the SAR discussed the impacts on major cities when people leave the land (see Chapter 10).

Small settlements in arid/semi-arid regions occasionally confront a higher risk of damage by flooding than their counterparts in more humid environments. This is usually because of the longer return periods or rarity of extreme rainfall. However, in a warmer world the frequency of these intense storms in semi-arid and arid regions may increase (Smith, 1996; Smith and Handmer, 1996; Smith *et al.*, 1999). During extreme rainfall events, houses, roads, irrigation systems, and other constructions are destroyed and human settlements in oases are isolated because telecommunication and traffic connections are broken. Because settlements have been adapted to dry conditions, the total numbers of deaths and the total amount of damages caused by drought and other impacts of dry conditions often are smaller than those caused by heavy rainfall.

7.2.2.1.2. Polar and subpolar settlements

There are two major types of polar and subpolar settlements: traditional indigenous communities that are based on hunting and gathering activities such as whaling, caribou hunting, and seal hunting and modern “outpost” settlements such as military, mining, and oil camps. The more traditional settlements are economically vulnerable to changes in the regional ecology that might occur as a result of climate change (changes in sea ice, migration routes, or abundance of game species). Although military and mining operations generally would not be concerned with game species, impacts of warming on permafrost areas, sea lanes, and flying weather could significantly improve or reduce the efficiency of resource extraction (Cohen, 1997).

Infrastructure in both types of settlements is vulnerable to permafrost melting, desiccation during warming, landslides, and flooding (see Chapter 16).

7.2.2.1.3. Forest settlements

Traditional settlements of indigenous peoples still exist in (mostly tropical) portions of Africa, Asia and nearby islands, and Latin America. Although these societies engage in subsistence agriculture and some cash activities such as guiding tourists, much of their economy is based on subsistence hunting and gathering. Already under threat from growth in farming, mining, and commercial forestry activities (which may themselves be affected by climate change), under climate change the traditional forest communities would face the additional challenge of changed ecology, which could change the availability of key species and adversely affect the sustainability of these communities.

7.2.2.1.4. Agricultural and fisheries settlements and related industry

Agroindustry is considered to be among the more adaptable industries affected by climate change. Brown and Rosenberg (1996) and Brown *et al.* (1998) were able to show, for example, that growing switchgrass (*Panicum virgatum*) for biomass is an effective adaptation in the warmer, drier climates expected in central North America under climate change. Chapter 5 also describes agriculture as adaptable and discusses adaptive responses. However, the capacity to adapt varies significantly among regions and among groups of farmers within regions. Adaptability and sustainability of agriculture and agroindustry depend not only on resources such as favorable climate, water, soils, and amount of land but also on the adaptability of whole market chains, which in turn are influenced by wealth levels, technical and financial sophistication, and institutional flexibility and strength (Tweeten, 1995; Nellis, 1996).

Changes in ocean conditions from El Niño episodes have demonstrated that changes such as ocean warming have substantial impacts on the locations and types of marine species available (UNEP, 1989; Meltzoff *et al.*, 1997; Suman, 2001). Fishery-based settlements would be strongly affected as fishermen follow high-valued stocks to other locations, make do with lower valued stocks, or even abandon fishing altogether (see Chapters 6, 10, 14, 15, and 17). Other communities may benefit if high-valued stocks become more accessible.

What often is not appreciated about resource-dependent settlements is the complexity of the economic and social relationships among participants. Changes in the technology of farming, transportation, and communications have integrated farming communities into national and world markets as never before and increasingly have made farming a part-time activity in some parts of the developed world (e.g., Sakamoto, 1996; Sasaki, 1996) and the developing world. The complexity of interactions and the increasing degree of integration offer

additional means of adaptation to climate change at the regional level, but these factors also mean that agriculture and agroindustry are being challenged from several directions at once, possibly complicating the impact of climate change alone (see, for example, Chapter 10).

To illustrate some of the complexities involved, in Japan agrarian structures have changed drastically during the past 30 years (Kumagai, 1996). Small farms have evolved through cooperative groups facing environmental requirements, double-cropping, cheaper imports, and high national economic growth (Sakamoto, 1996) into a regional system of farm households, hamlets, traditional villages, villages, and towns (Yoshino, 1997a,b), with significant part-time labor (Sasaki, 1996), and economics of large-scale production in farming, reductions in investment risks costs, diversification within farming, diversification between farming and other activities, and increases in nonfarm income.

Japanese rice-growing illustrates some constraints on adaptation and community sustainability. Inefficient agriculture (ironically) ties the younger generation to the rural community, where they play important roles in making the community active and viable. Provision of modern facilities and infrastructure does not lead to sustainable communities; more important, one must consider residents' pride or attachment to the community. Realization of a sustainable community requires investments in time, talent, and money for the future of the community (Tabayashi, 1996). Autonomous adaptation here, as elsewhere, might involve numerous social and economic dimensions that involve the entire settlement. It is unlikely to be simple or straightforward and may not result in sustaining every settlement.

7.2.2.1.5. Tourism and recreation

The SAR noted that tourism—a major and growing industry in many regions—will be affected by changes in precipitation patterns, severely affecting income-generating activities (IPCC, 1998). The outcome in any particular area depends in part on whether the tourist activity is summer- or winter-oriented and, for the latter, the elevation of the area and the impact of climate on alternative activities and destinations. For example, in spring 1997, when conditions in alternative destinations in the Alps were poor, the number of skiers in the High Atlas in Morocco increased (Parish and Funnell, 1999). Scotland has been predicted to have less snow cover at its lower elevation ski areas with global warming but may have drier and warmer summers for hill-walking and other summer activities (Harrison *et al.*, 1999) (see regional chapters for other examples).

The impacts of sea-level rise on coastal tourism are compounded by the fact that tourist facility development planning and execution in many cases has been inadequate even for current conditions, leading to environmental problems such as water shortages (Wong, 1998). Furthermore, tourism businesses, which usually are location-specific, have a lower potential than tourists themselves (who have a wide variety of options) to

adapt to climate change (Wall, 1998). Small island states may find themselves especially vulnerable to changes in the tourism economy because of their often high economic dependence on tourism, concentration of assets and infrastructure in the coastal zone, and often poor resident population (see Chapter 17).

Whetton *et al.* (1996) quantified the effects of climate change on snow cover in the Australian Alps, which illustrates the problems of snow-based recreation activities. Under the best-case scenario for 2030, simulated average snow-cover duration and the frequency of more than 60 days cover annually decline at all sites considered. However, this effect is not very marked at higher sites (above 1,700 m). For the worst-case scenario, at higher sites, simulated average snow cover roughly halves by 2030 and approaches zero by 2070. At lower sites, near-zero average values are simulated by 2030.

7.2.2.2. Riverine, Coastal, and Steeplands Settlements—Impacts on Infrastructure

Riverine and coastal settlements are notable largely for the potential that flooding and especially sea-level rise can have on them; steeplands in many regions are expected to become more vulnerable to landslides. The mechanisms of these effects depend on the settlement being located in harm's way. River floods can arise from intense local rainfall events or rapid snowmelt, for which long-term probabilities are difficult to forecast (see Chapter 4; Georgakakos *et al.*, 1998). Rapid snowmelt from rain-on-snow events or warm periods in the middle of winter is a potential threat in a warmer world in some heavily settled, snow-fed river systems such as the Rhine in Europe (see Chapter 13), whereas steeplands may suffer more landslides and snow avalanches (e.g., Evans and Clague, 1997). The mechanisms of adaptation are similar: defend against flooding or landslides with increasingly expensive protection structures; retreat from the floodplain and unstable areas to safe ground; or accommodate flooding and landslides in structure design, land-use planning, and evacuation plans (see also Chapters 9, 10, 11, 12, 13, 15, and 17).

The most widespread serious potential impact of climate change on human settlements is believed to be flooding. A growing literature suggests that a very wide variety of settlements in nearly every climate zone may be affected, although specific evidence is still very limited. Riverine and coastal settlements are believed to be particularly at risk, but urban flooding could be a problem anywhere storm drains, water supply, and waste management systems are not designed with enough system capacity or sophistication to avoid being overwhelmed. Urbanization itself explains much of the increase in runoff relative to precipitation in settled areas (Changnon and Demissie, 1996) and contributes to flood-prone situations.

In coastal regions (especially on river deltas and small islands), sea-level rise will be the most fundamental challenge of global warming that human settlements face. Some additional national and regional analyses of coastal vulnerability to sea-level rise

have been published since the SAR. Many of these studies are summarized in Chapters 6 and 8 because of the importance of the issue to these sectors. In general, estimates of potential damages continue to increase because of increased movement of people and property into the coastal zone, even though the expected degree of sea-level rise has decreased. Worldwide, depending on the degree of adaptive response, the number of people at risk from annual flooding as a result of a 40-cm sea-level rise and population increase in the coastal zone is expected to increase from today's level of 10 million to 22–29 million by the 2020s, 50–80 million by 2050s, and 88–241 million by the 2080s (Nicholls *et al.*, 1999). Without sea-level rise, the numbers were projected at 22–23 million in the 2020s, 27–32 million in the 2050s, and 13–36 million in the 2080s. The 40-cm sea-level rise is consistent with the middle of the range currently being projected for 2100 by Working Group I. In 2050, more than 70% (90% by the 2080s) of people in settlements that potentially would be flooded by sea-level rise are likely to be located in a few regions: west Africa, east Africa, the southern Mediterranean, south Asia, and southeast Asia. In terms of relative increase, however, some of the biggest impacts are in the small island states (Nicholls *et al.*, 1999).

Although a 1-m sea-level rise is not considered likely before 2100, it often is used to calibrate many damage estimates. For example, a macroscopic analysis of coastal vulnerability, areas, population, and amount of assets at risk from sea-level rise and storm surges for Japan shows about 861 km² of land currently is below the high-water level, with 2 million people and 54 trillion Japanese yen in assets. A 1-m sea-level rise would expand the area at risk 2.7 times, to 2,339 km², and increase population and assets at risk to 4.1 million and 109 trillion Japanese yen, respectively (Mimura *et al.*, 1998). El-Raey (1997) identifies potential impacts on Egypt: 2 million persons and 214,000 jobs affected, US\$35 billion in land value, property, and tourism income lost for a 50-cm sea-level rise. For a 100-cm rise, Zeidler (1997) identifies potential land losses of US\$30 billion, plus US\$18 billion at risk of flooding and as much as US\$6 billion of "full protection" in Poland. (See also Nicholls *et al.*, 1999, for potential damages to settlements on the world's coasts; Adger, 1999, specifically for damages to human settlements in Vietnam; Weerakkody, 1997, for Sri Lanka; and Liu, 1997, for China.)

If sea-level changes occur slowly, economically rational decisions could be made to protect only property that is worth more than its protection costs. With foresight, settlements can be planned to avoid much of the potential cost of protection, given that between 50 and 100 years are expected to pass before a 1-m sea-level rise would be expected. Yohe and Neumann (1997) offer a method by which this planning might be applied. This method can reduce the costs of protection by more than an order of magnitude. Yohe *et al.* (1996) estimate discounted (at 3% yr⁻¹) cumulative U.S. national protection costs plus property abandonment costs for a 1-m sea-level rise by the end of the 21st century at US\$5–6 billion, as opposed to previous estimates of \$73–111 billion (Smith and Tirpak, 1989).

Sea-level rise exacerbates beach erosion, changes sedimentation patterns, increases river floors in estuarine zones, and inundates wetlands and tidal flats. Groundwater salinization also is a serious problem in coastal zones and many small islands, where recharge does not keep up with usage even under current conditions (Liu, 1997). Higher sea levels are projected to further reduce the size of coastal fresh aquifers and exacerbate the problem. Directly, it causes drinking water quality problems for people in settlements; indirectly, it may limit agriculture in coastal zones (e.g., Dakar, Senegal—Timmerman and White, 1997). Groundwater pumping makes matters worse in many coastal zones by contributing to serious land subsidence. Examples of human settlements affected range from modern European cities (Venice) to large coastal settlements in developing countries (Alexandria, Tianjin, Jakarta, and Bangkok) (Timmerman and White, 1997; Nicholls *et al.*, 1999).

Vulnerabilities of settlements in coastal regions to higher sea levels are compounded by severe wind damage and storm surge caused by tropical cyclones and extra-tropical cyclones. The possibility of increasingly frequent (in some regions) or more intense tropical cyclones also cannot be rejected (see Chapter 3). Even if cyclones do not increase in intensity or frequency, with sea-level rise they would be expected to be an increasingly severe problem in low-lying coastal regions (e.g., for settlements along the North Sea coast in northwest Europe, the Seychelles, parts of Micronesia, the Gulf Coast of the United States and Mexico, the Nile Delta, the Gulf of Guinea, and the Bay of Bengal—specific vulnerable regions are identified in the FAR, SAR, RICC, and regional chapters of this report). Infrastructure hardening costs can be high if a decision were made to protect everything: The costs of protecting port facilities and coastal structures, raising wharves and quays, and reconstructing water gates and pumping stations for a 1-m sea-level rise in 39 prefectures in Japan has been estimated at 22 trillion Japanese yen (US\$194 billion), or about 7% of annual GDP (Mimura and Harasawa, 2000). In cases in which neither retreat nor defense is feasible, flooding can be accommodated through infrastructure that is designed to reduce damage and evacuation planning to reduce loss of life. Bangladesh, for example, provides hardened storm shelters (Choudhury, 1998).

When extreme weather disasters happen in these regions as a result of tropical or extra-tropical cyclones, the total costs of damages become very large and, where insured, often cause serious problems for insurance carriers (see Chapter 8). The United States' direct annual insured and uninsured costs for tropical cyclones (hurricanes), adjusting for inflation, averaged \$1.6 billion (1995 US\$) from 1950 to 1989 and \$6.2 billion from 1989 to 1995 (Hebert *et al.*, 1996). Estimates of worldwide annual direct costs have been placed at \$10–15 billion annually (Pielke, 1997). Increased losses in the United States and elsewhere have occurred during a period in which the number and intensity of tropical cyclones actually was declining (Landsea *et al.*, 1996; Pielke and Landsea, 1998). Thus, any future climate change-induced increase in tropical cyclone frequency or intensity remains a matter of great concern

to insurers and coastal facilities planners. A single US\$50 billion storm is not considered unlikely (Pielke and Landsea, 1998).

7.2.2.3. Urban Settlements

Urban settlements feature many of the same impacts of climate change as other settlements—such as air and water pollution, flooding, or consequences of increasingly viable disease vectors. These impacts may take unusual or extremely costly forms in urban areas—for example, flooding that results not from river flooding but from overwhelmed urban storm drains and sewers during extreme rainfall events (which may become more common in the future). Urban settlements also experience the consequences of accommodating migrant populations, the unique aspects of urban heat islands (which affect human health and energy demand), and some of the more severe aspects of air and water pollution. To some extent, the effects of climate change anywhere in the world are integrated through world markets, social and political changes, and migration. Many of these social and economic effects appear in the world's cities, including some of the world's largest (Rosenzweig and Solecki, 2000).

7.2.2.3.1. Migration

The SAR discussed at some length the potential impact of population movement in response to environmental impact and attractions of large urban areas. Human populations show significant tendencies to adapt to interannual variability of climate via migration, although migration may be the last of a complex set of coping strategies (Meze-Hausken, 2000). For example, decreases in crop and rice yields as a result of a prolonged dry season under ENSO conditions in Indonesia causes farmers to leave the villages to work in the surrounding cities. Population subsequently recovers (Yoshino, 1996b; Yoshino *et al.*, 1997). In some cases, immigration is more permanent and does not involve large urban areas. For example, after three successive typhoons hit Tau Island in American Samoa in 1987, 1990, and 1991, about one-third of the population abandoned their homes and moved to Pago Pago on Tutuila Island, putting more population pressure on the limited economic opportunities and services of that island (Meehl, 1996).

A school of thought based on observations of several ethnic conflicts in the developing world suggests that environmental degradation, loss of access to resources, and resulting human migration (including “environmental refugees”) in some circumstances could become a source of political and even military conflict (see Chapters 10 and 11). The result is possible, but the many intervening and contributory causes of intergroup and intragroup conflicts allow only low confidence in predictions of increases in such conflicts as a result of climate change, even where environmental resources are scarce and threatened (e.g., Wolf, 1998).

7.2.2.3.2. Human health

The impact of climate change on human health in settlements is a complicated mechanism that involves the interaction of physical attributes of settlements and precursors for direct effects of heat stress, vector-borne diseases such as malaria, and enteric diseases such as cholera (see Chapter 9). These impacts are common to all types of settlements, including traditional ones. The 1997–98 El Niño event provided a way to derive and test process models for the impacts of climate change. In Latin America, for example, outbreaks of malaria and Dengue fever appeared to be related to anomalously high nighttime minimum temperatures (Epstein *et al.*, 1998). Settlements provide disease vectors and organisms with habitat in the form of standing water, garbage dumps, and space sheltered from the elements. Flooding can flush organisms into settlements' clean water supplies, causing disease outbreaks. Heavy rainfall in normally dry areas leads to rapid increases in rodent populations, in turn leading to increases in rodent-borne diseases such as hantavirus (Glass *et al.*, 2000). Cholera-harboring marine plankton blooms also can be triggered by riverine flooding, which provides extra nutrients to the coastal environment (Colwell, 1996). Extremely dry conditions reduce the quantities and quality of water available for sanitary and drinking purposes, which also can trigger cholera and diarrheal outbreaks. Historically, this has been a problem on various Pacific islands during drought. Poverty, crowding, and poor sanitation in settlements add to these problems, as reported in the SAR.

7.2.2.3.3. Heat islands and human health

Warming of urban air increases in intensity and area as cities grow (Oke, 1982). This growing “heat island” tends to aggravate the risk of more frequent heat waves, as well as their impacts. Research indicates that variability in summer nighttime minimum temperature (temperatures above 32°C at night)—combined with lack of acclimatization, high humidity, and poorly ventilated and insulated housing stock—may be the most important factor in urban heat deaths (Chestnut *et al.*, 1998). Elderly people, the very young, people in ill health, and poor people are most likely to be affected (see Chapter 9 for these and other health effects). Because climate change is expected to raise nighttime minimum temperatures more than daytime highs, urban heat islands would be a significant health concern in the largest human settlements.

Conversely, during the rainy season (except in a few cities, such as Cairo, where practically no rain occurs) the heat island enhances the intensity and frequency of rain showers (Changnon, 1992; Jáuregui and Romales, 1996), leading to higher risk of street flooding or mudslides where the urban poor live. Moreover, warmer and drier climates may aggravate air pollution seasonally because of wind erosion of bare soil areas in cities with semi-arid or arid climates (e.g., Mexico City, Beijing, Delhi, and cities located in sub-Saharan Africa). Blowing dust and high summer temperatures are likely to

increase the incidence of heat stroke, respiratory illness, and transmission of disease by deposition of airborne bacteria in lungs and on food.

In warmer and drier climates, local minimum temperatures tend to be higher, which tends to attenuate the intensity (and depth) of temperature inversions formed by nocturnal radiation cooling and reduce the risk of poor air quality. However—and especially in large cities located in valleys (e.g., Mexico City, Santiago, Beijing, Delhi)—this attenuation effect could be compensated by a higher rate of radiation cooling to an air layer with less moisture content, aggravating the air pollution situation. Elevated subsidence inversions such as those on the descending branch of semi-permanent anticyclones and limiting vertical dispersion of pollutants in cities such as São Paulo, Los Angeles, or Tijuana are less likely to significantly change their thermal structure in a warmer world.

7.2.2.3.4. Water pollution

Despite massive investment in water treatment in the developed world and increasingly in the developing world over the past century, many settlements throughout the world (especially in rural areas) still are without adequate water treatment (UNCHS, 1999). In the case of drought, reduced water availability could force people to use polluted water sources in settlements at the same time that reduced flow rates reduce the rate of dilution of water contaminants. In the opposite case, flooding frequently

damages water treatment works and floods wells, pit latrines and septic tanks, and agricultural and waste disposal areas and sometimes simply overwhelms treatment systems, contaminating water supplies.

7.2.2.3.5. Air pollution

Air pollution is a serious problem in many cities of the world, even under the current climate. The following issues emerge from a review of developing country cities that are members of the 69 urban agglomerations with population of more than 3 million in 1990 (UNEP, 1992):

- Population trends have not yet stabilized, which means cities will continue to extend their urban area (and urban heat island).
- Motor vehicles now constitute the main source of pollutants in most cities of the industrialized world. Although the rate of growth in the number of vehicles in some settlements in the developing world has been very rapid (Simon, 1996), cities in developing countries (with exceptions) exhibit greater variety in air pollution sources. This depends on the level of motorization and the level, density, and type of industry present. Cities in Latin America, for example, tend to have high vehicle densities and high vehicle-to-total pollution loads. The major sources of air pollution in Delhi are 2.8 million vehicles, thermal power plants, industries, and domestic

Box 7-2. Air Pollution Problems of Large Cities in the Developing World—Update on the Case of Mexico City

The SAR notes the complex air pollution problems of Mexico City and expresses concern that increases in air stability episodes under climate change could exacerbate an already difficult situation. Although these problems remain severe, as noted below, Mexico City also shows that adaptation (mitigation of air pollution) is possible and effective.

Mexico City is located in an elevated inland valley (approximately 2,250 m above sea level) in central Mexico. The climate is subhumid tropical, tempered by the altitude. Industrial activity contributes 20% of the city's air pollution; 3 million motor vehicles that consume 17.3 million liters of gasoline and 5 million liters of diesel daily (in 1997) generate 75% of the pollution (Office of the Environment Annual Report, 1997). Typical anticyclonic weather prevailing during the dry season contributes to frequent thermal inversions that prevent dispersion of pollutants. Moreover, abundant insolation prevailing during the dry warm period (March to May) favors activation of precursors [mainly oxides of nitrogen (NO_x) and hydrocarbons (HC)] to produce high levels of ozone. This also is the season for dust storms and blowing dust (Jáuregui, 1989). Although transport may generate 75% of the airborne pollutants by weight, estimates made in 1989 regarding transport's contribution to air pollution in terms of toxicity suggested its contribution was 42.4%. A considerable contribution also comes from vegetation and topsoil (12% of all airborne pollutants by weight in 1994) (see Connolly, 1999).

The Mexico City Ministry of the Environment subsequently found that ozone—one of the most serious threats to health—was still above acceptable levels on 300 days in 1999 but that some progress had been achieved. During the worst days from 1990 to 1992, pollutants hit emergency levels on as many as 177 days annually. Emergency levels occurred on 5 days in 1999. This achievement was considered to be a result of anti-pollution efforts by the local government. For example, in the early 1990s, lead was removed from gasoline sold in the Valley of Mexico; laws restricted the use of cars without catalytic converters to 4 weekdays; and inspections of factories to reduce pollution doubled in 1999, to 152. The average ozone reading fell from 197.6 to 144, where the air quality norm is 100 points of ozone—equivalent to exposure to 0.11 ppm for 1 hour (Mexico City Ministry of the Environment, 2000). This progress in improving air quality suggests that even huge developing world cities can begin to reduce pollution.

fuel combustion. The problem has been compounded by unplanned development, inadequate public transport, poor road conditions, lack of traffic management, inadequate vehicle/engine maintenance, use of old vehicles, and poor fuel quality. Many developing countries' vehicle fleets tend to be older and poorly maintained (and not easily replaced because of the low incomes of their owners)—a factor that will increase the significance of motor vehicles as a pollution source (UNEP, 1992).

- Cities with seasonally warm, calm air and sunny weather with high traffic densities tend to be especially prone to the net formation of ozone and other photochemical oxidants, although it is not yet clear whether such conditions will be more or less prevalent under climate change. Volatile organic carbons (VOCs) from biogenic and anthropogenic sources such as automobiles increase at high temperatures, and thermal decomposition of peroxyacetyl nitrate (PAN) also increases (Samson *et al.*, 1989).
- Atmospheric and air-shed modeling exercises suggest that higher temperatures and more stable air episodes under global warming of 4°C could lead to 1–20% increases in peak urban ozone concentrations in the United States (Morris *et al.*, 1989; Penner *et al.*, 1989) and increased violation of clean air standards (Morris *et al.*, 1995). See Chapter 9 for the health effects of elevated ozone levels.

Box 7-2 shows that adaptive measures can be effective in reducing many of the precursors to adverse air quality under current climate. These measures also would help in the context of unfavorable atmospheric conditions as a result of climate change.

7.3. Energy, Transportation, and Other Climate-Sensitive Industry

7.3.1. Energy Supply and Demand

The SAR notes that climate change would impact energy supply and demand. Subsequent studies confirm this sensitivity. Hydropower generation is the energy source that is most likely to be impacted because it is sensitive to the amount, timing, and geographical pattern of precipitation as well as temperature (rain or snow, timing of melting) (see Chapter 4). Where reduced streamflows occur, they are expected to negatively impact hydropower production; greater streamflows, if they are timed correctly, might help hydroelectric production. In some regions, change of streamflow timing from spring to winter may increase hydropotential more in the winter than it reduces it in the spring and summer, but there is a question of whether the electric system can take advantage of the increase in winter flows and whether storage would be adequate. Hydroelectric projects generally are designed for a specific river flow regime, including a margin of safety. Projected climate changes are expected to change flow regimes—perhaps outside these safety margins in some instances (see Chapter 4). Although it is not

yet possible to provide reliable forecasts of shifts in flow regimes for world river systems as a consequence of climate change, what is known suggests more intense rainfall events (which would require more conservative water storage strategies to prevent flood damage), greater probability of drought (less hydroelectric production), and less precipitation falling as snow (less water available during warm months). All three factors point to less (or, at least, less flexible) hydroelectric capacity at current powerhouses. Reduced flows in rivers and higher temperatures reduce the capabilities of thermal electric generation (Herrington *et al.*, 1997); high temperatures also reduce transmission capabilities.

Some advanced energy technologies also may be affected. For example, the United States and Japan are trying to learn how to exploit the potential of methane hydrates. If global warming leads to warmer oceans or warms areas that currently are permafrost regions, these compounds are likely to become less stable, making it more problematic to attempt to recover methane from them (Kripowicz, 1998).

Increased cloudiness can reduce solar energy production. Wind energy production would be reduced if wind speeds increase above or fall below the acceptable operating range of the technology. Changes in growing conditions could affect the production of biomass, as well as prospects for carbon sequestration in soils and forest resources. Climate change could worsen current trends in depletion of biomass energy stocks in Africa, which is expected to become drier (see Chapters 3 and 10). The impact on biomass elsewhere is less clear; it may include enhancement of growth because of higher rainfall in Africa as well.

The portion of total energy supply from renewable energy sources varies among countries, developed and developing. In the United States in 1998, renewable sources provided roughly 7% of gross energy consumption—about half of that as hydroelectric energy (EIA, 1999a). In other countries, developed and developing, the percentages vary. For example, biomass accounts for 5% of north African, 15% of south African, and 86% of sub-Saharan (minus South Africa) energy consumption; in Cote d'Ivoire, the Democratic Republic of Congo, Ethiopia, Mozambique, and Zambia, the vast majority of on-grid electricity generation comes from hydropower (EIA, 1999b). Hydroelectricity represents the primary source of electricity in Canada and most South and Central American countries, with the highest reliance in Paraguay and Brazil (99 and 87% of generating capacity, respectively) (EIA, 1999c). Although renewable energy sources may be adaptable to new climate, larger percentages of renewables (especially hydroelectricity) in a country's energy supply might make the country relatively more sensitive to climate (see Chapters 10, 11, and 12). However, fossil fuel extraction may be adversely affected by increased wind and wave action, heavy precipitation, shoreline erosion, and permafrost melting in regions where this applies (see Chapter 16). In addition, thermal power plants can be adversely affected by loss of cooling water as a result of low flows (see Chapter 12).

If a warmer climate is characterized by more extreme weather events such as windstorms, ice storms, floods, tornadoes, and hail, the transmission systems of electric utilities may experience a higher rate of failure, with attendant costs (see, however, Chapter 3 and TAR WGI Chapter 10). These failures can be extremely costly, as illustrated by the great eastern Canada ice storm of January 1998, which toppled hundreds of transmission towers and downed 120,000 km of power lines—in some cases for a month to 6 weeks—and cost CDN\$3 billion in economic damage (only half of which was insured) (Kerry *et al.*, 1999). A 5-week power failure in the central business district of Auckland, New Zealand, occurred in February–March 1998 when four high-voltage transmission cables failed (Ministry of Commerce of New Zealand, 1998). Hot weather contributed to high demand and less-than-optimal operating conditions of these cables as a result of high soil temperature and dryness, although it was not ruled the direct cause. Transmission and distribution systems can be hardened to respond to greater risk, but only at substantial cost.

The SAR notes that on the demand side, space-cooling demand would increase and space-heating demand would decrease. Electrical system expansion (generation, transmission, and distribution) may be required to meet greater summer peaks. In warmer areas, it is expected that the demand for electricity will certainly increase, as may the demand for energy overall. Urbanization, rising incomes, and warmer climates could combine to increase energy used for space cooling—already a major concern in tropical and subtropical cities, most of which are in developing countries (e.g., as much as 60% of total electricity use in the commercial sector in Hong Kong, 60% of all electric energy in Riyadh—see Al-Rabghi *et al.*, 1999; Lam, 1999, 2000). Besides having a major impact on the energy sector, air conditioning would tend to enhance heat island effects because of the energy used. At the same time, research has found that air conditioning, where available and affordable, is a statistically significant factor in reducing the chances of hot-weather-related mortality (Chestnut *et al.*, 1998).

The heat island phenomenon may have a positive impact in cities with seasonally cool to cold winters. For example, during the 20th century, the long-term impact of the urban heat island has been to reduce potential energy demand for space heating by as much as 50% in the central quarters of megacities such as Tokyo and Mexico City (Jáuregui, 1998). Urban warming and increased demand for cooling is expected, even though urban aerosol production (e.g., from power plants) does have a cooling effect (*Science News*, 1992; Jáuregui and Luyando, 1999).

Additional studies that have been published since the SAR continue to show that whether *net* energy consumption will increase or decrease as a result of climate change depends very much on location—in particular, whether energy consumption includes larger heating loads or cooling loads. The north-south orientation of Japan provides some insight into this question. Ichinose (1996) (quoted in Mimura *et al.*, 1998) has shown for

Japan that reduction in heating would be about 30% in Sapporo on the northern island of Hokkaido, whereas it would be only 10% in Tokyo on the central island of Honshu. On the other hand, electricity consumption for cooling would increase hardly at all on Honshu and several percent in Naha on the southern island of Okinawa. The direction of net change also is sensitive to the future market penetration of air conditioning and to energy prices. In one Japanese study (Hattori *et al.*, 1991, summarized in Mimura *et al.*, 1998) the sensitivity of peak electric power demand to air temperature was shown to have increased 2.3 times during the 15 years between 1975 and 1990, largely as a result of the increase in the market penetration and unit size of air conditioners. Amano (1996, summarized in Mimura *et al.*, 1998) points out that a decline in energy prices contributed to the increase in the sensitivity of electricity consumption to climate.

Belzer *et al.* (1996) is among the few studies since the SAR that has estimated the effect of climate change on energy demand by the commercial sector. The study projects the change in demand at the national level for the United States in 2030. Accounting for changes in the building stock, a 4°C increase in average annual temperature, holding other loads constant, leads to an estimated 0–5% reduction in total energy consumption by the commercial sector in the year 2030 (note that 4°C was then considered possible at mid-latitudes if worldwide temperatures increased 2.5°C; now it is probably at the upper end of potential increases).

The SAR notes that energy used for irrigation would increase. Peart *et al.* (1995) studied the effects of climate change on energy efficiency in agriculture (including irrigation) in the southeastern United States. Results indicate that climate change would cause an increase in energy inputs required to produce a given amount of maize, soybeans, and peanuts.

Only a handful of studies since the SAR have looked at the effects of climate change on overall energy demand. Mendelsohn and Schlesinger (1999) estimated climate response functions and economic welfare for the entire energy sector in the United States, based on the cross-sectional study of household and firm energy expenditures in Mendelsohn and Neumann (1998). Two approaches were used: laboratory experiments coupled with process-based simulation models, and cross-sectional studies to substitute for impacts of climate change over time. Economic welfare associated with energy was found to have a quadratic relationship with temperature, with a maximum at 10°C. Although the experimental method succeeded in isolating the effect of climate from other variables, it failed to fully incorporate adaptive responses. The cross-sectional studies found that annual energy expenditures were minimized with an annual temperature of 12.8°C in the commercial energy sector and with 11.7°C in the residential energy sector. The cross-sectional approach, of course, does not allow for the transient response of the climate system or the actual dynamics of the energy sector in response to climate. It substitutes static history for a dynamic future and cannot deal with irreversibilities, higher moments of climatic changes such as alterations to diurnal

or seasonal cycles, synergic responses (see Section 7.6), or extreme events. (e.g., Schneider, 1997).

7.3.2. Transportation

Changnon (1996a) studied the effects of potential shifts in summer precipitation on transportation in Chicago, using data for 1977–79 and assuming continued use of current modes of transport. The study suggests that a future climate with more summer rainy days, somewhat higher rain rates, and more rainstorms would increase total vehicular accidents and total injuries in vehicular accidents, reduce travel on public transportation systems, and cause more aircraft accidents and delays. A drier climate probably would experience fewer moderate to heavy rain events, but results show that rain events during drier conditions produce a greater frequency of accidents and injuries per event than during wetter conditions. If high-heat events became more common with warmer climate, they also could become a problem. They have been known to soften asphalt roads, “explode” or buckle concrete roads, warp railroad rails, close airports because of lack of “lift” in extremely hot air, and increase mechanical failures in automobiles and trucks. On the other hand, there might be fewer mechanical failures resulting from extreme cold (Adams, 1997). Floods are costly to transportation systems, as they are to other infrastructure. Although the effect of climate change on flying weather is not clear, transportation by air is known to be sensitive to adverse weather conditions; major systemwide effects sometimes follow from flight cancellations, rerouting, or rescheduling. For example, one diverted flight can cause anywhere from 2 to 50 flight delays, and one canceled flight can result in 15–20 flight delays. The cost of a diverted flight can be as much as US\$150,000, and a cancellation can cost close to US\$40,000. The corresponding direct annual costs to 16 U.S. airlines are US\$47 million and US\$222 million, respectively (Quale, 1997). Several additional examples of impacts on transportation are cited in Chapter 13.

7.3.3. Construction

Flooding and other extreme weather events that damage buildings and infrastructure could cost the world’s economies billions of dollars under climate change simply to replace the damage—a cost that could divert funds from other needed investment (see Chapter 8). However, Mimura *et al.* (1998) note that cost increases for disaster rehabilitation and countermeasures against natural calamities could expand the market for the construction industry. Although no direct studies have been done, it is likely that a greater incidence of summer heat waves would reduce the productivity of this sector, but a lower incidence of cold waves and snowy conditions would increase the amount of year-round construction that could be accomplished in climates that currently have long, cold winters. Changes in design requirements for infrastructure, leading to additional requirements for construction, are discussed in the SAR.

7.3.4. Manufacturing

Manufacturing industries that are not directly dependent on natural resources generally would not be affected by climate unless key infrastructure is destroyed by flood or landslides, or unless shipments of inputs and outputs are affected (e.g., by snow blocking roads, airports, and train tracks; flooding or low flow that make river transportation untenable; or low water supplies that make process cooling and environmental activities more difficult). However, manufacturers are influenced by climate change in two other ways. First, they would be affected through the impact of government policies pertaining to climate change, such as carbon taxes (thereby increasing the cost of inputs). Second, they could be affected through consumer behavior that in turn is affected by climatic variations. For example, less cold-weather clothing and more warm-weather clothing might be ordered. Manufacture that depends on climate-sensitive natural resources would be affected by impacts on those resources. For example, food processing activity would follow the success of agriculture. Very little is known concerning the effects of warming on industry, and most information is highly speculative.

7.3.5. Financial Services and Insurance

Climate change increases risks for the insurance sector, but the effect on profitability is not likely to be severe because insurance companies are capable of shifting changed risks to the insured, provided that they are “properly and timely informed” on the consequences of climate change (Tol, 1998). For example, during the great storms in the early 1990s, the insurance sector reacted to increased risk and large losses by restricting coverage and raising premiums. Tucker (1997) also shows that increased climatic variability necessitates higher insurance premiums to account for the higher probability of damages. However, insurance companies still can be destabilized by large losses in a major weather-related catastrophe in a region where actuarial tables and estimated risks do not adequately reflect true weather risk (including greater variability), and companies therefore may not have made adequate provision for losses. See Chapter 8 for a description of impacts on financial services.

7.3.6. Estimating and Valuing Effects

Valuation of climate impacts remains difficult on three grounds. The first is uncertainty associated with determining physical changes and responses to these changes. The second is economic valuations of these changes that vary across regions. Fankhauser *et al.* (1998) show that damage cost estimates are sensitive to assumptions made on the basis of valuation (willingness to pay versus willingness to accept), accountability for impacts, differentiation of per unit values, and aggregation of damage costs over diverse regions. A third problem can be expressed as follows: “Which metric?” Five popular metrics are used: market costs, lives lost, species lost, changes in the

distribution of costs/benefits, changes in quality of life (loss of heritage sites, environmental refugees, etc). Schneider *et al.* (2000) conclude that when aggregation exercises are undertaken, disaggregation of all estimated effects into each of five numeraires is needed first, followed by a traceable account of any aggregation so others holding different weighting schemes for each numeraire can re-aggregate. This is done rarely, if ever.

The Workshop on the Social and Economic Impacts of Weather at the National Center for Atmospheric Research, 2–4 April 1997, in Boulder, CO, estimated that property losses from extreme weather of all types currently costs the United States about \$15 billion yr⁻¹ (\$6.2 billion related to hurricanes), as well as about 1,500 deaths (about half resulting from cold events); the worst flood and hurricane years yield about \$30–40 billion in property losses.

Smith (1996) standardized estimates of climate change damages for the United States for a 2.5°C warming, a 50-cm sea-level rise, 1990 income and population, and a 4% real rate of return on investments. Total damage estimates are slightly less than 1% of United States gross national product (GNP) in 1990. Within individual sectors such as agriculture and electricity, however, standardized damages differ by more than an order of magnitude. This level of uncertainty appears to apply among experts as well. For example, Nordhaus (1994) surveyed experts, and their damage estimates ranged over more than an order of magnitude.

Yohe *et al.* (1996) calculated the cost of a 50-cm sea-level rise trajectory for developed property along the U.S. coastline. Transient costs in 2065 were estimated to be approximately \$70 million (undiscounted and measured in constant 1990 US\$). These costs are nearly an order of magnitude lower than estimates published prior to 1995 (e.g., Fankhauser, 1995). This is because Yohe *et al.* (1996) incorporated the cost-reducing potential of market-based adaptation in anticipation of the threat of sea-level rise. In addition, they assumed efficient discrete decisions to protect or abandon small tracts of property, based on their economic merit. Some work since suggests that maladaptation may cause the costs of sea-level rise to be somewhat higher (West and Dowlatabadi, 1998).

7.3.7. Tools/Methods/Approaches/Models Used in Developing New Knowledge, including Assumptions, Sensitivities, and Scenarios Used in Models

Current impact assessment methods focus on comparing current conditions to a single alternative steady state—that associated with doubling of GHGs. Mendelsohn and Schlesinger (1999) attempt to estimate climate response functions for market sectors in the United States that reflect how damages change as climate changes through a range of values. Impacts are generated by using national climate values, rather than global values, and the timing of climate change is included in the modeling of capital-intensive sectors such as coastal resources and timber, which

cannot adjust quickly. Empirical estimates of climate response functions are based on laboratory experiments coupled with process-based simulation models and cross-sectional studies (Mendelsohn and Neumann, 1998). Both methods indicate that agriculture, forestry, and energy have a bell-shaped relationship to temperature. Similarly, an increase in precipitation is likely to be beneficial to some agriculture, forestry, and water sectors, although this effect is reversed at sufficiently high levels. However, this work captures neither the transient response of the climate system nor the actual dynamics of the energy sector in response to climate (e.g., Schneider, 1997).

7.4. Infrastructure

7.4.1. Water Supply and Demand

Increases in average atmospheric temperature accelerate the rate of evaporation and demand for cooling water in human settlements, thereby increasing overall water demand, while simultaneously either increasing or decreasing water supplies (depending on whether precipitation increases or decreases and whether additional supply, if any, can be captured or simply runs off and is lost). Shimizu (1993, quoted in Mimura *et al.*, 1998) showed that daily water demand in Nagoya, Japan, would increase by 10% as the highest daily temperature rose from 25 to 30°C. Boland (1997) looked at several climate transient forecasts for the Washington, DC, metropolitan area for the year 2030 and estimated increases in summertime use of 13 to 19% and annual use of -8 to +11% relative to a future increase from 1990 without climate change of approximately 100%. In China, using four GCMs for the year 2030, water deficiency under normal (50%) and extreme dry (95%) hydrological conditions for various basins was predicted as -1.6×10^8 to 1.43×10^9 m³ in the Beijing-Tianjin-Tangshan area and -1.1×10^8 to 121.2×10^8 m³ in the Yellow River Basin (China Country Study Team, 1999).

Estimates of effects on water supply mostly have dealt with linking atmospheric and hydrologic models in an attempt to produce more plausible forecasts with statistical variability. Although they do not directly forecast water supplies to human settlements, Kwadijk and Rotmans (1995) do show an increase in variability of supply in the Rhine River with climate change, but little change in estimated annual flow. The study is unusual in that it attempts to directly link impacts to mitigation policy. A more conventional study that still links water supply (directly for a municipal water system) and climate scenarios is Wood *et al.* (1997).

7.4.2. Buildings, Transportation, and Other Infrastructure

Additional research since the SAR seems to have added to concerns about increased intensity of rainfall and urban flooding (e.g., for the highly urbanized northeast United States—Rosensenzweig and Solecki, 2000). Increases in intensity are projected by Fowler and Hennessy (1995) and Hennessy *et al.*

(1997). Smith *et al.* (1999) have performed a series of four case studies that combine climate and hydrological modeling to directly model flood frequency and magnitude and economic losses under enhanced greenhouse rainfall intensities. The study concludes that there would be little change in forecast flood damage by the year 2030 but that there would be substantial increase in flood risk (shortened average return interval) and flood damage (as a result of building inundation and failure) by the year 2070. The estimation technique was an improvement over earlier studies that assumed that changes in intensities of rainfall events would be associated with changes in flood frequency (e.g., Minnery and Smith, 1996).

Generally speaking, climate change will change the level and type of climatic effects that need to be covered by infrastructure design codes. This could affect infrastructure durability and energy usage. Potential changes in humidity and climate may change distribution in factors such as termites, for example—with potential degradation of structures and more serious impacts from given extreme events. There also could be adverse effects of storms, heat, and humidity on walls and insulation, though perhaps less winter damage.

7.4.3. Estimating and Valuing Infrastructure Effects

There still are relatively few reports that estimate the impact of global warming on the value of economic losses resulting from effects on infrastructure. However, Smith *et al.* (1999) and Penning-Pownall *et al.* (1996) provide estimates that show that increases in damages from urban riverine flooding probably would be substantial. See also the discussion on sea-level rise in Section 7.2.2.2.

7.5. Management and Adaptation of Human Settlements

Social and natural sustainability are important for sustainable development of human settlements (Yoshino, 1994). Coping with flooding and drought; getting potable water, breathable air, and a stable environment; and so forth have been prime concerns of urban planners, engineers, governments, and citizenry for thousands of years (Priscoli, 1998). Climate change simply adds to the challenge. Some of the adaptations probably would take place autonomously, but some adaptations may be much improved by taking climate into account explicitly (Wood *et al.*, 1997).

7.5.1. Adaptation

Questions such as “adapt to what?”, “who or what adapts?”, and “how does adaptation occur?” (Smit *et al.*, 1998) are still difficult to answer in a strict sense. Management, adaptation, and vulnerabilities have been discussed for settlements in coastal (Fukuma, 1999/2000), arid, agrarian (Douguédroit, 1997; Douguédroit *et al.*, 1997; Le Treut 1997), and urban regions (Maunder, 1995). To be successful, adaptations must

be consistent with economic development, they must be environmentally and socially sustainable over time, and they must be equitable (that is, not have significantly deleterious effects on disadvantaged groups) (Munasinhge, 2000).

7.5.2. Adaptation to What and Why?

In most cases, human settlements have designed into them the ability to withstand most of the consequences of some environmental variability. In most regions, climate change would change the probability of certain weather conditions. The only effect for which average change would be important is sea-level rise, under which there could be increased risk of inundation of coastal settlements from average (higher) sea levels. Human settlements for the most part would have to adapt to more or less *frequent* or intense rain conditions or more or less *frequent* mild winters and hot summers, although individual days’ weather may be well within the range of current weather variability and thus not require exceptionally costly adaptation measures. The larger, more costly impacts of climate change on human settlements would occur through increased (or decreased) probability of extreme weather events that overwhelm the designed resiliency of human systems.

Much of the management of urban centers as well as the governance structures that direct and oversee them are related to reducing environmental hazards, including those posed by extreme weather events and other natural hazards. Most regulations and management practices related to buildings, land use, waste management, and transportation have important environmental aspects. So too do most public and private investments in infrastructure. A significant part of health care and emergency services exists to limit the health impacts of environmental hazards. Local capacity to limit environmental hazards or their health consequences in any settlement generally implies local capacity to adapt to climate change, unless adaptation implies particularly expensive infrastructure investment.

An increasing number of urban centers are developing more comprehensive plans to manage the environmental implications of urban development. Many techniques can contribute to better environmental planning and management including: market-based tools for pollution control, demand management and waste reduction, mixed-use zoning and transport planning (with appropriate provision for pedestrians and cyclists), environmental impact assessments, capacity studies, strategic environmental plans, environmental audit procedures, and state-of-the-environment reports (Haughton, 1999). Many cities have used a combination of these techniques in developing “Local Agenda 21s.” Many Local Agenda 21s deal with a list of urban problems that could closely interact with climate change in the future. Examples of these problems include (WRI, 1996; Velasquez, 1998):

- Transport and road infrastructure systems that are inappropriate to the settlement’s topography (could be

damaged by landslides or flooding with climate change)

- Dwellings that are located in high-risk locations for floods, landslides, air and water pollution, or disease (vulnerable to flood or landslides; disease vectors more likely)
- Industrial contamination of rivers, lakes, wetlands, or coastal zones (vulnerable to flooding)
- Degradation of landscape (interacts with climate change to produce flash floods or desertification)
- Shortage of green spaces and public recreation areas (enhanced heat island effects)
- Lack of education, training, or effective institutional cooperation in environmental management (lack of adaptive capacity).

7.5.3. Sustainable Cities Activities

The following generic lessons from Curitiba, Brazil—which come from the context of “sustainable cities” under *existing* conditions—may be applicable to future adaptation responses (Rabinovitch, 1998):

- Top priority should be given to public transportation rather than to automobiles and other light-duty vehicles, and to pedestrians and cyclists rather than to motorized vehicles. This reduces air pollution and some other forms of pollution. It was noted that some alternative fuels such as hydrogen are particularly attractive for reducing local air quality problems, as well as mitigating GHG emissions.
- There can be an action plan for each set of urban problems, but solutions within a city are connected, not isolated.
- Action plans must be participatory, with partnerships involving all responsible parties [government, private sector, nongovernmental organizations (NGOs), individuals].
- Creativity can substitute for financial resources (labor-intensive and creative ideas can substitute for capital).
- Even during rapid demographic growth, physical expansion can be guided by integrated road planning, investment in public transportation, and enforcement of appropriate land-use legislation.
- Technological solutions and standards for everything from public transit to recycling should be chosen on the basis of affordability (cost-effectiveness, combined with sensitivity to total cost).
- Public information and awareness are essential.

The most effective pathways for adaptation that result in sustainable development are likely to arise out of an informed evolution of existing institutions. Several authors emphasize the importance of the support and will of local public officials in developing successful environmental solutions (e.g., Gilbert *et al.*, 1996; Foronda, 1998). Others emphasize the need in traditional societies to build from and integrate modern techniques into traditional management practices and kinship and community networks, to effectively collect and disseminate data needed for assessing impacts, to open public participation

processes for formulating policy, and to provide a process for strengthening financial, legal, institutional, and technical elements (Huang, 1997).

7.5.4. Adaptation Options

Adaptation to climate changes involves planning of settlements and their infrastructure, placement of industrial facilities, and making similar long-lived decisions to reduce the adverse effects of events that are of low (but increasing) probability and high (and perhaps rising) consequences. The adaptation response consists of planning to reduce the sensitivity of key assets, designing resilience and flexibility into the public and private infrastructure on appropriate time scales, and managing settlements and institutions in a climate-resilient manner. The following discussion of example options and strategies is divided into Planning and Design, Management, and Institutional Frameworks (see Table 7-2 for a summary):

- *Planning and Design*
 - Take advantage of rapidly increasing populations in many regions. Growing populations and cities provide economic advantages, not just costs (Satterthwaite, 1998). In the case of infrastructure, growing populations provide an opportunity for new construction that can be designed for increased resilience and flexibility with respect to climate change. With good planning and building practices in new construction, considerable energy and environmental cost can be saved at relatively small incremental construction costs compared with later retrofit or protection (Rabinovitch, 1998). It can be less costly to design and build flood works “oversized” in the beginning than to rebuild them later to add capacity (this is not a foregone conclusion and depends on local uncertainties; see Wood *et al.*, 1997).
 - Take advantage of replacement schedules. Many short-lived assets such as consumer goods, motor vehicles, and space heating/cooling systems will be replaced several times in the course of a few decades, offering considerable opportunities for adaptation. Even medium-life assets such as industrial plants, oil and gas pipelines, and conventional power stations are likely to be completely replaced over such a time scale, though there will be less opportunity for adaptation through upgrades and relocation.
 - Community design tools such as floodplain and hillside building practices and landscape design (zoning in developed countries; perhaps land-use planning in developing countries) can be improved to limit damage. Reducing heat islands (through judicious use of vegetation and light-colored surfaces, reducing motor transportation, and taking advantage of solar resources) also should be included in the package of possibilities.

Table 7-2: Planning and design, management, and institutional frameworks actions for human settlements, by type of settlement.

	Resource-Dependent Settlements	Coastal, Riverine, and Steplands Settlements	Urban Settlements
Planning and Design	<ul style="list-style-type: none"> – Increase economic diversification – Oasis development – Windbreaks – Develop irrigation and water supply – Rural planning – Redevelop tourism and recreation industry – Take advantage of replacement schedules for buildings and infrastructure 	<ul style="list-style-type: none"> – Zoning in developed countries; perhaps land-use planning in developing countries – Better building codes to limit impact of extreme events, reduce resource use – Soft and hard measures to reduce risk of floods: <ul style="list-style-type: none"> • Reconstruction of harbor facilities and infrastructure • Flood barriers • Managed retreat (acquisition of properties; fiscal and financial incentives) • Hazard mapping • Tsunami damage-prevention facilities – Take advantage of rapidly increasing populations for sizing infrastructure – Take advantage of replacement schedules for buildings and infrastructure – Use community design tools such as floodplain and hillside building practices, public transportation – Improve sanitation, water supply, electric power distribution systems – Employ design practices to prevent fire damage (development densities and/or lot sizes, setbacks, etc.) 	<ul style="list-style-type: none"> – Site designs and building materials and technologies that moderate temperature extremes indoors – Improve infrastructure and services, including water, sanitation, storm and surface water drainage, and solid waste collection and disposal – For higher temperatures: <ul style="list-style-type: none"> • Building and planning regulations and incentives that encourage building measures to limit development of “heat islands” – Take advantage of rapidly increasing populations for sizing infrastructure
Management	<ul style="list-style-type: none"> – Employ countermeasures for desertification – Increase environmental education – Improve landscape management – Develop agricultural and fisheries cooperatives to reduce risk – Preserve and maintain environmental quality – Institute emergency preparedness and improve neighborhood response systems 	<ul style="list-style-type: none"> – Provide warning systems and evacuation plans; salvage; emergency services; insurance and flood relief – Better implement/enforce existing building codes – Employ special measures to promote adaptation and disaster preparedness in sites or cities at high risk from such events – Institute market-like mechanisms and more efficient management of water supplies (e.g., fix leaks) – Institute neighborhood water wholesaling and improve delivery 	<ul style="list-style-type: none"> – Institute neighborhood water wholesaling and improve delivery systems – Improve sanitation and waste disposal – Create and enforce pollution controls for solid, liquid, and gaseous wastes – Efficiently operate public transportation systems – Institute emergency preparedness and improve neighborhood response systems – Improve health education

Table 7-2 (continued)

	Resource-Dependent Settlements	Coastal, Riverine, and Steplands Settlements	Urban Settlements
Management (continued)		<ul style="list-style-type: none"> – Institute emergency preparedness and improve neighborhood response systems – Improve health education 	
Institutional Frameworks	<ul style="list-style-type: none"> – Build institutional capacity in environmental management – Create partnerships between all responsible parties (government, private sector, NGOs, individuals) – Regularize property rights for informal settlements and other measures to allow low-income groups to buy, rent, or build good quality housing on safe sites – Improve technology of farm machinery, herbicides, computers, etc. 	<ul style="list-style-type: none"> – Build institutional capacity in environmental management – Create partnerships between all responsible parties (government, private sector, NGOs, individuals) – Regularize property rights for informal settlements and other measures to allow low-income groups to buy, rent, or build good quality housing on safe sites 	<ul style="list-style-type: none"> – Build institutional capacity in environmental management – Create partnerships between all responsible parties (government, private sector, NGOs, individuals) – Regularize property rights for informal settlements and other measures to allow low-income groups to buy, rent, or build good quality housing on safe sites
	<ul style="list-style-type: none"> – Improved sanitation, water supply, and electric power distribution systems can be planned in an integrated manner, with sensitivity to the location of air sheds and water sheds and efficient utilization of plant (e.g., properly price water to reflect scarcity and reduce leakage in water supply systems) (Wood <i>et al.</i>, 1997; Lettenmaier <i>et al.</i>, 1998; Tindleni, 1998). In some cases, this requires “hardening” the system. In other cases, it requires flexible approaches to plans for cleanup and movement of waste facilities in the flood zone throughout the watershed and, for example, sanitation (Bartone, 1998). There are more opportunities to do this in developing countries, which are still acquiring their basic urban infrastructure. According to the United Nations Center for Human Settlements (UNCHS) Global Urban Indicators Program Web site in 1999, which developed city data collection systems in 237 cities in 110 countries, about 38.5% of African urban households were connected to water systems, 15.4% to sewerage, 46.9% to electricity, and 14.1% to telephones; in Asia the corresponding connection rates were 52.4, 33.2, 82.5, and 26.5%, respectively, and in the industrialized countries the percentages were 99.4, 95.8, 99.2, and 78.2% (UNCHS, 1999). – Measures can be taken by governments to anticipate floods (Smith and Handmer, 1984), including “hard” engineering measures such as dams, levees, diversions, channels, and retarding basins and “soft” or “nonstructural” methods such as acquisition of properties, fiscal and financial incentives, regulations such as zoning and building regulations, 	<p>information and education campaigns, forecasts/warning systems/evacuation plans, salvage, emergency services, insurance, and flood relief. “Designing with nature” is an effective strategy for curbing flood losses even with current climate (Rabinovitch, 1998). In some cases, this may require cleanup and movement of waste facilities in the flood zone throughout the watershed, an issue also discussed in the SAR. FEMA (1997) has concluded that the process of establishing and implementing state and community comprehensive development and land-use plans provides significant opportunities to mitigate damages caused by natural hazards. Losses from floods in the upper Mississippi valley in 1996 (after some of these actions had been taken) were two orders of magnitude lower than in 1993 for similar-sized floods. Albergel and Dacosta (1996) propose analyzing runoff patterns from non-normal storm events as a basis for more sustainable water resource management in the specific instance of Senegal to deal with extreme events more effectively. Colombo, Sri Lanka, has an ambitious plan to redesign and rebuild its flood management system, incorporating improved maintenance of the existing system, development of flood retention areas, cost-effective defined flood safety margins, movement of people out of flood-prone lands immediately adjacent to canals, and even a plan to move industries and public organizations out of Colombo to hold constant the amount of unbuilt lands in the face of increased urbanization (Gooneratne, 1998).</p>	

- Put key infrastructure in less vulnerable areas and (as appropriate) harden against fire. Urban/wildlands interface fires at locations such as Oakland/East Bay Hills in California and Sydney, Australia, have yielded examples of design practices to prevent such occurrences, including limiting development densities and/or requiring large lot sizes; setting buildings back from flood, landslide, and fault hazard zones; requiring adequate minimum paved street widths and grades; requiring second access points; restricting the lengths of cul-de-sacs; developing adequate water supply, flows, and redundant storage; and using open space easements for fire breaks, equipment staging, and evacuation areas (Topping, 1996). Wildlands fires also may affect settlements at a distance. In 1997, health and haze effects of wildfires alone cost Indonesia US\$1 billion (EEPSEA, 1999; Wheeler, 2000). Total costs were about US\$4.5 billion.
- Diversifying economic activity could be an important precautionary response that would facilitate successful adaptation to climate change for resource-dependent settlements.
- Use suitable design techniques to reduce cooling demand in many buildings. For example, the U.S. Department of Energy's Building America Program uses a systems engineering approach and works with the home building industry to produce quality homes that use 30–50% less energy without increasing building costs, that reduce construction time and waste by as much as 50%, and that improve builder productivity. Eliminating inefficiencies is not strictly an adaptation option, but these improvements also would have the benefit of reducing the impact of warming on energy use. Adaptive measures that can effectively reduce energy use relating to space cooling include better design of building envelopes (which can cut cooling energy consumption by more than one-third in current subtropical conditions or 5–30% under current European conditions—see Chan and Chow, 1998; Balarus *et al.*, 2000); high-albedo roofs (field tests in Florida show savings of 2–40%—Akbari *et al.*, 1999); and development of urban trees and other greenery (Avissar, 1996; Spronkensmith and Oke, 1998; Upmais *et al.*, 1998), reducing summertime urban cooling loads by 3–5% (Sailor, 1998). See also Angioletti (1996) for criteria for sustainable building practices. Low-income energy assistance and weatherization can play a role in assuring equity (Miller *et al.*, 2000).
- *Management*
 - To stretch water supplies further, especially in high-income parts of developed countries, institute market-like mechanisms and more efficient management of water supplies. Experiments with market systems in the United States have yielded water surpluses during drought in California, but such schemes must consider distribution and equity effects when water consumption is very low already (Hardoy *et al.*, 2000), as well as external environmental effects on third parties (Frederick, 1997). In some urban water systems, a significant percentage of water put into the system is lost through leakage (e.g., 23%—or about eight times the expected increase in demand resulting from climate change—in the case of the southern part of Britain). Urban water systems may lose as much as 40–60% of their water in distribution (Cairncross, 1990; Daniere, 1996; Rahman *et al.*, 1997). Simply fixing leaks in cases such as this would go a long way toward making sure that supplies are available (Arnell, 1998). Boland (1997) found that mandating and widely promoting conservation measures in the Washington, DC, area (such as a 50% increase in tariff level, industrial/commercial water reuse and recycling, and a moderate conservation-oriented plumbing code) could cut the increase in baseline water use in the year 2030 from 100% to about 45%. This would more than offset any increase in use resulting from climate warming. In developing-world cities' poor neighborhoods, where water use already may be below levels that are conducive to good health, a mixed response involving improving pipes, instituting neighborhood water wholesaling, and improving water vendors and kiosks may be effective and affordable, if coordinated with organized liquid waste disposal (Hardoy *et al.*, 2000).
 - Provide flood control and other forms of property assurance (not necessarily insurance). On the insurance side, Germany and France have taken very different approaches, with Germans adopting private insurance and minimal flood assistance and the French adopting compulsory extended coverage under the "cat 'nat" system. Neither system has proved to be able "to provide sufficient coverage at reasonable cost (Gardette, 1997). The United States has been able to provide flood insurance through a national system—at the cost of not controlling losses. Much more activity is now going into loss prevention in the United States (FEMA, 2000). The FEMA Hazard Mitigation Grant Program (HMGP) provides grants to states and local governments to reduce loss of life and property from natural disasters and to enable mitigation measures to be implemented during the immediate recovery from a disaster (FEMA, 2000). Some authors argue that loss prevention could be anticipatory (Miller *et al.*, 2000).
 - Institute emergency preparedness and improve neighborhood response systems and mutual assistance. This strategy is featured in many of

- the local initiatives cataloged by the International Council for Local Environmental Initiatives (ICLEI). Increasing access to cooling stations and city heat emergency response plans for urban heat island effects are an example. Plans for extreme events have improved considerably in the past 50 years, especially in developed countries, and can be very effective against some of the anticipated consequences of climate change. For example, preparation of disaster prevention organization in Japan, including forecast techniques and information systems between weather bureau/meteorological offices and individuals through local government/offices, has resulted in a dramatic decrease in the number of deaths and houses destroyed, especially for middle-sized typhoons (Class III) in the past 4 decades. This trend suggests that disaster prevention systems such as river improvement, establishment of information systems, improvement of typhoon forecasting, and so forth were most effective for middle-sized typhoons (Fukuma, 1996; Yoshino, 1996a). In most developing countries, local governments are particularly weak and ineffective at environmental management and have little capacity to integrate disaster preparedness into their current tasks and responsibilities. For example, no significant change has been found in deaths per violent hurricane in Bangladesh (Fukuma, 1999/2000), whereas there has been a significant decline in the United States (Pielke, 1997). However, some of the differences may be partly a result of a reduction in violent hurricanes making landfall in populated areas. U.S. property damages increased while the incidence of hurricanes fell (see Pielke and Landsea, 1998). Analysis of 15 years of simulation and observations show that typhoon frequency has decreased off the Philippine Islands and that the location of their generation shifts toward the east during El Niño years (Matsuura *et al.*, 1999). If similar conditions in typhoon regions also occur under global warming, more effective prediction and tracking of tropical typhoons in the 21st century could reduce typhoon disasters.
- Improve health education. Because the consequences of flood and drought on water quantity and quality are fairly straightforward to predict, concerted public awareness campaigns can significantly reduce adverse health consequences on populations from water-borne enteric diseases. For example, in the Marshall Islands in 1997–1998, a public awareness campaign to boil all water supplies was triggered by public health officials' concerns over dwindling water availability. The number of hospitalizations for diarrheal disease was lower than normal (Lewis *et al.*, 1998).

- *Institutional Frameworks*

- An institutional framework can be put in place that is more “friendly” for adaptation strategies. Some key features of such a strategy include regularizing property rights for informal settlements and other measures to allow low-income groups to buy, rent, or build good-quality housing on safe sites. Much of the poor-quality settlement infrastructure in the developing world in particular is traceable to the questionable legal status of housing in these settlements (e.g., Jaglin, 1994; Acho-Chi, 1998; Perlman, 1998). Thus, the occupants of such housing units can be reluctant to spend much on quality construction and may have little legal standing to demand municipal government services such as piped water, sewerage, or waste collection. Perhaps more important, even if they are financially able to do so, governments may be unable or reluctant to extend services to households and communities lacking legal standing, especially if such extension of service thereby “validates” the settlement.
- Build institutional capacity in environmental management. Capacity to adapt to climate change, as with other environmental problems, will be realized only if the necessary information is available, enterprises and organizations have the institutional and financial capacity to manage change, and there is an appropriate framework within which to operate. In this respect, autonomous adaptation cannot necessarily be relied on. Governments may have a role in terms of disseminating information (Miranda and Hordijk, 1998) and in any case should not stand in the way through indifference, hostility, or inefficient or corrupt management (Foronda, 1998). Building efficient environmental institutions requires coherent policy, planning, mechanisms for implementation, procedures for monitoring and corrective action, and a means for review. Mechanisms include use of market-based regulatory instruments to limit contributory pollution and to organize land use; development of appropriate roles for central and local governments; involvement of communities and civil societies in adaptive strategies (including traditional environmental knowledge and informal regulation as appropriate); and expansion of the scope for international cooperation (World Bank, 1999).

7.5.5. Barriers and Opportunities for Adaptation

Most urban authorities in developing regions have very little investment capacity despite rapid growth in their populations and the need for infrastructure. Problems arise from inadequate and inappropriate planning for settlements. Yet the need for planning becomes even more pressing in light of increased

social, economic, and environmental impacts of urbanization; growing consumption levels; and renewed concern for sustainable development since the adoption of Agenda 21 (UNCHS, 1996). Environmental management tends to be more difficult in very large cities (WRI, 1996). Although there are commitments from developed countries in Article 4.4 of the United Nations Framework Convention on Climate Change (UNFCCC) to assist particularly vulnerable countries with adaptation, the financial resources needed to provide services to tens of millions of people are daunting.

Increasingly, settlements are exchanging ideas concerning methods and experiences for community design and management to improve sustainability and livability. For example, ICLEI is an association of local governments dedicated to prevention and solution of local, regional, and global environmental problems through local action. More than 300 cities, towns, counties, and their associations from around the world are members of the Council (ICLEI, 1995).

Environmentally sound land-use planning is central to achievement of healthy, productive, and socially accountable human settlements within societies whose draw on natural resources and ecosystems is sustainable. The challenge is not only how to direct and contain urban growth but also how to mobilize human, financial, and technical resources to ensure that social, economic, and environmental needs are addressed adequately (UNCHS, 1996).

7.6. Integration

There are multiple pressures on human settlements that interact with climate change. The discussion in this chapter shows that these other effects are more important in the short run; climate is a *potential* player in the long run. For example, urban population in the least-developed countries currently is growing at about 5% yr⁻¹, compared with 0.3% yr⁻¹ in highly industrialized countries.¹ Providing for this rapidly urbanizing population will be much higher on most countries' agendas than longer term issues with climate change.

Other environmental problems will tend to interact with climate change, adversely affecting human settlements. For example, 25–90% of domestic energy supply in the developing world is met by biomass resources, especially in small urban centers (Barnes *et al.*, 1998). In some countries, 11–20% of all deforestation may be attributable to charcoal production (Ribot, 1993), much of it to meet urban needs. If biomass growth is slowed via climate change effects, the impacts on biomass may be compounded.

Deforestation and cultivation of marginal lands can compound the effects of extreme events. For example, floods resulting

from Hurricane Mitch, though not caused by climate change, illustrate the fact that poor watershed management can contribute to flooding and landslides—which, in turn, causes loss of life and destroys infrastructure and the means of livelihood. Mitch cost Honduras 80% and Nicaragua 49% of one year's GDP (FAO, 1999). Poor watershed management and technical failures has contributed to loss of life in landslides in Sri Lanka, Peru, Brazil, several European countries, and the United States (Katupotha, 1994).

Urban water resources already are in extremely short supply in 19 Middle Eastern and African countries (IPCC, 1998) and in cities in many parts of the world, where as many as 60% of poorer residents may not have access to reliable water supplies (Foronda, 1998). Poor urban water management may be responsible for losses through leakage of 20–50% in cities in the developing world and even in some cities in the industrialized world (WRI, 1996). If climate change makes water more scarce—by increasing demand (even in regions that currently are not particularly short of water, such as Great Britain—see Arnell, 1998) or by reducing supply (reduced surface runoff, exacerbation of water quality problems as a result of warmer temperatures and reduced flows, or salinization of coastal aquifers resulting from sea-level rise)—water supply problems would be exacerbated.

Liquid waste disposal is a significant problem in urban areas as diverse as Chimbote, Peru (Foronda, 1998); Buenos Aires, Argentina (Pirez, 1998); Cotonou, Benin (Dedehouanou, 1998); and Chicago, USA (Changnon and Glantz, 1996). There are two ways in which climate could interact with this problem: reductions in supplies of water with which wastes are diluted and the impact of more severe flooding episodes that overtop sewer systems and treatment plants (Walsh and Pittock, 1998). Where most inhabitants rely on pit latrines and wells, flooding spreads excreta from pit latrines everywhere and contaminates wells (Boko, 1991, 1993, 1994). Land-use changes associated with urbanization also have reduced the absorptive capacity of many river basins, increasing the ratio of runoff to precipitation and making flooding more likely (Changnon and Demissie, 1996).

Large urban areas, especially in the developed world, depend on extended "linkage systems" for their viability (Timmerman and White, 1997; Rosenzweig and Solecki, 2000). They depend on imports from the local area, region, nation, and even the world for everything from raw material and food, to product and waste exports and communications. These linkage systems often are vulnerable to severe storms, floods, and other severe weather events. Management, redundancy, and robustness of these interlocking systems is a top priority for developed world settlements especially, but increasingly so for the developing world (Timmerman and White, 1997).

7.6.1. Key Vulnerabilities

Key climate-related sensitivities in urban areas of the world include water supply and the effects of extreme events (primarily

¹See <www.sustainabledevelopment.org>, which provides data on growth for 237 world cities by development level, based on the UNCHS (Habitat) Global Urban Indicators database.

flooding) on infrastructure in river floodplains and coastal zones. These areas should be considered sensitive to climate change. To the extent that sensitive settlements coincide with conditions of poverty and lack of technical infrastructure, these settlements also will be particularly vulnerable to climate change.

7.6.2. Potential for Nonlinear Interactions and Synergistic Effects

Because of their role as centers for administration and commerce, urban areas integrate all of the environmental effects that visit a society and to some extent buffer their human occupants from natural environmental fluctuations. However, these urban areas still may be affected by several stresses that interact with each other in a nonlinear fashion (Rosenzweig and Solecki, 2000; Wilbanks and Wilkinson, 2001). Whatever cash economy there is in a country tends to reside in its biggest cities, and trade routes also focus on these areas. These are two very important coping mechanisms. Thus, for example, climate-related food shortages are more likely to be experienced in urban areas as an increase in migrants from the countryside or loss of business in agriculture-related business rather than as famine *per se*.

Once populations are housed in urban settlements, there are other potential interactions among climate effects that lead to nonlinear impacts on them. Flooding events that are beyond the designed capacity of settlement infrastructure are a case in point, especially in cases in which systems already may be degraded. Urban flooding can overwhelm sewage treatment systems, thereby increasing the risk of disease at the same time that water treatment systems are compromised, health services are disrupted, disease vector species are driven into close contact with people, and people are exposed to the elements because of lost housing. Outbreaks of epidemics are always a risk under such circumstances, whereas the breakdown of any single one of the affected systems might be merely inconvenient. Although all of these effects and mechanisms are well understood,

however, it is not possible to predict impacts *quantitatively* at this time.

Table 7-3 shows the primary synergistic effects between climate-related factors that may affect human settlements and the primary types of settlements or industries affected. Each cell identifies a synergistic effect between the climate impact featured in the row and another effect shown in the column. For example, climate-related impacts of flooding, landslides, and fire are compounded when they occur in settlements that also might be crowded by migration. Likewise, flooding in particular exacerbates water pollution and human health impacts and probably would compound problems in obtaining drinking water and transportation. In addition, the agricultural base and energy supplies could be affected in regions that already are water-deficient.

Air and water pollution effects of climate change would be worse if the health of human populations already is compromised (e.g., asthma attacks may be more severe or prolonged in a weakened population). Charlot-Valdieu *et al.* (1999) argue for reducing some stresses in a multiple-stress context to handle other stresses in a more sustainable manner.

Access to energy, clean water, sanitation, and selected other resources is essential to maintain human settlements and the health of the populations within. Flooding, landslides, or fire resulting from extreme weather could compound the shortage of resources by destroying critical infrastructure (floods in Honduras in 1998 and Mozambique in 2000 are examples of the phenomenon under current climate) and, in the case of water, polluting the sources. Similarly, water pollution reduces the effective water supply by making some sources unusable.

7.7. Science and Information Needs

Our ability to answer questions about climate change, vulnerability, and adaptation on the basis of research evidence is very limited

Table 7-3: Matrix of synergistic effects, by type of effect and settlement and industry type.^{a,b}

Primary Impact Mechanism	Synergistic Impact Mechanism, Settlement Type or Industry				
	Migration	Flooding, Landslides, Fire	Air and Water Pollution	Human Health	Energy, Water, Other Resources
Migration	—	U,RCS	U,RCS	U,RCS	U,E,A
Flooding , Landslides, Fire	U,RCS,TR	—	U,RD,RCS	U,RD,RCS	U,RD,RCS,TR
Air and Water Pollution	U,RCS	U,RD,RCS,RE	—	U,RD,RCS,RE,A	RE
Human Health	U	U,RD,RCS	U,RC,RE	—	U
Energy, Water, Other Resources	U,RD,RCS,A	U,RD,RCS	U,RD,RCS	—	—

^a Settlement types: RD = resource-dependent, RCS = riverine, coastal, steeplands, U = urban.

^b Industry types: A = agroindustry, E = energy, TR = transportation, RE = recreation.

for human settlements, energy, and industry. Energy has been regarded mainly as an issue for Working Group III, related more to causes of climate change than to impacts. Industry generally has been considered relatively insensitive to most primary climate change impacts, although some sectors (e.g., agroindustry) are dependent on supply streams that could be vulnerable to climate change impacts. Impacts of climate change on human settlements are hard to forecast, at least partly because the ability to project climate change at an urban or smaller scale has been so limited. As a result, more research is needed on impacts and adaptations in human settlements. Several activities also have been developed by governments in the area of "sustainable communities," which are designed primarily to reduce the impact of human settlements on the environment. Many of the actions recommended also reduce the vulnerability of settlements to global warming. Some areas of information required to support these programs have been identified by organizations such as the United Nations' International Decade for Natural Disaster Reduction (IDNDR Secretariat), the ICLEI, and the U.S. President's Council on Sustainable Development. Others were identified during preparation of the FAR, SAR, RICC, and this report.

The highest priority needs for research on impacts, adaptation, and vulnerabilities in human settlements are as follows:

- A much larger number and variety of bottom-up empirical case studies of climate change impacts and possible responses in settlements in the developing and industrialized world
- More reliable climate change scenarios at the scale of urban and even smaller areas
- Improved understanding of how climate change interacts with integrated multiple-stress contexts in human settlements, including possible ramifications of global urbanization
- Improved understanding of adaptation pathways, their costs and benefits, and what can reasonably be expected from them, especially in resource-constrained developing regions (includes autonomous and planned adaptation, as well as traditional and local adaptation; for example, analysis of water demand lags analysis of energy use in most countries)
- Improved understanding of the effects of climate on human migration and the effects of migration on source and destination settlements
- Improved understanding of critical climate change vulnerabilities in settlements, including conceivable low-probability, high-impact effects of climate change (need for continuing research and capacity-building efforts to improve preparedness and strengthen early warning and other mitigation aspects; establishment of a tropical cyclone landfall program is regarded as a logical vehicle for carrying research and development initiatives into the 21st century)
- Better understanding of the particular vulnerabilities of livelihoods and settlements of low-income and marginalized groups

- Improved understanding of the implications of climate variability and change for the well-being of human settlements as they relate to other sectors, other places, and the broader sustainable development process
- Improved understanding of the cascading of climate change through primary, secondary, and tertiary impacts within human settlements (a conclusion of the RICC, but not yet addressed effectively)
- Improved analytical capability to incorporate uncertainty, ambiguity, and indeterminacy in assessments of impacts and response strategies, at least partly by strengthening the science base for integrating quantitative and qualitative analysis, including undertakings such as scenario development and stakeholder participation.

Other key challenges to be faced include development of essential scientific and technical capacity in vulnerable regions, establishment and maintenance of adequate meteorological and hydrological monitoring networks, and improvement of seasonal and interannual prediction.

EXECUTIVE SUMMARY

The financial services sector—defined as private and public institutions that offer insurance, banking, and asset management services—is a unique qualitative indicator of the potential socioeconomic impacts of climate change because the sector is sensitive to climate change and offers an integrator of effects on other sectors. This assessment highlights insurance and other components of the financial services sector because they represent a risk-spreading mechanism through which the costs of weather-related events are distributed among other sectors and throughout society. The effects of natural and human-induced climate change on the financial services sector are likely to become manifest primarily through changes in the spatial distribution, frequencies, and intensities of ordinary and catastrophic weather events. There is high confidence that climate change and anticipated changes in weather-related events that are perceived to be linked to climate change would increase actuarial uncertainty in risk assessment and thus in the functioning of insurance markets.

The costs of ordinary and catastrophic weather events have exhibited a rapid upward trend in recent decades. Yearly global economic losses¹ from catastrophic events increased from US\$4 billion in the 1950s to US\$40 billion yr⁻¹ in the 1990s (all 1999 US\$). Including events of all sizes increases these totals by approximately two-fold. The insured portion of these losses rose from a negligible level to US\$9.2 billion annually during the same period, with a significantly higher insured fraction in industrialized countries. As a measure of increasing insurance industry vulnerability, the ratio of global property/casualty insurance premiums to weather-related losses—an important indicator of adaptive capacity—fell by a factor of three between 1985 and 1999. Chapter 15 discusses insurance issues for North America in depth.

The costs of weather events have risen rapidly despite significant and increasing efforts at fortifying infrastructure and enhancing disaster preparedness. These efforts dampen the observed rise in loss costs to an unknown degree, although the literature attempting to separate natural from human driving forces has not quantified this effect. Demographic and socioeconomic trends are increasing society’s exposure to weather-related losses. Part of the observed upward trend in historical disaster losses is linked to socioeconomic factors such as population growth, increased wealth, and urbanization in vulnerable areas, and part is linked to climatic factors such as observed changes in precipitation, flooding, and drought events (e.g., see Section 8.2.2 and Chapter 10). Precise attribution is complex, and there are differences in the balance of these two causes by region and by type of event. Notably, the growth rate in the damage cost

of non-weather-related and anthropogenic losses was one-third that of weather-related events for the period 1960–1999 (Munich Re, 2000). Many of the observed upward trends in weather-related losses are consistent with what would be expected under human-induced climate change.

Recent history has shown that weather-related losses can stress insurance companies to the point of bankruptcies, elevated consumer prices, withdrawal of insurance coverage, and elevated demand for publicly funded compensation and relief. Increased uncertainty regarding the frequency, intensity, and/or spatial distribution of weather-related losses will increase the vulnerability of the insurance and government sectors and complicate adaptation efforts.

The financial services sector as a whole is expected to be able to cope with the impacts of future climate change, although low-probability, high-impact events or multiple closely spaced events could severely affect parts of the sector. Trends toward increasing firm size, greater diversification, greater integration of insurance with other financial services, and improved tools to transfer risk all potentially contribute to this robustness. However, the property/casualty insurance and reinsurance

¹Total economic losses are dominated by direct damages (insured and uninsured)—defined as damage to fixed assets (including property or crops), capital, and inventories of finished and semi-finished goods or raw materials and finished products—that occur simultaneously or as a direct consequence of the natural phenomenon causing a disaster. Economic loss data also can include indirect or other secondary damages such as business interruptions, personal loss (e.g., injuries and death), or temporary relocation expenses for displaced households and businesses, as well as the effect on flow of goods that will not be produced and services that will not be provided. More loosely related damages such as impacts on national gross domestic product (GDP) are not included. Insured losses are a subset of economic losses. The data presented here are based on a diversity of sources compiled by the Geosciences Group at Munich Re for the period 1950–1999, and are unadjusted for purchasing power parity. The particular costs included can vary somewhat among countries and over time. In some cases, country definitions of losses set minimum thresholds for inclusion; thus, the totals presented here are underestimates of actual losses. For example, because of the minimum cost threshold of US\$5 million until 1996 and US\$25 million thereafter in the United States, no winter storms were included in the statistics for the 46-year period 1949–1974, and few were included thereafter (Kunkel *et al.*, 1999). Although large in aggregate, highly diffuse losses resulting from structural damages from land subsidence (e.g., approaching as much as US\$1 billion yr⁻¹ during periods of low rainfall in the UK; see Figure 8-3) also would rarely be captured in these statistics.

segments have greater sensitivity, and small, specialized, or undiversified companies even run the risk of bankruptcy. The banking industry as a provider of loans may be vulnerable to climate change under some conditions and in some regions. However, in many cases the banking sector transfers its risk back to the insurers who often purchase debt products.

Adaptation to climate change presents complex challenges, but it also presents opportunities to the sector. [It is worth noting that the term “mitigation” often is used in the insurance and financial services sectors in much the same way that the term “adaptation” is used in the climate research and policy communities.] Regulatory involvement in pricing, tax treatment of reserves, and the (in)ability of firms to withdraw from at-risk markets are examples of factors that influence the resilience of the sector. Management of climate-related risk varies by country and region. Usually it is a mixture of commercial and public arrangements and self-insurance. In the face of climate change, the relative role of each can be expected to change. Some potential response options offer co-benefits (e.g., stemming from climate change mitigation opportunities), in addition to helping the sector adapt to climate changes.

The effects of climate change—in terms of loss of life, effects on investment, and effects on the economy—are expected to be greatest in developing countries. Several countries experience impacts on their GDP as a consequence of natural disasters; damages have been as high as half of GDP in one case. Weather disasters set back development, particularly when funds are redirected from development projects to recovery projects.

Equity issues and development constraints would arise if weather-related risks become uninsurable, prices increase, or

availability becomes limited. Increased uncertainty could constrain the availability of insurance and investment funds and thus development. Conversely, more-extensive penetration of or access to insurance would increase the ability of developing countries to adapt to climate change. More widespread introduction of microfinancing schemes and development banking also could be an effective mechanism in helping developing countries and communities adapt.

The need for financial resources for adaptation in developing countries is addressed in the United Nations Framework Convention on Climate Change (UNFCCC) and the Kyoto Protocol. However, development of financing arrangements and analysis of the role of the financial services sector in developed and developing countries still is a relatively unexplored area.

This assessment of financial services identifies some areas of improved knowledge and has corroborated and further augmented conclusions reached in the Intergovernmental Panel on Climate Change’s Second Assessment Report (Dlugolecki *et al.*, 1996). It also highlights many areas in which greater understanding is needed—in particular, improved knowledge of future patterns of extreme weather; better analysis of economic losses to determine their causation; exploration of financial resources involved in dealing with climate change damage and adaptation; evaluation of alternative methods to generate such resources; deeper investigation of the sector’s vulnerability and resilience to a range of extreme weather event scenarios; and more research into how the sector (private and public elements) could innovate to meet the potential increase in demand for adaptation funding in developed and developing countries, both to spread and to reduce risks from climate change.

8.1. Introduction

Our definition of the financial services sector includes private and public institutions that offer insurance, disaster preparedness/recovery, banking, and asset management services. Analysis of the financial services sector provides a unique opportunity to quantify the potential socioeconomic impacts of climate change and offers a barometer of effects on other sectors (including the government sector). The Intergovernmental Panel on Climate Change (IPCC) Third Assessment Report (TAR) highlights insurance and other components of the financial services sector because they represent a risk-spreading mechanism through which the costs of weather-related events are distributed among other sectors and throughout society. The sector also is among the world's largest and is captured less effectively in other parts of the TAR. The financial services sector also stands to play a central part in adaptation and mitigation activities and is a major source of global and regional data on the costs of weather-related events (Mills, 1996; Changnon *et al.*, 2000; Kunreuther, 2000).

This chapter is about the impact of climate change on the financial services sector, as well as the way this sector can adapt and help society to adapt to climate change. Still, little can be said about the total financial cost of adapting to climate change. Short-term effects are likely to be felt most through changing frequencies and intensities of ordinary and catastrophic weather events.

The Second Assessment Report (SAR) chapter on financial services concluded that "within financial services the property insurance industry is most likely to be directly affected by climate change, since it is already vulnerable to variability in extreme weather events" (Dlugolecki *et al.*, 1996). Experience and analyses over the past 5 years has confirmed the trend of growing weather-related damage costs since the 1950s (see Section 8.2).

The vulnerability of and challenges for the insurance sector, private and public, are addressed in Section 8.3. Section 8.4 discusses the implications for other financial services, such as corporate, retail, and investment banking. There is evidence that the banking and insurance industries have become more aware of opportunities and threats with regard to climate change since the SAR. However, little information is available on climate change impact and adaptation implications for the banking sector.

Climate change impacts are expected to be greatest in the developing world. There is only limited penetration of or access to insurance in these regions. This situation makes these regions more vulnerable and will impair their ability to adapt. Over the past few years, several multilateral organizations and banks have taken initiatives to develop new financial schemes for coping with natural disasters in developing countries (see Section 8.5).

Issues regarding funding for adaptation are addressed in Section 8.6. Although knowledge about the financial services

sector, private and public, generally has increased since the SAR, major questions remain. Research could help explore the potential roles of the sector in helping society respond to the challenge of climate change (see Section 8.7).

8.2. Climate Change and Extreme Events that are Relevant to the Financial Services Sector

8.2.1. Present-Day Conditions

Present-day impacts of weather events on financial services are caused mainly by extreme events. Differences in vulnerability exist, caused by geographical location, population distribution, and national wealth. In developing countries, there may be very high mortality from extreme weather but relatively small costs to the financial sector because of low insurance penetration. In developed nations, the loss of life may be much less but may have enormous—even catastrophic—costs to the insurance industry (see Section 8.3.1). Swiss Re (2000b) has compiled lists of the 40 worst catastrophes between 1970 and 1999 in terms of insurance losses and fatalities. These lists show that:

- Of the 40 worst insured losses since 1970, only six were not weather related.
- Nineteen of the weather-related catastrophes affected the United States.
- Twenty-eight were related to windstorm (tropical and temperate latitudes).

In contrast, of the 40 worst events in terms of fatalities, only 16 were weather related, of which 13 occurred in Asia. A list of natural disasters causing billion-dollar losses drawn up by Munich Re (2000; see Table 8-3) shows that, of 30 such disasters, 15 affected the United States and seven affected Europe. Eighteen were related to windstorm. With the exception of earthquakes, all were weather related.

In recent decades, economic and insured losses related to weather extremes have increased rapidly (see Figure 8-1). An important part of this trend is related to socioeconomic factors; another part may be explained by climatic factors. Where trends in climate variables do occur, there are two possible principle causes:

- Variability in the natural modes of variability of the global climate system—for example, the Southern Oscillation, with its two characteristic modes of El Niño and La Niña. In the 1980s and 1990s, El Niño events occurred more frequently and lasted longer. The longest El Niño of the 20th century persisted from 1991 to 1995 and was rapidly succeeded by the most intense El Niño of the 20th century, in 1997–1998 (WMO, 1999).
- Anthropogenic global warming, which may be expected to lead to changes in all attributes of the climate system. Most obviously, we would expect it to lead to an increased frequency of high-temperature

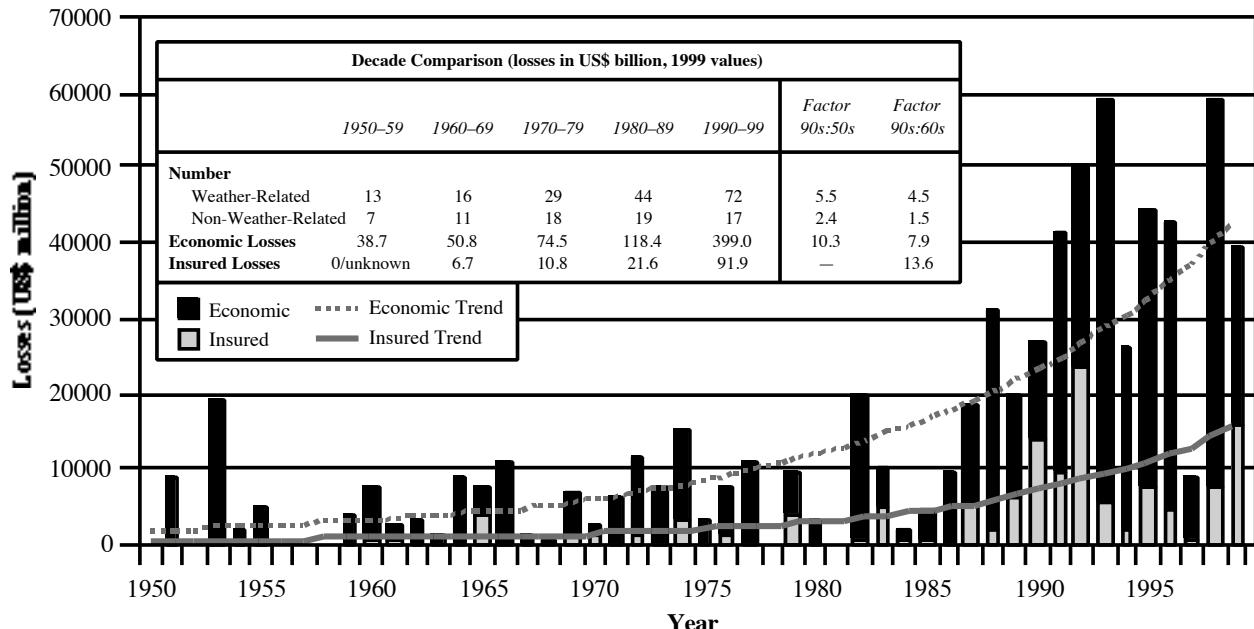

Figure 8-1: The costs of catastrophic weather events have exhibited a rapid upward trend in recent decades. Yearly economic losses from large events increased 10.3-fold from US\$4 billion in the 1950s to US\$40 billion per year in the 1990s (all in 1999 US\$). The insured portion of these losses rose from a negligible level to US\$9.2 billion annually during the same period, and the ratio of premiums to catastrophe losses fell by two-thirds. Notably, costs are larger by a factor of 2 when losses from ordinary, noncatastrophic weather-related events are included (e.g., as shown in Figure 8-6). The numbers generally include “captive” self-insurers but not the less-formal types of self-insurance (Munich Re, 2000).

extremes and a reduction in days with very low temperatures. There is evidence that the latter trend already is occurring (Easterling *et al.*, 2000b).

Whatever the cause, it is important to note that a relatively small change in the mean of a climate variable can lead to a large change in the occurrence of extremes. Mehl *et al.* (2000a) explore the implications for extremes of changes in the mean and/or variance; they show clearly that the relationship between a change in the mean and a change in the occurrence of extremes is nonlinear, as illustrated in Figure 8-2.

8.2.2. Attribution Analyses of Loss Trends

Weather-related events of all magnitudes resulted in US\$707 billion in insured and uninsured economic losses between 1985 and 1999 (Munich Re, 2000). A longer term comparison of large catastrophic events over the past 50 years reveals that economic losses (adjusted for inflation) increased by a factor of 10.3 (Figure 8-1). Over this same period, population grew by a factor of 2.4.

One of the vexing dilemmas in analyzing such historical data is disentangling causal factors related to human-induced climatic change, natural variability, and those having to do with human activity that could accelerate or dampen measured impacts. Numerous human factors are in operation that contribute to the

upward trends in real economic losses, including population growth, rising standard of living, urbanization and industrialization in high-risk regions, vulnerability of modern societies and technologies, environmental degradation, penetration of insurance, and changing societal attitudes toward compensation (the latter two factors may lead to an increase in losses reported). Data on the numbers of events also show an increase in many cases. The number of disasters (defined as annual requests from states for federal disaster declarations) has roughly doubled in the United States since the early 1980s (Anderson, 2000). It is relevant to note here that such requests involve considerations of significant social effects (Kunkel *et al.*, 1999); as a consequence, it is an indirect and subjective proxy for the frequency of events.

Growth trends in non-climate-related losses have been relatively constant over the past 3 decades. Losses from human-induced catastrophes have remained relatively constant (Swiss Re, 1999a). Earthquake losses have increased, but more slowly than weather-related losses (Bruce *et al.*, 1999). The number of disasters causing more than 1% GDP damage to affected countries has increased two to three times as rapidly for weather-related disasters as for earthquakes in the period 1963–1992 (United Nations, 1994).

Insurers have pointed out that local environmental factors such as soil degradation, loss of biodiversity, lack of drinkable water, pollution, deforestation, forest degradation, and land-use changes can amplify the impacts of weather-related catastrophes

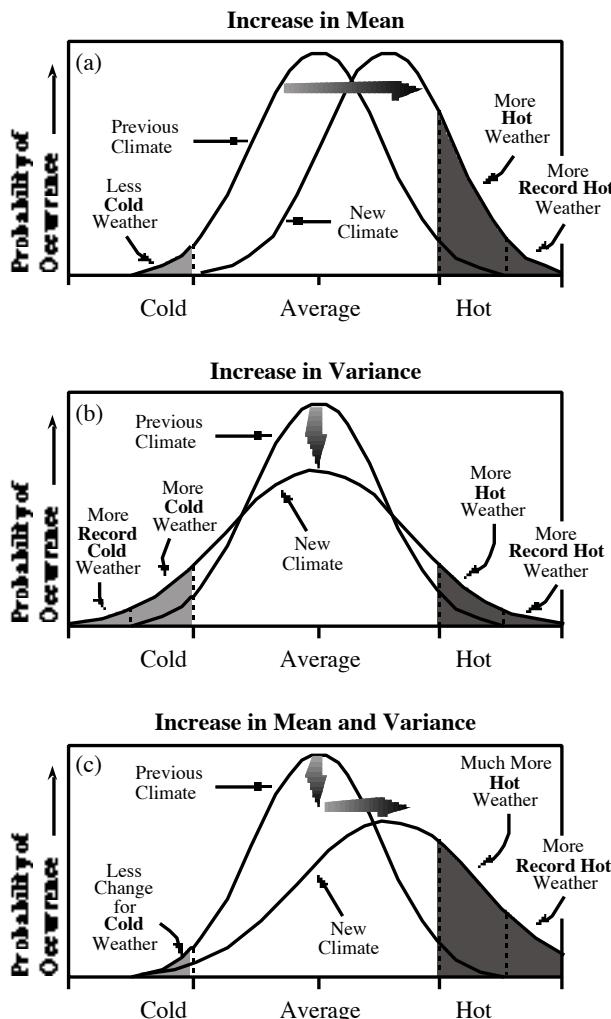

Figure 8-2: Schematic showing effect on extreme temperatures when (a) mean temperature increases, (b) variance increases, and (c) when both mean and variance increase for a normal distribution of temperature (TAR WGI, Figure 2.32).

(Zeng and Kelly, 1997). As an illustration, the extent of flood losses from Hurricane Mitch was attributed in part to deforestation in Central America.

Attempts to analyze the underlying causes of trends in natural disasters also must allow for the effects of human activities that offset growth factors (Kunkel *et al.*, 1999). A considerable leveling off or reduction in loss of life during U.S. disasters is one indicator that mitigation has been effective (Easterling *et al.*, 2000a). Loss-reduction efforts—typically unaccounted for in analyses we have seen—include considerable efforts to avert or reduce natural disaster impacts (e.g., coastal protection structures along coastlines; cloud seeding to deflect hailstorms; improved building codes; tightened land-use zoning; enhanced fire-suppression capacity; improved weather forecasts and early-warning systems; and improved disaster preparedness, response, and recovery). Within the insurance arena, increasing

deductibles (the initial tier of loss costs paid for by the insured) and withdrawal of coverage from particularly high-risk areas have reduced observed losses. The literature has not attempted to quantify the contribution of these activities.

The relative contributions of human and climatic factors to the changing patterns of losses varies, depending on place and type of event (see Table 8-1; also see Easterling *et al.*, 2000a,b for a review). U.S. studies have found that demography largely explains increases in losses for hurricanes, wind, hail, and tornado events, whereas winter storm damage has mixed causation (Pielke and Landsea, 1998; Changnon, 1999; Changnon and Changnon, 1999; Kunkel *et al.*, 1999). In addition, decadal-scale trends have been discerned for tropical cyclones. There is good evidence that the intensity and frequency of precipitation and flood-related extreme events in the United States is increasing (Zeng and Kelly, 1997; Karl and Knight, 1998; Pielke and Downton, 2000). This trend also has been found for precipitation in many other parts of the world (see Chapter 3). In a study of hailstorms in France, Dessens (1995) used insurance loss information as a proxy for storm occurrence and found a statistically significant upward trend between 1946 and 1990.

In one global analysis, Munich Re (1999b) estimates that economic losses from large natural disasters increased two-fold between the 1970s and 1990s, after correcting for inflation, insurance penetration and pricing effects, and increases in the material standard of living. A similar result was reported for UK buildings in the SAR (Dlugolecki *et al.*, 1996).

Based on the findings of TAR WGI, the information summarized in Table 8-1, and the analysis presented above, we conclude that some part of the upward trend in the cost of weather-related disasters illustrated in Figure 8-1 is linked to socioeconomic factors (increased wealth, shifts of population to the coasts, etc.) and some part is linked to climatic factors such as observed changes in precipitation and drought events. There are regional differences in the balance of these two causes.

8.2.3. Climate Events that are Relevant to the Insurance and Other Financial Services Sectors

Most weather extremes have relevance for the financial sector, as shown in Table 8-1. Column 6 summarizes the impacts of extremes on the main sectors of activity considered by TAR WGII. The ways in which these impacts affect the insurance industry are shown in Column 7.

Hot Temperature Extremes. Hot summers are likely to become more common as a result of global warming. The nonlinear effect of global warming on extreme events (see Figure 8-2) can be clearly illustrated by the example of temperature. Hulme (1997) estimates for the UK that the change in mean annual temperature in 2035 relative to the 1961–1990 mean will be approximately 1°C. Yet as a result, temperature conditions similar to those in the exceptional (1-in-300 years) summer of 1995 should occur once every 10 years on average between

Table 8-1: Extreme climate-related phenomena and their effects on the insurance industry: observed changes and projected changes during the 21st century [after Table 3-10; Munich Re, 1999b (p. 106)].

Changes in Extreme Climate Phenomena	Observed Changes	Projected Changes	Type of Event			Sensitive Insurance Branches ^b
			Likelihood	Relevant to Insurance Sector	Sensitive Time Scale	
<i>Temperature Extremes</i>						
Higher maximum temperatures, more hot days and heat waves ^c over nearly all land areas	Likely ^a (mixed trends for heatwaves in several regions)	Very likely ^a	Heat wave	Daily-weekly maximum	Electric reliability, human settlements	Health, life, property, business interruption
			Heat wave, droughts	Monthly-seasonal maximum	Forests (tree health), natural resources, agriculture, water resources, electricity demand and reliability, industry, health, tourism	Health, crop, business interruption
Higher (increasing) minimum temperatures, fewer cold days, frost days, and cold waves ^c over nearly all land areas	Very likely ^a (cold waves not treated by WGI)	Very likely ^a	Frost, frost heave	Daily-monthly minimum	Agriculture, energy demand, health, transport, human settlements	Health, crop, property, business interruption, vehicle
<i>Rainfall/Precipitation Extremes</i>						
More intense precipitation events	Likely ^a over many Northern Hemisphere mid- to high-latitude land areas	Very likely ^a over many areas	Flash flood	Hourly-daily maximum	Human settlements	Property, flood, vehicle, business interruption, life, health
			Flood, inundation, mudslide	Weekly-monthly maximum	Agriculture, forests, transport, water quality, human settlements, tourism	Property, flood, crop, marine, business interruption
Increased summer drying and associated risk of drought	Likely ^a in a few areas	Likely ^a over most mid-latitude continental interiors (lack of consistent projections in other areas)	Summer drought, land subsidence, wildfire	Monthly-seasonal minimum	Forests (tree health), natural resources, agriculture, water resources, (hydro) energy supply, human settlements	Crop, property, health

2021 and 2050. Insurance claims could rise because of land subsidence, business interruption, and crop failure. Although heat waves have been shown to lead to an increase in daily mortality and morbidity (see Section 9.4.1)—an impact that may be compounded by poor air quality—the effect is likely to be too small to noticeably affect the financial services sector.

Cold Temperature Extremes. As a result of global warming, cold extremes of winter weather are likely to become rarer. In

temperate latitudes, this development generally would be beneficial for business activities in, for example, the construction and transport sectors, with concomitant reductions in claims for business interruption. Although cold conditions should become rarer, a more active hydrological cycle might lead to more episodes of heavy snowfall, provided that temperatures remain below freezing. Regional shifts in the occurrence of phenomena such as ice storms may be expected. Ice storms occur when precipitation falls as rain but freezes on contact

Table 8-1 (continued)

Changes in Extreme Climate Phenomena	Observed Changes	Projected Changes	Type of Event			Sensitive Insurance Branches ^b
			Relevant to Insurance Sector	Time Scale	Sensitive Sectors/Activities	
<i>Rainfall/Precipitation Extremes (continued)</i>						
Increased intensity of mid-latitude storms ^c	Medium likelihood ^a of increase in Northern Hemisphere, decrease in Southern Hemisphere	Little agreement among current models	Snowstorm, ice storm, avalanche	Hourly-weekly	Forests, agriculture, energy distribution and reliability, human settlements, mortality, tourism	Property, crop, vehicle, aviation, life, business interruption
			Hailstorm	Hourly	Agriculture, property	Crop, vehicle, property, aviation
Intensified droughts and floods associated with El Niño events in many different regions (see also droughts and extreme precipitation events)	Inconclusive information	Likely ^a	Drought and floods	Various	Forests (tree health), natural resources, agriculture, water resources, (hydro) energy supply, human settlements	Property, flood, vehicle, crop, marine, business interruption, life, health
<i>Wind Extremes</i>						
Increased intensity of mid-latitude storms ^c	No compelling evidence for change	Little agreement among current models	Mid-latitude windstorm	Hourly-daily	Forests, electricity distribution and reliability, human settlements	Property, vehicle, aviation, marine, business interruption, life
			Tornadoes	Hourly	Forests, electricity distribution and reliability, human settlements	Property, vehicle, aviation, marine, business interruption
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities ^d	Wind extremes not observed in the few analyses available; insufficient data for precipitation	Likely ^a over some areas	Tropical storms, including cyclones, hurricanes, and typhoons	Hourly-weekly	Forests, electricity distribution and reliability, human settlements, agriculture	Property, vehicle, aviation, marine, business interruption, life

with a solid surface. Air temperatures close to freezing are ideal for ice storm occurrence. Thus, in colder regions where the weather currently is well below freezing in the winter, ice storms may become more common as a result of global warming, although they could become less frequent in areas where they occur at present (Francis and Hengeveld, 1998). An ice storm that occurred 7-10 January 1998, in the northeastern United States and eastern Canada, led to insured damage estimated at US\$1.2 billion (Lecomte *et al.*, 1998).

Heavy Rainfall and Flooding. TAR WGI Chapter 9 indicates that “many models” now project that conditions in the tropical Pacific may become more El Niño-like, with associated changes in precipitation patterns (Meehl *et al.*, 2000b). This would lead to more frequent patterns of El Niño-like floods and drought conditions in areas where teleconnections to the El Niño-Southern Oscillation (ENSO) exist. Observational studies assessed in TAR WGI Chapter 2 suggest that there has been a widespread increase in heavy and extreme precipitation

Table 8-1 (continued)

Changes in Extreme Climate Phenomena	Observed Changes	Projected Changes	Type of Event				Sensitive Insurance Branches ^b
			Likelihood	Relevant to Insurance Sector	Time Scale	Sensitive Sectors/Activities	
<i>Other Extremes</i>							
Refer to entries above for higher temperatures, increased tropical and mid-latitude storms	Refer to relevant entries above	Refer to relevant entries above	Lightning	Instantaneous	Electricity distribution and reliability, human settlements, wildfire	Life, property, vehicle, aviation, marine, business interruption	
Refer to entries above for increased tropical cyclones, Asian summer monsoon, and intensity of mid-latitude storms	Refer to relevant entries above	Refer to relevant entries above	Tidal surge (associated with onshore gales), coastal inundation	Daily	Coastal zone infrastructure, agriculture and industry, tourism	Life, marine, property, crop	
Increased Asian summer monsoon precipitation variability	Not treated by WGI	Likely ^a	Flood and drought	Seasonal	Agriculture, human settlements	Crop, property, health, life	

^a Likelihood refers to judgmental estimates of confidence used by Working Group I: *very likely* (90–99% chance); *likely* (66–90% chance). Unless otherwise stated, information on climate phenomena is taken from Working Group I's Summary for Policymakers and Technical Summary. These likelihoods refer to observed and projected changes in extreme climate phenomena and likelihood shown in first three columns of this table.

^b All findings in this column are high confidence, as described in Section 1.4 of the Technical Summary.

^c Information from Working Group I, Technical Summary, Section F.5.

^d Changes in regional distribution of tropical cyclones are possible but have not been established.

events in regions where total precipitation has increased (i.e., the middle and high latitudes of the Northern Hemisphere). Flooding is responsible for 40% of total economic losses and 10% of weather-related insurance losses globally.

Tropical hurricanes can lead to landslides. Hurricane Mitch probably is the most well-known event in recent years. This system, the strongest ever October tropical storm in the Atlantic Basin, stalled over Central America and produced more than 600 mm of rainfall in 48 hours. Resulting landslides and mudslides led to an estimated 9,000 deaths and insured losses of US\$513 million (Swiss Re, 2000b). In disasters of this magnitude, preparedness and planning can make a huge difference in loss of life and the amount of damage sustained.

Large river basin floods develop over huge areas following weeks of unusually high rainfall. In July and August 1997, flooding in central Europe caused 54 fatalities in Poland and required the evacuation of 162,000 people (Kundzewicz *et al.*, 1999). The value of the economic losses throughout central Europe amounted to approximately US\$5 billion, with insured losses of US\$940 million. The intensity of such flood events is driven not only by climatology but also by human management of the watershed.

Low Rainfall—Drought, Land Subsidence, and Wildfire. Drought is important for the financial sector through impacts on

commercial agriculture, building foundations, and wildfire occurrence. Figure 8-3 shows the cost of subsidence claims to the industry from 1975 to 1997 in England and Wales. There is a clear relationship with rainfall (with some lag effects). Similar effects are seen in France (Radevsky, 1999). Where insurance is used as the mechanism to finance repairs to building

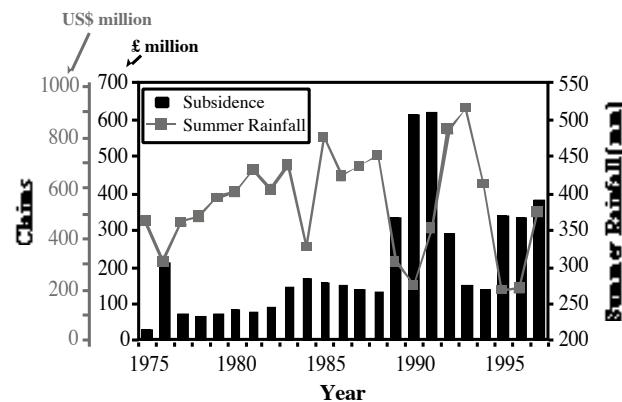

Figure 8-3: Summer rainfall and subsidence claims in the UK: 1975–1997. Rainfall data are for England and Wales, April to September (from Climatic Research Unit, University of East Anglia, UK). Subsidence claim costs are in original-year values (from Association of British Insurers).

foundations, as in the UK and France, costs for domestic properties can be higher than where the damage is not insured, as in Australia. Adaptive responses such as stronger foundations in new buildings and repairs to older housing capital should reduce the problem.

The worst drought of recent decades has occurred (indeed, it persists) in the Sahelian region of West Africa, where since 1968 rainfall has been below the long-term average in almost every year (Nicholson *et al.*, 2000). The strength and persistence of this deficit is unparalleled in recent times. Despite the drought's severity, it has had minimal impact on the commercial financial sector because of the low penetration of insurance in the region. However, the drought's role in the development of the region has been significant.

Wildfire is an increasingly important insurance issue, as illustrated by the US\$140 million economic losses sustained in the Los Alamos fire of 2000 (Hofmann, 2000b). Outdoor fire occurrence is likely to increase in a future warmer climate, particularly along the increasingly popular urban-rural fringe (Swiss Re, 1992; Torn *et al.*, 1998). Whereas in Europe most wildfires are of human origin (either deliberate or accidental), lightning (see below) is still the leading cause of forest fires in the western United States and Alaska (the regions of North America with the greatest number of wildfires).

Even if rainfall amounts are unchanged by global warming, higher temperatures will increase the level of risk associated with these hazards because of increased water loss through evaporation and transpiration.

Lightning Strikes. Model experiments are not able to tell us anything directly about changes in lightning occurrence as a result of global warming. Any increase in convective activity should lead to more frequent electrical storms and lightning discharges, and it seems likely that global warming will have such an effect in the tropics (Lal *et al.*, 1998) and in extratropical latitudes (White and Etkin, 1997). Reeve and Toumi (1999) suggest that a 1°C increase in average wet-bulb temperature can be accompanied in mid-latitudes by a 40% increase in lightning. Of relevance to insurers, lightning is a cause of fires and damage to electrical equipment, with associated business interruption claims (Mills *et al.*, 2001).

Tropical and Extratropical Windstorm. Experiments with climate models to date have not produced a consensus regarding the likely future occurrence of tropical and extratropical wind storms. Both have a very large capacity to cause damage. Hurricane Andrew, for example, occurred in 1992 in the Atlantic Basin and made landfall over the United States, causing US\$21 billion (1999 US\$) in insured damage. Hurricane Floyd, which caused US\$2.2 billion in insured losses in 1999, required the evacuation of 2 million people and imposed huge stress on infrastructure, resources, and ultimately health. The most damaging extratropical windstorm was Daria in 1990, which caused US\$6.8 billion in insured losses in northwestern Europe. In December 1999, windstorms Martin and Lothar

tracked south of the normal route, affecting France, northern Spain, and central Europe. Together they caused 140 fatalities and US\$8.4 billion in insured damage.

Sea-Level Rise. Increases in sea level pose a major potential risk to coastal zones (TAR WGI Chapter 6), especially if they are associated with an increase in storminess. The mid-range increase in sea level by the year 2100 as a result of anthropogenic climate change is 49 cm, taking into account atmospheric aerosol concentrations, with estimates ranging from 26 to 72 cm (TAR WGI Chapter 11). The main risk to the financial sector is in the effect that this change in mean sea level may imply for the occurrence of tidal surges, which already cause enormous damage and loss of life, especially in the developing world (see Box 8-4). One of Europe's greatest natural disasters in terms of loss of life was the 1953 storm surge in the North Sea, which led to almost 2,000 fatalities in The Netherlands and the UK.

8.3. Private and Public Insurance

This section examines the sensitivity, vulnerability, and adaptability of private- and public-sector insurance to climate change. Activities within these segments are significantly interrelated, and the role of each varies widely from country to country and over time (Van Schoubroeck, 1997; Ryland, 2000). Government programs exist primarily to correct market failures in the private sector, when insurance cannot be provided at a reasonable rate, or when insufficient capacity exists to pay claims (Mittler, 1992). In addition, the nature of events anticipated under climate change (e.g., increased flooding) draws into question their very insurability by private companies (Denenberg, 1964; Mittler, 1992; White and Etkin, 1997; Hausmann, 1998; Kunreuther, 1998; Nuttall, 1998).

Insurers are sensitive to a diversity of potential climate changes (Ross, 2000). Understanding and adapting to weather-related losses are high priorities in the insurance industry. Loss growth has resulted in the absence of commercial insurance for the most vulnerable risks, such as flood or crop damage in many countries. Changes in weather-related events associated with global climate change would increase the sector's vulnerability (Vellinga and Tol, 1993; Changnon *et al.*, 2000; TAR WGI Chapters 9 and 10). Recent history has shown that weather-related losses can stress insurance firms to the point of elevated prices, withdrawal of coverage, and insolvency (bankruptcy).

The private insurance sector is highly heterogeneous, and the penetration of insurance varies dramatically across regions and within countries, as does the exposure and vulnerability of human populations and property to natural disaster events. Analyses that are meaningful to local policymakers, governments, and economies must adopt a variety of perspectives: regional, state, municipality, company, and the growing number who are self-insured.

Based on observations over the past decade, the property/casualty (P/C) segment is more vulnerable to weather-related events

than the life/health segment (Table 8-2). The P/C segment is extremely diverse. The single most vulnerable branch appears to be property insurance, including business interruption (Bowers, 1998). Other lines, such as personal automobile insurance, have more limited exposure.

Of 8,820 loss events analyzed worldwide by Munich Re between 1985 and 1999, 85% were weather related, as were 75% of the economic losses and 87% of the insured losses (Munich Re, 1999b, 2000). The weather-related share of total

losses is as high as 100% in Africa and 98% in Europe. Global weather-related insurance losses from large events² have escalated from a negligible level in the 1950s to an average of US\$9.2 billion yr⁻¹ in the 1990s (Figure 8-1)—13.6-fold for the 1960–1999 period for which detailed data are available. Insurance losses have grown significantly faster than total economic losses and insurance reserves and assets (i.e., adaptive capacity). Since the 1950s, the decadal number of catastrophic weather-related events experienced by the insurance sector has grown 5.5-fold.

Table 8-2: Distribution of the global insurance market, including life/health and property/casualty, by region (Swiss Re, 1999b). Note that weightings between property/casualty and life/health vary considerably among countries. Swiss Re (1999b) provides detailed information by country. In some cases (e.g., Japan), life insurance premiums include annuities, which eventually are reimbursed to the insured.

Total Business	Premiums in 1998 (US\$M)	Share of World Market in 1998 (%)	Premiums as % of GDP in 1998	Premiums per capita in 1998 (US\$)	Property/Casualty Premiums as % of Total
America	817,858	38.0	7.7	1,021	54
– North America	779,593	36.2	9.0	2,592	53
– Latin America	38,265	1.8	2.0	77	72
Europe	699,474	32.5	6.9	614	42
– Western Europe	684,848	31.8	7.3	1,466	42
– Central/Eastern Europe	14,626	0.7	2.1	23	75
Asia	571,272	26.5	7.8	36	23

These trends would be exacerbated by increased vulnerability resulting from development of high-hazard zones and increasingly sensitive infrastructure (Swiss Re, 1998a; Hooke, 2000; see Chapter 4).

Insurers have differing views on climate change (Mills *et al.*, 2001). Although several insurers have devoted significant attention to the issue (especially in Europe and Asia), the vast majority have given it little visible consideration. Some have taken definitive precautionary positions in stating that there is a material threat (Swiss Re, 1994; UNEP, 1995, 1996; Jakobi, 1996; Nutter, 1996; Zeng and Kelly, 1997; Berz, 1999; Bruce *et al.*, 1999; Munich Re, 1999b; Storebrand, 2000), whereas others have taken a different view (Mooney, 1998; Unnewehr, 1999). Some have elected to focus on disaster preparedness; others have adopted a “wait-and-see” stance.

8.3.1. Major Market Segments: Property/Casualty and Life/Health

The world insurance market enjoyed revenues of US\$2.155 trillion in 1998 (7.4% of global GDP) (Table 8-2). Although insurance penetration is relatively low in developing countries and economies in transition, their insurance market growth rate averages approximately twice that in industrialized countries. Expenditures on insurance in developing countries typically represent between 0.5 and 4% of GDP, compared to 5–15% percent in developed countries (Swiss Re, 1999c). With 36% of total global insurance premiums, North America is the largest regional market (see Chapter 15), closely followed by Western Europe at 32%. Reinsurance is particularly focused on high-value loss situations, in developing countries, or for smaller primary insurers. Reinsurers typically collect US\$100 billion in premiums globally each year from primary insurers from whom they assume various (mostly property) risks.

The P/C insurance segment represented 41% of global industry premiums collected in 1998. As shown in Figure 8-4, the segment as a whole exhibits sensitivity to major natural disaster events, as evidenced by the reductions in U.S. insurer profitability during

²Economic losses are defined in footnote 1. The definition of “large” weather-related events is those in which the response capacity is overtaxed and interregional or international assistance becomes necessary, often in cases where thousands of people are killed, hundreds of thousands are left homeless, or the economic loss is substantial (Munich Re, 2000). Thus, events that are small but frequent tend to be excluded from these statistics. For example, land subsidence losses from two droughts during the 1990s in France resulted in losses of US\$2.5 billion, and even more in the UK, but these losses are largely absent from the “large” event data series. A similar case involves frequent but relatively small winterstorm events in northern latitudes and their losses. Figure 8-6 includes a fuller range of events, which tend to result in an adjusted loss level that is approximately twice that indicated by data on “large” events alone. “Large” events represent only 1% of the total number of events globally.

1992 (Hurricane Andrew and Iniki) and 1994 (Northridge earthquake). A list of the most costly events is presented in Table 8-3. Over the past 15 years, the global ratio of P/C premium income to natural catastrophe losses has decreased from 351:1 to 122:1—almost a three-fold rise in “exposure” (Figure 8-5; see Figure 15-6 for North America).

Climate- and weather-related risks faced by life/health insurers include injuries or death resulting from extreme weather episodes, water- or vector-borne diseases, degraded urban air quality, pressure on the quality and adequacy of food and water supplies, and increased vulnerability to power failures (see Chapters 4, 5, 9, 15; TAR WGIII Chapter 8; World Bank, 1997a; Epstein, 1999). In some areas, climate changes may yield health benefits, but negative health impacts are expected to outweigh positive ones if no actions are taken to adjust (Chapter 9). Such impacts will not be significant for the global financial sector in the near term, because life/heath insurance penetration currently is low in developing countries; the burden will fall largely on the informal and government sectors.

Owing to structural changes underway in the industry, the financial distinction between life and P/C insurers is blurring somewhat as a result of consolidation and mergers. Life insurers also are major holders of real estate and providers of mortgage lending; thus, they participate as property owners in weather-related property risks and may additionally assume property risk as investors in catastrophe bonds or other weather derivatives.

8.3.2. Risk Sharing between the Private and Public Sectors

The private insurance industry is part of a larger community that bears the costs of weather-related events (Ryland, 2000). The nature and cost of weather-related losses vary considerably around the globe, as does the portion of the loss that is privately insured. Private insurance pays a higher proportion of benefits for storm-related losses than for any other weather-related event, although flood insurance has a particularly low rate of coverage (Figure 8-6).

Insurers bear only 20% of the total economic costs of weather-related events globally. The ratio is far lower in developing countries (e.g., 7% in Africa and 4% in Asia for the year 1998) (Munich Re, 1999b). Even in countries where insurance penetration is high, insurance can account for less than half of the weather-related payouts—for example, 27% in Europe, 30% in the United States, 34% in Australia (Munich Re, 1999b), and 20% in Canada (EPC, 2000). In a review of four major wildfire and flood catastrophes in Australia, Leigh *et al.* (1998a,b) found that private-sector insurers bore 9–39% of the total economic losses; a comparable amount was provided by local and federal governments. Other entities assuming such costs include federal disaster relief providers, local governments, and uninsured property owners (Pielke and

Landsea, 1998)—as in the case of Hurricane Andrew, in which only half of the losses were insured (Pielke, 1997).

One important risk-assuming group, the corporate self-insurance market, is growing rapidly. In the United States, such premiums are approaching the level of the traditional commercial insurance market (roughly US\$134 billion) (Best's Review, 1998; Bowers, 1999).

Where insurers will not or are directly or indirectly regulated not to accept specific catastrophe risks, governments in many countries—including Belgium, France, Japan, The Netherlands, New Zealand, Norway, Spain, and the United States—may adopt the role of insurer or reinsurer or of regulator in establishing risk-pooling mechanisms (III, 2000b). Programs in France,

Japan, and New Zealand explicitly define the governments' role as paying for “uninsurable damages” (CCR, 1999; Gastel, 1999). In some countries (e.g., Canada, Finland, France, Norway, the United States) this is the case for drought or other agricultural risks, and in others (e.g., Japan) this is limited to earthquake risks. Such schemes can grow rapidly, as illustrated by the jump in the numbers of policies under the Florida Windstorm Underwriting Association from 62,000 to 417,000 between 1992 and 1997 (Anderson, 2000).

Government's role in providing resources for disaster preparedness and recovery and insurance products related to natural disasters also is a key moderating factor in insurers' involvement in such risks. It can be a two-edged sword: It provides a platform for private industry to participate, but it

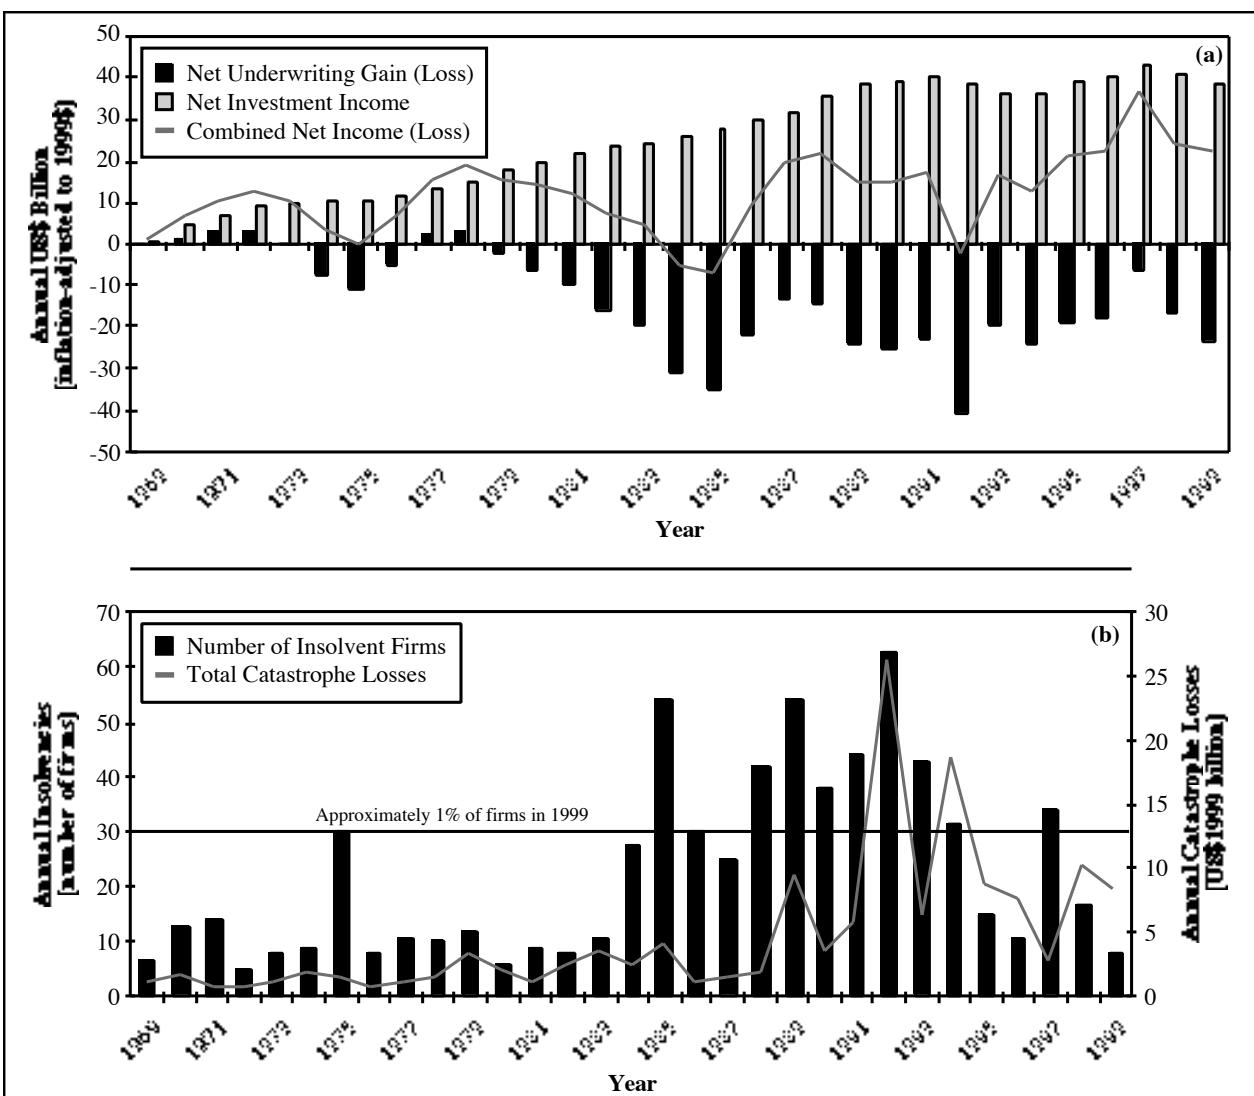

Figure 8-4: Trends in U.S. natural disasters, insurance industry profitability, and solvency, 1969–1999: (a) Sensitivity of property/casualty insurance sector net financial results to investment income and underwriting gain/loss. Upper bars indicate investment income; lower bars indicate net result of core business (premium revenues vs. claims paid). Curve is the net result. (b) Annual number of insolvencies and natural disaster losses (Mills *et al.*, 2001).

Table 8-3: Billion-dollar and larger insurance losses, 1970–1999, as of December 2000 (Munich Re, 2000). Figures are adjusted for inflation (1999 values).

Year	Event	Area	Insured Losses (US\$M)	Economic losses (US\$M)	Ratio of Insured/ Economic Losses
1992	Hurricane Andrew	USA	20,800	36,600	0.57
1994	Northridge earthquake	USA	17,600	50,600	0.35
1991	Typhoon Mireille	Japan	6,900	12,700	0.54

1991	Oakland fire	USA	2,200	2,600	0.85
1993	Blizzard	USA	2,000	5,800	0.34
1992	Hurricane Iniki	Hawaii	2,000	3,700	0.54
1999	Winterstorm Anatol	Europe	2,000	2,300	0.87
1996	Hurricane Fran	USA	1,800	5,700	0.32
1990	Winterstorm Wiebke	Europe	1,800	3,000	0.60
1990	Winterstorm Herta	Europe	1,800	2,600	0.69
1995	Hurricane Luis	Caribbean	1,700	2,800	0.61
1999	Tornadoes	USA	1,485	2,000	0.74
1998	Hailstorm, tempest	USA	1,400	1,900	0.74
1995	Hailstorm	USA	1,300	2,300	0.57
1993	Floods	USA	1,200	18,600	0.06
1998	Ice storm	Canada, USA	1,200	2,600	0.46
1999	Hailstorm	Australia	1,100	1,500	0.67
1998	Floods	China	1,050	30,900	0.03

also can drive consumers away from commercial market solutions (Klein, 1997; Pullen, 1999a). The absolute value of government payments for natural disasters is poorly documented, and the statistical record is fragmented. The United States made disaster-related payments of US\$119 billion (1993 US\$) over the 1977–1993 period, equivalent to an average of US\$7 billion yr⁻¹ (Anderson, 2000). The Japanese government has devoted 5–9% of its national budget to disaster preparedness and recovery in recent decades (Sudo *et al.*, 2000).

Flood insurance merits special mention, given the magnitude of risks and losses, the difficulty of establishing fair and actuarially based rates, and the connection between flood and climate change (see Chapter 4; Aldred, 2000). Recent analyses in the United States found that 25% of homes and other structures within 150 m of the coastline will fall victim to the effects of erosion within 60 years (Heinz Center, 2000). Sea-level rise will impact flood insurance through inundation and erosion resulting from storm surge (see Chapter 6). Countries differ widely with regard to their approach to defining and financing flood

risks via private-sector (re)insurance versus public mechanisms (Van Schoubroeck, 1997; Gaschen *et al.*, 1998; Hausmann, 1998). Hybrid public-private systems and government-only systems also can be found (e.g., in the United States), as can systems with no formal flood insurance whatsoever.

A central question is whether changes in natural disaster-related losses will generate increased reliance on already overburdened government-provided insurance mechanisms and disaster assistance. Governments already are showing decreased willingness to assume new weather-related liabilities, and tensions concerning risk-sharing between local and federal government bodies also are evident (Fletcher, 2000).

8.3.3. Insurers' Vulnerability and Capacity to Absorb Losses

A central component of vulnerability for public and private insurers alike is actuarial uncertainty in the dimensions, location, or timing of extreme weather events. This is particularly true

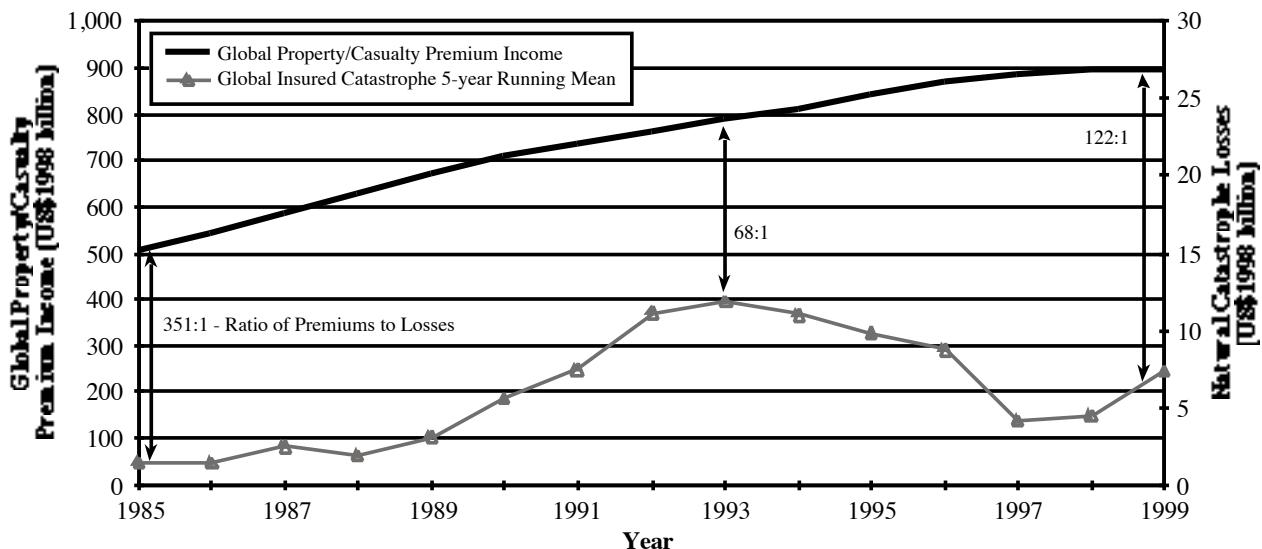

Figure 8-5: Global insured natural catastrophe losses (right-hand scale) vs. property/casualty premium income (left-hand scale), using a 5-year running mean. Global losses are from Munich Re (2000) and premiums from Swiss Re (1999b and earlier years). Note that these data include only major weather-related losses (approximately half of total weather-related losses). Premiums include considerable revenues (and associated reserves and surplus, not usable to pay catastrophe losses) from non-weather-related business segments and from self-insurers. The numbers generally include “captive” self-insurers but not the less-formal types of self-insurance. Exposure—measured as the ratio of premiums to losses—increased by a factor of 2.9 between the endpoints and by 5.2 in the worst single year (1993) within this time interval.

for insurance where the rate of damage rises faster than the driving weather phenomenon. Examples include the relationships between peak wind speeds and structural damages (Dlugolecki *et al.*, 1996), average temperature changes and lightning strokes (Price and Rind, 1994; Dinnis, 1999; Reeve and Toumi, 1999), extreme temperature events and electric power reductions or crop damages (Colombo *et al.*, 1999) and heat stress mortality (see Chapter 9), and precipitation and flooding (White and Etkin, 1997).

Changes in the spatial distribution of natural disasters pose special risks and challenges for the insurance sector. Localities to which risks shift will tend to be relatively inexperienced and unprepared to handle such risks, potentially resulting in a net societal increase in losses. A given insurer’s vulnerability often extends internationally. For example, U.S. insurers collected nearly 15% of their premiums overseas in 1997, and the ratio has been growing (III, 1999). Reinsurers have a particularly high degree of international exposure.

8.3.3.1. Quantifying Vulnerability and Adaptive Capacity

For insurers, vulnerability can be viewed broadly in terms of the sector’s capacity to pay for extreme events, together with the temporal sequence of such events. The key to vulnerability is the probable maximum loss (PML), which is the best estimate of the cost that is likely to emanate from an event with a specified probability of occurrence. In recent times, PMLs often have been revised upward significantly. The European winter storms Lothar and Martin of 1999 (US\$8.4 billion insured losses) caught

European insurers and reinsurers offguard, presenting losses that substantially exceeded prevailing expectations. These storms constituted the most serious natural disaster ever covered by insurance in France, with about 3 million claims (FFSA, 2000). One recent estimate for the United States was a combined PML of US\$155 billion for 1-in-100-year (i.e., 1% yr⁻¹ likelihood) for all types of natural disasters nationally (see Figure 15-8).

Unnewehr (1999) segmented the market and estimated that 17% of 1997 U.S. P/C insurance premiums were associated with “significant” exposure to weather-related loss. The paper did not explore other measures or sources of vulnerability and exposure, such as total insured property values at risk (US\$4 trillion in insured property in the Gulf and Atlantic coastal counties of the United States) (Hooke, 2000), or the extent of insolvency risk. These results are not transferable to other regions, where insurance systems and natural hazards can be very unlike those in the United States (see Figure 8-6).

The particular role of weather in vehicle-related losses is not well studied. Vehicle insurance represents 48% of U.S. P/C premiums; it is ranked in the aforementioned study as having “minor” weather sensitivity. Of total vehicle-related accidents, 16% of those in the United States are caused by adverse weather conditions (NHTSA, 1999); 33% of those in Canada are weather related (White and Etkin, 1997). Physical damage to vehicles during U.S. natural catastrophes between 1996 and mid-2000 represented an additional \$3.4 billion (10%) of total insured property losses, ranging as high as 55% for individual events (PCS, 2000; Mills *et al.*, 2001).

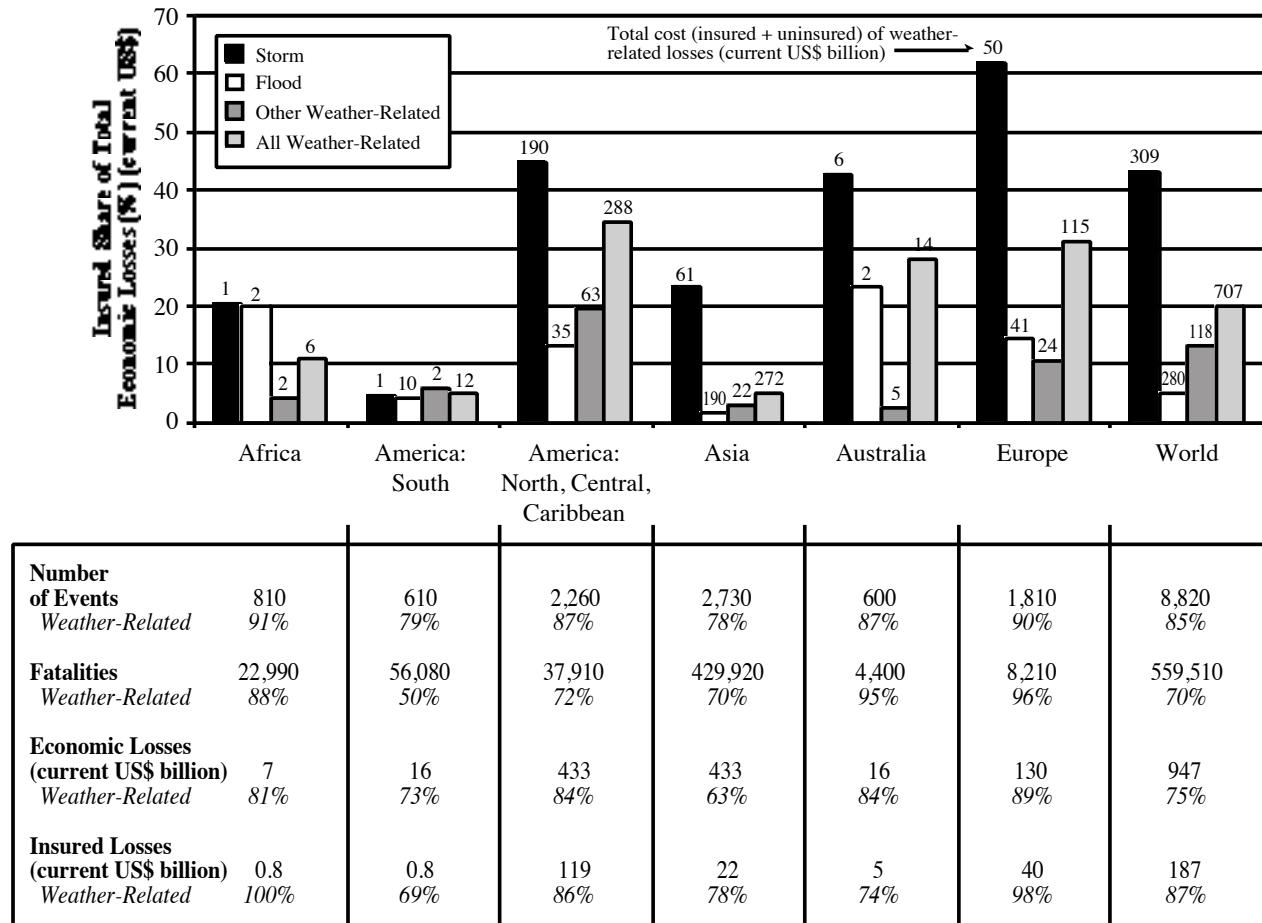

Figure 8-6: Regional insurance coverage for weather- and non-weather-related natural disasters, 1985–1999. The role of insurance in paying weather-related losses varies by event type and region, generally dominated by windstorm (Munich Re, 1999b). “Other” includes weather-related events such as wildfire, landslides, land subsidence, avalanches, extreme temperature events, droughts, lightning, frost, and ice/snow damages (Munich Re, 2000). The numbers generally include “captive” self-insurers but not the less-formal types of self-insurance. Total costs are higher than those summarized in Figure 8-1 because of the restriction of Figure 8-1 losses to those from large catastrophic events. Rounding errors may appear in data labels.

Although aggregate industry assessments are useful, analyses of vulnerability clearly must take into account the complexity and specialized structure of the insurance sector (GAO, 2000a). Although an aggregate U.S. insurance surplus of US\$200–350 billion often is cited (Doherty, 1997; GAO, 2000a), roughly 80% of this surplus is required for non-weather-sensitive branches (e.g., workers’ compensation), assuming proportionality with premium-based risk figures quoted by Unnewehr (1999). In addition, insurers are independent and have radically different mixes of risks, so individual firms may become insolvent long before losses approach the industry’s aggregate capacity (Doherty, 1997; Klein, 1997). Single-state PML events at the 1% likelihood level would result in economic stress ranging from 5 to 60% of insurers by market share (Pullen, 1999b). Moreover, catastrophes can disrupt insurance markets and harm insurance companies and consumers even in cases in which all claims are paid (GAO, 2000a; Ryland, 2000).

Reinsurance adequacy is another issue in vulnerability assessment. Swiss Re (1997) concluded that the availability of reinsurance coverage for natural disasters in 14 major markets was insufficient and that following a major event, primary insurers’ (the customers of reinsurers) equity base (surplus) would come under considerable strain. For PML windstorm events in Australia, Japan, and the United States, the impact on aggregate surplus would be reductions of 24, 41, and 11%, respectively (Swiss Re, 1997). Solvency analyses typically give only “partial credit” to primary insurers for reinsurance (e.g., 50% in the European Union) because of the uncertain viability of reinsurance contracts or reinsurers themselves following catastrophic losses (Doherty *et al.*, 1992; Swiss Re, 2000a).

Aside from issues of solvency, past extreme weather events clearly have measurable short- to medium-term impacts on insurance and reinsurance profitability—even at a national

scale (Figure 8-4a) and on the availability of insurance following the event (Davidson 1996; Pullen, 1999b). Catastrophe losses during 1999 and 2000 contributed to marked short-term depressions in earnings and stock prices for several large insurers and reinsurers (Edgecliffe-Johnson, 1999; Carpenter, 2000; Lonkevich, 2000). This development can restrict insurers' ability to raise new capital for expansion or even to continue the operations of highly exposed branches.

The overarching insurance business environment also is a key factor in determining vulnerability. Cyclical pressures or incidental broad-based stresses on the industry—such as major tobacco litigation (Bradford, 2000; Clow, 2000; Hofmann, 2000a), the crisis in environmental liability insurance (U.S. Superfund, asbestos, and lead paint claims), the Asian financial crisis, or increased competition from Internet sales (Ceniceros, 2000)—could place considerable demands on surplus (Mooney, 1999; GAO, 2000a; Swiss Re, 1998b, 2000a). Developments in financial markets can influence the level and availability of insurance surplus (Cummins *et al.*, 1999; GAO, 2000b; Swiss Re, 2000a). More than three-quarters of the growth in the U.S. insurance industry's surplus since 1995 resulted from capital gains (GAO, 2000a).

On one hand, the trend toward convergence between banking and insurance potentially increases diversification and robustness. On the other hand, it exposes one sector to risks faced in the other, and, in some cases, geographical diversification of a company's insurance business has moved it into the path of increased disaster losses (Berry, 2000; Greenwald, 2000; Howard, 2000b; Lonkevich, 2000). Weather-related vulnerability could increase if insurers participate in emerging capital market alternatives for risk financing (Marcon, 1999). In general, such convergence is more likely for the life insurance segment.

8.3.3.2. Natural Catastrophes and Insurer Solvency

Historical weather-related insolvencies illustrate the vulnerability of large and small insurers to the types of natural disasters that potentially are associated with climate change (Stipp, 1997; Swiss Re, 2000a; Mills *et al.*, 2001). Nearly 650 U.S. insurers became insolvent between 1969 and 1998 (Figure 8-4b) (Matthews *et al.*, 1999).

Of the 36 of 426 specifically attributed insolvencies occurring primarily as a result of natural catastrophes, more than half occurred between 1989 and 1993—the period of Hurricanes Hugo, Iniki, and Andrew—despite increased insurer capacity (Davidson, 1997; Doherty, 1997; Matthews *et al.*, 1999; Swiss Re, 2000b). Given the multi-factorial nature of most insolvencies, weather-related losses were no doubt a contributing factor in other cases as well. Although small or geographically specialized firms are most vulnerable, insolvencies of larger and more regionally diversified companies have occurred in the European Union (Swiss Re, 2000a) and in the United States (see Section 15.2.7). As a result of Hurricane Andrew, the largest U.S. home insurer, State Farm Fire and Casualty, was

brought to the brink of insolvency by a US\$4 billion loss and had to be rescued by its parent company (Stipp, 1997). The second largest U.S. home insurer, Allstate, paid out US\$1.9 billion (which was US\$500 million more than it had made in profits from its Florida operations from all types of insurance, including investment income, over the 53 years it had been in business) and also had to be rescued by its parent company (III, 2000a).

Little analysis of historic insolvencies in relation to natural catastrophes has been conducted outside the United States. Data for property/casualty firms in France, Germany, the UK, and the United States show that annual “baseline” insolvencies range from 0 to 0.5% of all firms to more than 2% in years with larger natural disasters (Swiss Re, 2000a). Natural disasters contributed to the severe difficulties experienced by the London market, including Lloyd's of London's near insolvency.

Future-oriented analyses of insurer solvency also have been conducted; these analyses show PMLs of US\$45–100 billion, which—despite several recognized conservatisms in the analyses—would result in serious levels of insolvency in the industry (ISO, 1996; Cummins *et al.*, 1999; Kelly and Zeng, 1999). As many as 45% of insurers in the United States (representing 62% of the market share) could be placed in this position (GAO, 2000a,b). These findings are comparable to an earlier study showing that the rise in PMLs is stretching insurers' adaptive capacity (AIRAC, 1986).

Although much attention is focused on catastrophic loss events, “small” loss events are responsible for 50% of total economic and insured losses from weather-related events globally (Munich Re, 2000). If such events are closely spaced, they also can generate insolvencies or deplete surplus (Swiss Re, 1997; Ryland, 2000). Hybrid events involving multiple sources of insurance losses are of particular concern (White and Etkin, 1997; Francis and Hengeveld, 1998). This concern is exemplified in the case of ENSO events. A series of small events could be worse for insurers, in fact, than a single large event because individual losses per event often are capped (Stipp, 1997). Very little has been published on this subject since the mid-1980s (AIRAC, 1986).

8.3.3.3. Vulnerability of Reinsurers

Reinsurance provides a significant and essential form of risk-spreading capacity for primary insurers. For natural catastrophes, this risk-spreading normally takes the form of an “excess” contract; primary insurers retain the first tier of losses up to a “trigger point” above which they purchase reinsurance, which operates up to a specified “exit point” or upper limit. After the catastrophes of the past 2 decades, reinsurers are leaving more of the risks with primary insurers, by increasing trigger points and lowering exit points (Stipp, 1997).

Many of the vulnerabilities experienced by primary insurers also apply to reinsurers. Several reinsurers became insolvent or were absorbed by larger firms during the crisis period of

1989–1993 (ISO, 1999; Mooney, 2000). The unexpectedly costly European windstorms of 1999 caused further problems (Andrews, 2000). For example, an already weakened Australian reinsurer covering these storms became insolvent despite total assets of US\$2.3 billion (Howard, 2000a). According to the Insurance Information Institute (III, 2000a), the world's catastrophe reinsurance industry "...lacks the capacity to insure mega-losses in excess of US\$50 billion." Government reinsurance systems also have shown signs of stress—as evidenced in France, where reserves fell by 50% during the 1990s and reinsurance rates rose sharply (CCR, 1999).

8.3.3.4. Regulatory Uncertainties

An additional source of vulnerability arises from regulatory uncertainties, such as the degree of flexibility afforded in withdrawing from markets and risks and in raising insurance prices (Davidson, 1996; Insurance Regulator, 1998; III, 2000a; Ryland, 2000). In some jurisdictions, regulators have restricted policy cancellations and nonrenewals following natural disaster losses such as Hurricane Andrew (ISO, 1994a,b; Lecomte and Gahagan, 1998). Recent requests from Florida insurers to double rates to protect insurers from hurricane risks also have been resisted by regulators (III, 2000b). On the other hand, under some conditions regulators can force insurers to withdraw from markets or otherwise change their business practices so they maintain minimum solvency requirements (GAO, 2000a). Pre-event accumulation and taxation of reserves also is an important issue, and policies vary by country (Eley, 1996; Davidson, 1997).

8.3.3.5. Vulnerability of Local, State, and Federal Governments as Providers of Insurance and Relief Assistance

Under climate change, sustained increases in the frequency and/or intensity of extreme weather events could stress the government sector itself as a provider of insurance, a provider of domestic and international disaster preparedness/recovery services, and an entity that itself manages property and undertakes weather-sensitive activities (e.g., ranging from mail delivery to operation of military facilities near coastlines or waterways). Increasingly, governments seek to cap or reduce existing exposures (ISO 1994b, 1999; Gastel, 1999; Pullen 1999b; FEMA, 2000; III, 2000b). Governments in developing countries participate especially deeply in weather-related risks, given the low level of private insurance availability and often a higher level of government-owned infrastructure.

Disaster relief provided by the U.S. government has totaled \$30 billion since 1953 (Changnon and Easterling 2000). Nearly half of these losses have occurred since 1990, and inflation-corrected payments rose six-fold between the late 1960s and the early 1990s (Easterling *et al.*, 2000a). These costs do not include temporary housing, unemployment insurance, and small business loans also provided by government.

Governments are particularly sensitive to changes in flood- and crop-related losses because they often are the primary or sole providers of such insurance, and climate changes are expected to exacerbate these losses (see Chapters 4 and 5; Rosenzweig *et al.*, 2000). U.S. government-insured crop/hail losses grew 11-fold between the 1950s and the 1990s (Easterling *et al.*, 2000a). In Japan, the majority of international relief—7–8 billion yen in 1990—is related to floods (Sudo *et al.*, 2000). Solvency is a material issue for government programs, as exemplified by the \$810 million deficit in the U.S. flood insurance program in the mid-1990s (Anderson, 2000). U.S. crop and flood insurance programs have never been profitable (GAO, 2000a; Heinz Center, 2000). The French catastrophe reinsurance fund (Caisse Centrale de Réassurance) had become depleted as of the late 1990s and could no longer deal with a major catastrophe from accumulated surplus (CCR, 1999).

8.3.4. Adaptation

Insurance losses are paid out of premiums and from surplus (net assets). The ability to generate premiums and rebuild surpluses cannot be increased quickly in response to changes in the incidence of losses. In a developing country context, where insurance markets are nascent, this problem is particularly acute.

Insurers have many tools for reducing their financial vulnerability to losses (Mooney, 1998; Berz, 1999; Bruce *et al.*, 1999; Unnewehr, 1999; III, 2000b). These tools include raising prices, nonrenewal of existing policies, cessation of writing new policies, limiting maximum losses claimable, paying for the depreciated value of damaged property instead of new-replacement value, or raising deductibles. The additional strategies of improved pricing and better claims-handling were reviewed in some detail in the SAR (Dlugolecki *et al.*, 1996). Many adaptation strategies in use or under discussion make good sense for insurers irrespective of potential changes in the climate resulting from human activities (Sarewitz *et al.*, 2000) (see Box 8-1).

Insurance prices exhibit sensitivity to disaster events (Paragon Reinsurance Risk Management Services, as cited in Klein, 1997; Edgecliffe-Johnson, 1999). Reinsurance prices rose by approximately 250% following Hurricane Andrew (see Section 15.2.7). Following the upsurge in catastrophe losses in 1999, the trend once again is toward upward pressure on prices (Mooney, 2000).

Following the period of (upward) price adjustments in response to a major natural disaster, however, insurers often enter or re-enter a battered market that offers substantial nonactuarially based discounts, resulting in inadequate prices for all players in the market (Matthews *et al.*, 1999). Similar behavior has been observed among reinsurers (Stipp, 1997). Insurers also may reduce risk management efforts and incentives in the face of competitive pressures on prices. Competitive pressures can cause some insurers to assume greater risk to offer more attractive

Box 8-1. Co-Benefits that Are Relevant for the Insurance and Other Financial Services Sectors

Co-benefits are discussed elsewhere in the Third Assessment Report (TAR WGIII Chapters 3 and 8). Several adaptation mechanisms that are relevant to public and private disaster risk management possess important co-benefits, but these mechanisms are rarely accounted for in cost-effectiveness analyses. Though they normally are associated with mitigation (e.g., emissions reductions or enhanced carbon sinks), some also stand to enhance adaptive capacity or otherwise benefit insurers and other parties in the financial services sector (Sarewitz *et al.*, 2000). Further research on this topic is merited.

- *Energy End-Use Efficiency.* Various co-benefits pertaining to energy-efficient technologies have been documented (Mills and Rosenfeld, 1996; Vine *et al.*, 1999, 2000; Changnon and Easterling, 2000; Zwirner, 2000; TAR WGIII Chapter 5). Improved insulation and equipment efficiency can reduce the vulnerability of structures to extreme temperature episodes and contribute to reduced greenhouse gas emissions. Other examples include linkages between public transit and reduced speed limits and improved highway safety (Unnewehr, 1999; TAR WGIII Chapter 9); energy-efficient ultraviolet water disinfection to conserve fuelwood and reduce deforestation (Gadgil *et al.*, 1997); and emission reductions resulting in improved air quality and reduced respiratory disease (see Chapter 9).
- *Renewable Energy and Distributed Energy Systems.* Certain renewable and distributed energy supply technologies have attributes that are relevant to risk management and disaster recovery (Mills, 1996, 1999; Mills and Knoepfel, 1997). For example, low-power/energy-efficient technologies can reduce business interruption risks by extending the reliability and operating range of backup power systems (Stauffer, 1995; Kats, 1998; Lecomte and Gahagan, 1998; Vine *et al.*, 1999; Deering and Thornton, 2000). Substitution of biofuels for fossil fuels can yield improved air quality and reduced flood risk (IPCC, 2000; TAR WGIII Chapter 9).
- *Sustainable Forestry, Agriculture, and Wetlands Management.* Enhancing organic soil content benefits crop insurance as well as contributing to improved water quality and food security. Sustainable forestry practices yield benefits of watershed management and flood/mudflow control, which are necessary foundations for establishing a modern economy (Scott, 1996; IFRC-RCS, 1999b; IPCC, 2000; Hamilton, 2000; see also Chapter 5). Wetlands restoration helps to protect against flooding and coastal erosion, although methane release from wetlands also must be considered (IPCC, 2000).
- *“Green” Financial Products.* Initiatives such as innovative financing of energy-efficiency improvements, insurance products that promote better environmental management, or insurance for adaptation/mitigation projects under the U.N. Framework Convention on Climate Change (UNFCCC) can simultaneously support adaptation and mitigation objectives (Hugenschmidt and Janssen, 1999; Mills, 1999; UNEP, 1999; Zwirner, 2000). However, considerable business risk and liability may be associated with UNFCCC projects if measurement and verification are poor or issues of buyer/seller liability are not addressed by insurers in the drafting of insurance contracts.

prices and products to consumers, through acquisitions of weakened companies and destabilizing growth rates (Matthews *et al.*, 1999).

Favorable underwriting or investment experience may generate surpluses, but many legislatures do not permit insurers explicitly to fund pre-event catastrophe reserves to account for anticipated changes in climate and weather. Alternatively, insurers may try to raise more capital or reduce dividends paid to shareholders, but such actions will not be acceptable to financial markets if the risk-to-reward ratio is not competitive with that of other companies or sectors. The trend toward consolidation within the insurance sector is sometimes regarded as a factor that reduces insurer vulnerability to catastrophic losses.

8.3.4.1. Adaptation Mechanisms: Risk-Spreading

Public and private insurance is inherently a risk-spreading mechanism. Insurers also can spread risks through reinsurance, depending on its availability and price. Losses associated with

uninsurable risks, or unpaid claims in the event of insurer insolvencies, often are partly spread to the community through disaster relief or guaranty (“solvency”) funds. State-managed guaranty funds—to which insurers must contribute—are used for specified catastrophe losses in France, Germany, Japan, The Netherlands, the UK, and the United States (III, 2000a; Swiss Re, 2000a). Of the 25 largest U.S. P/C insolvencies (amounting to US\$5 billion in claims), 29% of the losses were recoverable through guaranty funds; national capacity was only US\$3.4 billion as of 1998 (NCIGF, 1999). In the United States, the property insurance residual markets known as Fair Access to Insurance Requirements (FAIR Plans), Beach or Windstorm Plans, and joint underwriting associations (JUAs) represented insured property value (exposure) of US\$24 billion in 1970 and US\$285 billion in 1998 (III, 1999; Gastel, 2000).

Although risks also can be spread between public and private insurers, governments have elected to cap their exposures by formally limiting government-paid losses for weather-related events in the United States (GAO, 1994; Pullen, 1999b; III, 2000b) and earthquake losses in Japan (Gastel, 1999).

Governments also are trying to reduce their insurance and disaster recovery spending (ISO, 1994b, 1999; FEMA, 2000).

Nonconventional “alternative risk transfer” (ART) mechanisms have begun to emerge and are regarded by some banks and insurers as playing a role in the continued viability of insurance (see Section 8.4). On the other hand, some insurers, consumers, and members of the financial community question the efficacy and attractiveness of these new risk-spreading mechanisms (Tol, 1998; Peara, 1999; Swiss Re, 1999b; Bantwal and Kunreuther, 2000; Freeman, 2000; GAO, 2000a; Jamison, 2000; Nutter, 2000).

“Moral hazard”—a pervasive issue in the industry—results when, by virtue of adaptation efforts or the very availability of insurance (or reinsurance or government aid), the insured feels less compelled to prevent losses (White and Etkin, 1997; Ryland, 2000). Government programs have been faulted for unintentionally encouraging such maladaptation and risky behavior (Anderson, 2000; Changnon and Easterling, 2000). For example, it is estimated that one-quarter of the development over the past 20 years in at-risk areas along the U.S. coastline is a result of the presence of the National Flood Insurance Program (Heinz Center, 2000). Moral hazard also has been ascribed to primary insurers or reinsurers who rely excessively on state-maintained guaranty funds (Kunreuther and Roth, 1998; Swiss Re, 2000a).

8.3.4.2. Adaptation Mechanisms: Risk Reduction

Although risk-spreading is largely an economic and distributional process, risk reduction focuses more on technology, environmental management, land-use planning, engineered disaster preparedness/recovery, and predictive modeling. Hooke (2000) provides a good overview of the challenges facing risk-reduction initiatives. The UN’s International Decade for Natural Disaster Reduction (IDNDR) is a leading example of international cooperation in this area.

The insurance industry is an important participant in partnership with other public and private entities (Ryland, 2000). Examples include the use of geographic information systems to better understand and pinpoint risks, land-use planning, flood control programs, early warning systems, sustainable forest management, coastal defense, and wind-resistant construction techniques supported by building codes (Bourrelier *et al.*, 2000; Davenport, 2000; Hamilton, 2000; Hooke, 2000; Sudo *et al.*, 2000). However, the scale of effort has been much smaller than that anticipated for global climatic changes, and loss prevention generally has focused on fortifying the individual against perils, rather than reducing the peril itself (Kunreuther and Roth, 1998) and on post-disaster actions (Ryland, 2000).

Any discussion of vulnerability, impacts, and adaptation also should include insurance brokers, agents, risk managers, and trade associations. In 1998, there were more than 750,000 such workers in the United States alone (III, 1999).

A key but often untapped opportunity is to rebuild damaged structures in a more disaster-resistant fashion following loss events, as in the U.S. National Flood Insurance Program. Pervasive problems with building code enforcement and compliance have emerged following natural disasters. For example, 70% of the losses from Hurricane Alicia were traced to lax code enforcement (III, 2000a). Building industry stakeholders often resist new codes. Reinvigorating businesses and other forms of economic activity also is central to disaster recovery (Carrido, 2000).

Energy systems can have important implications for economic and insured losses through the vulnerability (reliability and/or physical damage) of energy generation, transmission, and distribution technologies (Epps, 1997; Keener, 1997; Deering and Thornton, 2000). Hydroelectric power resources, for example, are weather sensitive (see Chapter 15). Climate change may confound the actuarial basis for weather-related insurance provided to energy producers and for utility interruption insurance provided to energy users. Energy-related business interruption (via lightning damages, interrupted operations, inventory spoilage, event cancellation, disrupted tourism, etc.) is a significant weather-related exposure faced by the insurance sector (as evidenced by the extended power failure faced by Auckland, New Zealand, following a major heat wave in 1998). The North American ice storm of 1998 offers another dramatic example of the role of power disruption in disaster-related insurance losses (Lecomte and Gahagan, 1998; Table 15-5). Improved appraisal of the physical vulnerability of existing energy systems and of new technologies deployed for emission-reduction projects (e.g., as part of Clean Development Mechanism or Joint Implementation) would help to reduce vulnerability to extreme weather events and other losses (World Bank, 1999; Zwirner, 2000). The aftermath of Hurricane Andrew illustrated the complex nature of losses caused by natural disasters. About 20% of insured economic losses were related to business interruption (40% in the case of Hurricane Hugo) (Mills, 1996).

Effective risk reduction requires foresight. The insurance sector participates in a limited way in weather- and climate-related research and modeling (Kelly and Zeng, 1999). The Risk Prediction Initiative and the World Institute for Disaster Risk Management are two examples of insurer-funded research centers. Insurers’ catastrophe models are not presently used in association with climate-prediction tools such as general circulation models (Peara and Mills, 1999). Their predictive power is poorly validated (Pielke, 1998; Pielke *et al.*, 1999) and often exhibits significant unexplained model-to-model variation (Matthews *et al.*, 1999; GAO, 2000a). Insurance regulators in the United States have resisted efforts to include them in ratemaking proceedings (III, 2000b). Thus, the insurance community may stand to benefit from analytical collaboration with the natural sciences community (Nutter 1996; Changnon *et al.*, 1997; Zeng, 2000; Mills *et al.*, 2001). Formal solvency analyses conducted by insurance regulators also could benefit from more explicit treatment of future climate scenarios.

Box 8-2. Equity Issues that are Relevant for the Insurance and Other Financial Services Sectors

Equity is a material issue facing the financial services sector systems, within and among countries. For example, inequities can be created when the premiums paid by insureds become severely decoupled from the risks they face. On the other hand, strictly equalized insurance payments can result in a problem known as “adverse selection,” wherein only those with higher-than-average risk will actively purchase insurance, causing the system to become ineffective.

The burden of natural disasters tends to fall disproportionately on economically disadvantaged people, especially in developing countries (Hooke, 2000; Kreimer and Arnold, 2000). However, access to the benefits of insurance is correlated with income level. Lower income consumers in poor and wealthy countries alike have difficulty affording insurance or financing even at current rates (Miller *et al.*, 2000) and often live and work in more vulnerable locations. Immigrant cultural groups, as well as aboriginal peoples, may have less access to pre-disaster information and be more vulnerable to natural disasters themselves (Solis *et al.*, 1997).

As an illustration of price-related stresses, projected increases in coastal erosion in the United States would require a doubling of current insurance rates—probably requiring cross-subsidies among insureds (Heinz Center, 2000).

In developing nations, the availability of insurance and financing has considerably lower penetration than in wealthy nations. At the global scale, one form of inequity arises in which a greater share of the costs of extreme weather events are borne by governments and consumers in the “south” than in the “north.” Rising uncertainties could reduce the availability of insurance in some areas and impede the expansion of adaptive capacity offered by insurance markets in developing countries. Governments’ ability to compensate by providing more insurance and disaster relief would be similarly strained.

Although much progress has been made in risk-reduction technology *per se*, attention is increasingly focused on problems of implementation. Key issues identified by IDNDR include public awareness of risks, training of practitioners, commitment by public officials, and justification and financing of risk-reduction strategies (Hamilton, 2000; Hooke, 2000)—all areas where the financial services sector can play a part.

8.4. Impacts and the Role of the Banking Industry

In the private sector, the insurance and banking industries play leading roles as investors, although they focus on different aspects of this business. The role of banks is to cover the credit part (by providing loans), whereas insurance companies act as investors on the capital markets, as well as in the property/casualty branches; they also insure projects financed by banks. This section focuses on the banking industry.

8.4.1. Climate Change Impacts

Environmental issues such as climate change may have substantive impacts on the global economy. From a financial point of view, such problems are regarded as environmentally induced economic risks (Figge, 1998). In general, the size of the players, their diversification, and increasingly sophisticated techniques of risk reduction make it unlikely that banks and asset managers will perceive climate change as presenting any material threat to their economic viability.

On the positive side, banks could provide services and develop financing techniques that accommodate and facilitate adaptation

to weather extremes (e.g., private insurance, catastrophe bonds, weather-related trading). Assessment of expected benefits of an investment decision—whether it is a direct investment, through financing of an infrastructure project, or an indirect investment that involves investing in shares—is core to financial institutions. Economic assessment of an investment is based on three different factors: expected revenues, operating costs, and risks. Climate change can have an impact on all three aspects but is probably more important for the risk side of an investment decision (Figge, 1998; Mag, 1990).

Lending and Climate Change

Most private and corporate loans are secured by property. If a region becomes more exposed to climate-related natural disasters such as floods or windstorms, the prices for property could go down—which could result in a loss of confidence in the local economy and may even trigger a credit crunch (Grabbe, 1998; Heinz Center, 2000). As an indirect effect, other types of business such as management of private assets and granting of private loans that are not backed by property also will be affected (Bender, 1991; Thompson, 1996).

In terms of the impacts of climate change on the banking industry, there is no clear scientific evidence on how this sector will be affected. One view is that the banking sector is likely to be largely unaffected by climate change because the sector increasingly transfers loans directly to the capital market through asset-backed securities and similar instruments. The major commercial banks are large and diversified and are getting more so as the industry concentrates in the face of global competition. They prefer not to keep any substantial

portion of the loans they make on a long-term basis. Instead, driven by capital constraints and return requirements, they actively syndicate and/or securitize their loan commitments (i.e., sell down the loans or shift the loan exposure to other banks and institutions). Even the portion they retain is increasingly likely to be held for a shorter period of time (a maturity under 1 year is better from a capital requirement standpoint) than other institutional lenders such as insurance companies and pension funds. The question still remains: At the end of the day, who will bear the risk of climate change on investments? It is particularly the insurance and asset management sectors that invest in asset-backed securities. So the insurance industry may even get hit twice, first through direct losses in property-related claims but also through impacts on their investments (Salt, 2000). Detailed information on what this increased vulnerability means for insurers and asset managers must be further explored.

On the other hand, it is obvious that banks could be affected indirectly as climate change affects their customers' operations, consumption, and financial circumstances. Any investment activity could be affected if property insurers withdraw coverage or drastically increase premiums, as happened in Florida and the Caribbean. Sectors that are likely to be affected by a drastic change in the local climate are agriculture and tourism. Warm winters in Europe already have negatively impacted the performance of skiing resorts in the Alps and have led some banks to review their credit applications in view of possible impacts of climate change (Credit Suisse Group, 1999).

8.4.2. Adaptation Issues

To date, the literature does not explicitly address financial services firms outside the insurance sector. There is emerging evidence that some investors or businesses as a group are modifying their risk perception to incorporate the potential for climate change. Partly this is driven by pension funds that are filing shareholder resolutions against polluting companies or banks that finance such practices (Behn, 2000). Similarly, there also is emerging evidence that financial services firms are including consideration of potential climate change as a risk factor in evaluating investments or developing new products (World Bank, 1999; Jeucken and Bouma, 2000). However, history has shown that the ability of banks and asset management firms to respond and adapt to external shocks is strongly tied to the ability of those institutions to diversify risk, both for themselves and for their customers. Over the past 25 years or so, financial services firms have changed significantly in response to a variety of circumstances, including macroeconomic disturbances of local and global proportions, advances in communications and information technologies, and changing regulatory regimes (Kaufman, 1992; Downing *et al.*, 1999). Several types of tools can be identified for managing risk: improved information and research, diversification, building up reserves, and new product development.

The Role of New Product Development

Over the years, banks as a whole have demonstrated their ability to continuously develop new products and services to respond to changes in their own business environment as well as the changing needs of their customers (Folkerts-Landau and Mathieson, 1988; Haraf and Kushmeider, 1988; Jeucken and Bouma, 2000). The ability of those firms to respond and adapt to any impacts of potential climate change will be determined largely by their ability to identify any changes in their customers' views of asset risk and to develop new products to hedge and diversify that risk. Again, the literature does not discuss explicitly which specific existing products might be useful in responding to changes in risk stemming from potential climate change or what types of new products might be developed to respond to such potential changes in risk. However, the industry continues to apply basic concepts—including options, swaps, and futures contracts—in new and different ways to create new products that provide investors and businesses with useful tools for reducing well-known and understood risks (Mills, 1999; Vine *et al.*, 1999). These products can range from environmentally and socially screened investment funds to very sophisticated derivatives that hedge against weather risks.

In the past few years, such weather derivatives have seen rapidly growing use to hedge the risks of businesses whose sales and revenues are strongly affected by the weather. Securitization is becoming more and more widely used as a means of spreading risk and obtaining resources for investment banking with a secure flow of income in the future. Financial institutions other than insurance companies have been developing and offering such instruments in the form of catastrophe bonds, for example (see Box 8-3).

In summary, the banking industry is more likely to see climate change and the possible response more as an opportunity than as a threat. In the new global competition, banks and asset managers are likely to be less concerned about any possible threat posed to their existing portfolios by weather extremes induced by climate change and more preoccupied with adjusting to a rapidly changing and increasingly competitive global market in which failure to adjust leads rapidly to loss of market share and net revenue and a decline in share price and shareholder value. They have little incentive to try to change the rules, but they are highly motivated to respond once changes are imminent or implemented.

8.4.3. The Role of UNEP Financial Services Initiatives in the Climate Change Debate

The United Nations Environment Programme (UNEP) has brokered statements of environmental commitment by banks and insurance companies that have been endorsed by many of the major players in these industries. These statements have

Box 8-3. Capital Market Alternatives for Risk Financing

Alternative catastrophe risk financing mechanisms through weather derivatives have begun to emerge and are regarded by some observers as playing a role in the continued viability of the insurance sector. Other authors suggest that these instruments will continue to be a niche product because of inability to come up with adequate pricing for these mechanisms as offered through the capital markets. Such products also raise the awareness and visibility of natural disasters and climate change issues within the financial markets (Swiss Re, 1996; Credit Suisse Group, 1998; Lester, 1999; Mahoney, 1999; Punter, 1999).

Contingent Capital Securities. The two types of capital contingency securities available to investors are contingent surplus notes and catastrophe equity puts. Investors in these securities become—at the insurer's option—creditors of or equity investors in the insurer. The exercised “notes” and “puts” are shown as surplus on an insurer's balances sheet and thus increase assets without an offsetting increase in the liability portion of the balance sheet. The insurer can draw from surplus to pay unreserved catastrophe losses and have the funds (surplus) necessary to take on new exposures.

Catastrophe Risk Securities. Two forms of “cat risk securities” are available that transfer underwriting risk to investors: catastrophe bonds and catastrophe insurance options. Primary insurers and reinsurers can make use of these securities. Both benefit insurers by making monies available to offset catastrophe losses. In contrast to contingent capital securities, these instruments do not bolster an insurer's surplus; they provide funds for the payment of losses. They are reflected as both an asset and as a liability on the insurer's financial statements.

These approaches are relatively new, and their efficacy and robustness must be evaluated (see Tol, 1998; Peara, 1999; Swiss Re, 1999b; Bantwal and Kunreuther, 2000; GAO, 2000a; Nutter, 2000; Jamison, 2000; Mills *et al.*, 2001). Among the questions to address include:

- In a more competitive environment, would insurers and reinsurers be inclined to participate in or encourage (subsidize) risk-reduction measures?
- Do derivatives signal a potential means by which self-insurers can expand their capacity, thereby providing greater competition for primary insurers and reinsurers?
- Will the occurrence(s) of catastrophic weather-related events turn away investors after an event?
- Do existing catastrophe and climate modeling techniques yield information necessary to adequately evaluate financial risks and thus the prices of these derivatives?

Of 11 major trends in investing, catastrophe bonds were rated by members of the International Securities Market Association as least likely to have significant impacts on securities markets in the future (Freeman, 2000).

Despite doubts about these new instruments, banks and insurance companies consider this a growing business. In 1999, the cumulative volume of weather-related bonds/derivatives reached US\$3 billion. It can be assumed that an increasing number of such instruments will be available to hedge against climate risks. This, in turn, will allow banks to get the “insurance” coverage they need for their lending activities (Nicholls, 2000).

now been signed by almost 300 banks and insurance companies from all parts of the world (most from Europe and Asia) (UNEP, 2000). By signing the statement, companies undertake to make every effort to incorporate environmental considerations into their internal and external processes (UNEP, 1995; Schanzenbächer, 1997). Measures implemented by signatories range from reduction of energy consumption of buildings under their management to incorporation of environmental issues in credit business and risk management considerations. One might think that financial services is a clean industry with very little direct impact on climate change, but insurance companies in particular own huge physical assets (e.g., ~500 million f² of building space in the United States alone, which corresponds to an energy bill of US\$750 million a year) (Mills and Knoepfel, 1997).

8.5. Special Issues in Developing Countries

8.5.1. Statistics on Disasters

Although the vast majority of weather-related insurance losses occur in wealthy countries, most of the human suffering occurs in poor countries (Figure 8-6). Whereas 45% of the natural disaster losses between 1985 and 1999 took place in wealthy countries (those with per capita income of more than US\$9,360), these countries represent 57% of the US\$984 billion in total economic losses and 92% of the US\$178 billion in insured losses (Munich Re, 1999b). In contrast, 25% of the economic losses and 65% of the 587,000 deaths took place in the poorest countries (those with per capita income below US\$760).

Other literature sources, using slightly different definitions and different time periods, conclude that about 90% of deaths from natural disasters from 1973 to 1997 occurred in Africa and Asia (IFRC-RCS, 1999a). Figures from the World Disasters Report 1999 (IFRC-RCS, 1999a) indicate that, in the period from 1973 to 1997, on average nearly 85,000 persons were killed each year by natural disasters; the number of otherwise affected (impoverished, homeless, injured) was more than 140 million annually. The record of disasters (see Figure 8-6) is a further illustration of the geographic distribution of weather-related disasters.

As indicated in Chapter 3, climate change comes with changing frequencies and intensities of extreme weather events. The most vulnerable regions and communities are those that are both highly exposed to hazardous climate change effects and have limited adaptive capacity. Countries with limited economic resources, low levels of technology, poor information and skills, poor infrastructure, unstable or weak institutions, and inequitable empowerment and access to resources have little capacity to adapt and are highly vulnerable (see Chapter 18). The regional chapters in this volume (Chapters 10–17) indicate that developing countries, because of their limited or nonexistent financial buffers, are particularly vulnerable to the effects of climate change. Human-induced climate change is expected to result in a further upward trend of disaster losses.

Developing countries—especially those that are reliant on primary production as a major source of income—are particularly vulnerable because these countries and their communities hardly have any financial buffer and there is very little penetration of insurance (see also Figure 8-6). The conditions facing private insurance markets and government disaster relief differ considerably in developing countries. The penetration of private insurance is extremely low in most cases, although it is growing quickly. The degree of preparedness also is low. The government sector is far less able to operate as a surrogate insurer, even in areas such as crop and flood insurance where governments traditionally are essential in the developed world. In developing countries, the economic and social impacts of catastrophic weather events can pose a material impediment to development. Increased frequency or intensity of such events as a result of climate change could render these markets less attractive than they are at present for private insurers, in turn compounding the adverse impact on development. Thus, developing countries tend to have greater vulnerability and less adaptive capacity than developed countries.

8.5.2. Disaster Relief

Because of the lack of insurance, disaster relief is the major input for disaster recovery in many developing countries. After a disaster, the first relief usually is provided by the national government in the form of assistance by the military, the police, and other government services. Often, governments also act as the insurer for uninsured damages in these cases. When the capacity of local disaster relief institutions is exceeded,

countries tend to call for help from international institutions. In the period 1992–2000, a yearly average of US\$330 million was transferred from country to country for disaster aid (United Nations, 2000).

The institutional setting of international disaster relief is complicated. Presently, 16 UN agencies have a mandate that allows them to work in emergency situations. The UN Office for the Coordination of Humanitarian Affairs (UN-OCHA) is supposed to coordinate efforts in disaster relief. The International Committee of the Red Cross and the International Federation of Red Cross and Red Crescent Societies (IFRC-RCS) have a basis in international law. Médecins sans Frontières (MSF) and OXFAM are examples of internationally operating nongovernmental organizations (NGOs), of which there are hundreds. In addition, all types of local NGOs may be involved in the relief work, along with the national government and local authorities. In a typical disaster situation, one has to cope with a multitude of different agencies (Frerks *et al.*, 1999). Donor governments and agencies as well as international organizations provide the funds; substantial amounts may be raised directly from the public at large.

The large amount of relief amount for cyclones in 1998 was largely a result of Hurricane Mitch, which struck Central America in that year. In the same year, Bangladesh and China were struck by very large flood disasters. The foregoing numbers show that on an annual basis, international relief is in hundreds of millions of dollars. This is a small number compared with total global damage from natural disasters (tens of billions of dollars).

8.5.3. Natural Disasters and Development

Disasters may have a significant impact on the national economy of the country concerned. Some countries lose annually up to 1% or more of their annual GDP as a consequence of recurring natural disaster; in individual cases, damages have been as high as 50% of GDP. The typical Chinese loss experience in bad years is in the range of 5–7% of annual GDP. In 1974, losses in Honduras from Hurricane Fifi were equivalent to 50% of the country's 1973 GDP (Hooke, 2000). Setbacks in development may have been up to 1 decade or more. The majority of these damages usually are covered by the affected population itself or from other domestic sources (United Nations, 1994). In some cases, the relation between GDP and disasters is ambiguous because post-disaster investments may increase GDP. Long-term problems arise when the return period of a disaster is the same order of magnitude or smaller than the time needed for reconstruction. In such cases, the economy of a country or a specific region is likely to spiral downward (Downing *et al.*, 1999). In fact, GDP is a very limited way of describing the impact of weather-related disasters. For example, the UN has defined a disaster as *large* when the ability of the region to cope with the effects of the disaster on its own is exceeded.

Urban and rural infrastructure loss in the developing world as a result of natural disasters has impacted the activity of the

world's international lending institutions. The World Bank has estimated that it has loaned US\$14 billion to developing countries in the past 20 years for damages from natural disasters. This amount is nearly 2.5 times the amount loaned by the Bank for relief from civil disturbance worldwide (Kreimer *et al.*, 1998). The Asian Development Bank (ADB) has estimated that between 1988 and 1998, 5.6% of ADB loans were for disaster rehabilitation. In 1992, nearly 20% of ADB loans were for rehabilitative assistance to natural disaster recovery (Arriens and Benson, 1999). The World Bank has estimated that during the past decade in Mexico, as much as 35% of its lending earmarked for infrastructure has been diverted to pay for the costs of (Mexican) natural catastrophes (Freeman, 1999). In recent years, the World Bank has recognized the importance of disaster prevention and mitigation for development and poverty reduction (Kreimer and Arnold, 2000).

8.5.4. Vulnerability and Financial Adaptation in Developing Countries

Spreading the risks of catastrophes presents special difficulties in developing countries, particularly rural areas. In general, there is very limited use of commercial insurance because of long histories of economic instability, fluctuating and prohibitive insurance costs as related to agricultural prices, lack of enforcement of building codes and land-use regulations, subjective evaluation of risk by consumers ("it won't happen to me"), and non-monitored economies. In some developing countries, government-organized crop and disaster insurance exists on paper, but with large debt loads and weak economies, many such programs are inactive. In many cases, governments are unable to respond to public expectations.

A World Bank/UN Development Programme (UNDP) workshop reports that disaster mitigation is evolving from the phases of relief and contingency planning, technical preparedness, and structural solutions to a phase in which there is a greater emphasis on reducing social and economic vulnerabilities and investing in long-term mitigation activities. However, formal sector mechanisms may completely bypass the poorest households. Therefore, the need to develop informal and flexible financial instruments such as microfinance for disaster mitigation has become extremely important (World Bank, 2000).

Although targeted microfinance programs have been able to meet the financial needs of individual households, the same attributes of microfinance also could be applied to deal with natural disaster reduction. There is a potential for microfinance to provide explicit and implicit insurance to households (World Bank, 2000). However, limitations of microfinance as a risk-reduction mechanism arise from issues of moral hazard (see Section 8.3.4), inadequate monitoring of credit programs after large spatial shocks, and reduction in informal insurance arrangements provided by social networks. There also is the possibility of governments committing much less to relief programs in the wake of a disaster if affected communities are served by microfinance institutions. Small microfinance

programs without access to reinsurance may collapse in a natural disaster. For nationwide disasters, even the largest microfinance programs may require international arrangements (World Bank, 2000).

Several microfinance organizations in Bangladesh have been seriously affected by the floods in 1998 in terms of maintaining savings mobilization, credit repayment, and cash availability. Larger microfinance organizations with greater capitalization and preparedness cope better with disasters than small microfinance organizations, many of which get completely wiped out. There is now a recognition of the need for providing a financial cushion for the unexpected. It could be provided through a Central Reserve Fund/Emergency Fund and bigger microfinance organizations such as Grameen Bank setting aside part of their funds to meet the contingencies of natural disasters (World Bank, 2000).

8.6. Issues that are Related to Funding for Adaptation

Although some discussion of adaptation appears in virtually all chapters of the WGII report, Chapter 18 addresses core concepts and considerations. It states that key factors affecting the adaptive capacity of a region or country include economic resources, technology, information and skills, infrastructure, and institutions; it notes that there is considerable variability among countries with regard to their ability to adapt to climate change. However, Chapter 18 does not address specifics of how adaptation is likely to be funded in developed and developing countries or how the need to fund adaptation will affect the financial services sector.

Chapter 18 also states that adaptive actions are most likely to be implemented when they are components of or changes to existing resource management or development programs (see World Bank, 1999). Klein (1998) has suggested that investments for adaptation should essentially be incremental to projects justified for other reasons, where a project has value even if climate change were not to occur. When the impact of climate change is uncertain, this is probably the best way to proceed. The financial sector would then play its traditional role, and financial institutional arrangements would be the same as for present-day investments in infrastructure. However, when projections of climate are more certain and/or when the assets exposed are of high value or when many people are at risk, dedicated additional climate change adaptation investments may be required and special funding arrangements may be developed. In these situations, new climate change-related financing schemes may emerge whereby funds are generated through fees on emissions of greenhouse gases or fees on trading of greenhouse gases. The Clean Development Mechanism developed in the framework of the Kyoto Protocol is an example of the development of such a financing arrangement. Such arrangements could generate new roles for the financial sector.

An example of early cost estimates of measures meant to protect people and properties against the risk of increasing rainfall,

Box 8-4. Case Study: Bangladesh Flooding 1998

Bangladesh witnessed 35 cyclones from 1960 to 1991 (Haider *et al.*, 1991) and seven major floods from 1974 to 1998 (Matin, 1998). The flood of 1998 is considered to be one of the worst natural disasters experienced by the country in the 20th century. It occurred from July 12 to September 14, a duration of 65 days (Choudhury, 1998). The flood affected about 100,000 km² (68% of the country's geographical area). The numbers of affected families and population were more than 5,700,000 and 30,900,000, respectively (Choudhury, 1998). The flood caused 918 fatalities and disease among 242,500 people. Approximately 1.3 Mha of standing crops were fully or partially damaged. Total economic losses amounted to US\$3.3 billion (8% of GDP, 1998 value), according to a study by Choudhury *et al.* (1999). The study also shows that there is a wide discrepancy between its estimates and estimates by other agencies, which is mainly a result of coverage error.

Generally, victims have to depend on their own resources to rehabilitate themselves. During the emergency period, however, the government and NGOs mobilized considerable financial resources to provide relief in the form of food, clothing, and building materials.

To reduce the damage from natural catastrophes, planned activities by the government and NGOs (national and international) include construction of an adequate number of cyclone shelters, embankments, and other shelters in coastal areas, especially in the offshore islands.

With regard to insurance against such calamities, there is not much available except for the large industries and the commercial sector. Flood victims were paid US\$27.7 million as compensation by the insurance companies, of which about 70% went to large industrial units. There was virtually no insurance coverage for losses in the agricultural sector. Losses incurred by shrimp farms and water transports, however, received sizeable compensation by the insurance systems, according to government sources (Choudhury *et al.*, 1999).

increasing river run-off, and sea-level rise, using an integral approach, is the white paper of The Netherlands National Committee on Water Management. This white paper projects the additional cost of water management in The Netherlands, taking into account climate change and long-term land subsidence and land-use changes. The paper concludes that a budget of approximately US\$2.5 billion is required for investments until 2015 and an additional US\$8 billion for the 2015–2050 period to maintain adequate safety levels for people and property (Netherlands National Committee on Water Management, 2000).

Developing countries seeking to adapt in a timely manner face major needs, including availability of capital and access to technology. Given the present state of knowledge, many actions for adaptation are likely to be integrated with and incremental to projects that already are occurring for other reasons. The World Bank (1999) states that "there is no case to be made for 'stand-alone' projects on adaptation to climate change." It also has noted that projects for adaptation should be designed as incremental to projects that are justified for economic development purposes. However, providing financing for projects in developing countries is a complex matter. Even for projects for which the risks and expected returns are commensurate with the requirements of the financial markets, matching investors that have available funds with projects seeking funding is by no means easy. Most simplistically, this process involves linking investors with projects via appropriate sets of institutional and financial intermediaries. The ability to do this successfully depends, in part, on the level of development of financial markets

and the financial services sector in the country where the project will be implemented (World Bank, 1997b).

However, returns that can be expected from many prospective projects are not sufficient for investors to assume the risks that they believe are inherent in any individual project. This complicates the process further. If such projects are going to be funded, some creative modification must be made to bring each project's risk/return profile in line with the requirements of the financial markets. Unfortunately, there is no straightforward, standardized means for identifying and implementing needed changes. The process is guided in part by the principle that risks should be assumed by the party best able to manage them (IFC, 1996).

This need for financial resources for adaptation in developing countries is addressed in the UNFCCC (or "Convention") and the Kyoto Protocol. The Convention explicitly states that:

- All Parties have responsibilities to make and implement plans for adapting to any human-induced climate change.
- The developed countries shall assist developing countries in meeting the costs of adapting to any adverse effects of such climate change.³

Both accords also address this notion more generally in identifying potential actions to aid developing countries, including provision

³See Articles 4.1(b), 4.1(e), 4.1(f), 4.3, 4.4, and 4.5 of the Convention.

of “environmentally sound” technology.⁴ In addition, the Protocol indicates that a portion of the proceeds from Clean Development Mechanism (CDM) projects is to be used to meet the needs of “particularly vulnerable” Parties for Adaptation⁵ (UNFCCC, 1992, 1997). Taken together, provisions in these two accords provide new sources of public sector funding for developing countries to implement adaptation measures.

The Global Environment Facility (GEF), as the main focus of financial commitments under the Convention thus far, has been the institutional mechanism for this funding. GEF projects provide financial models for promoting technology diffusion in developing countries, with some projects designed to mobilize private-sector financing (UNFCCC, 1999). However, GEF activity generally has not addressed the adaptation elements of the Convention. This lack of activity is driven by internal requirements that GEF projects have global benefits, as well as directives that such funding should cover only planning activities that are associated with adaptation (Yamin, 1998). Caribbean Planning for Adaptation to Climate Change is one example of a GEF project that is addressing adaptation. This US\$6.3 million project is focusing largely on planning and capacity-building needs for addressing adaptation in the Caribbean (GEF, 1998).

However, there are still many issues to be addressed in connection with both the Convention and the Protocol (Werksman, 1998; Yamin, 1998). Differing interpretations of various provisions of the accords remain.

For example, detailed provisions of the CDM have yet to be worked out, including those related to adaptation funding. One key issue is the size of the “set-aside” from CDM projects that is dedicated to funding adaptation. If this set-aside is too large, it will make otherwise viable mitigation projects uneconomic and serve as a disincentive to undertake projects. This would be counterproductive to the creation of a viable source of funding for adaptation. There also have been no decisions on how these “set-aside” funds would be allocated to adaptation projects. They could be used to fully fund projects or leveraged to simply supplement other sources of funding. Any resulting allocation will be driven by more technical and financial elements of the merits of alternative projects, as well as political considerations of equity and fairness. As a result, it may be some time before any of these provisions can produce a viable source of funding for adaptation. An overview and analysis of the literature on climate change policies and equity appears in Banuri *et al.* (1996). Linnerooth-Bayer and Amendola (2000) propose that subsidized risk transfer can be an efficient and equitable way for industrialized countries to assume partial responsibility for increasing disaster losses in developing countries. Review of the literature indicates that understanding of adaptation and the financial resources involved is still in its early stages. As knowledge grows, the potential role(s) for the financial sector will become clearer.

⁴See Articles 4.8 and 4.9 of the Convention and Article 3.14 of the Protocol.

⁵See Article 12 of the Protocol.

8.7. Future Challenges and Research Needs

This assessment reviews our improved knowledge since the SAR. However, it also identifies many areas in which greater understanding is still needed and suggests several challenges for the research community. These challenges can be summarized as follows.

Improve the transfer of knowledge from the scientific community studying climate change and weather forecasting to the financial services community. There clearly is a need for better understanding of how extreme weather events that are important to financial service firms could be affected by climate change. New knowledge should be communicated to the financial community and society for practical use. There is a specific need to:

- Develop ways for the insurance sector to blend information from the scientific community’s climate models, as they evolve, with its own loss estimation models
- Improve daily, seasonal, and annual forecasting of extreme weather, and adapt it for use in disaster prevention.

Advance the understanding of the relative global and regional vulnerability and adaptability of insurance and other financial services to climate change. The trend in losses from extreme weather events has raised questions about the insurance sector’s vulnerability to climate change in some respects, although as a whole the industry could be quite resilient. Even less is known about the relative vulnerability or resiliency of other segments of the financial services sector. A more definitive assessment of the industry’s strengths and weaknesses in the face of climate change is necessary, with specific needs to:

- Continue analysis to disaggregate climate change, socioeconomic, and any other non-climate drivers of observed trends in historic economic (insured and uninsured) losses
- Explore specific aspects of the industry’s vulnerability and resiliency, including maximum probable insurance losses; insurer surplus available for paying claims; insolvency risk in local insurance markets; and ability to raise rates, reduce coverage, or otherwise decrease losses by shifting risk to others
- Assess how climate change could affect the actual and perceived risk of existing loan and investment portfolios
- Understand if or how investors are changing their perceptions of investment risk in light of potential climate change and explore actions that investors are taking in light of any changes in the perception of risk.

Explore the role of the financial services sector in dealing with risks to society from climate change. As intermediaries and risk experts, the financial services sector could play a positive role in efforts to deal with the risks of climate change. The sector also could play an important role in identifying potential

synergies and conflicts regarding funding for adaptation and mitigation measures. Work is needed to:

- Assess and develop financial instruments that can spread and hedge against the risks of climate change for developing and developed countries
- Quantify the need for financial resources for investment in adaptation
- Determine how the availability of funds for adaptation could be affected by the use of funds for mitigation activities and vice versa
- Identify any synergies between options for adaptation and for mitigation.

Explore the range of possible financing arrangements to cover the cost of adapting to climate change:

- Investigate potential financial resources needed over the next few decades to cover the cost of damage from climate change and adaptation to climate change
- Evaluate alternative methods of covering such costs
- Develop innovative finance schemes for issues of risk and security regarding long-term investments
- Investigate the potential role of and effects on private and public financial services providers.

Acknowledgments

The author team thanks Patrick Bidan, Hessel Dooper, Emily Horning, Richard Radevsky, and Caroline van Schoubroeck for their participation in the workshop on natural disasters and financial services in Amsterdam on 10 March 2000, and their help in identifying topics and providing useful literature. Els Hunfeld is thanked for her many helping hands and dedication during the writing process. Grace Koshida and Angelika Wirtz also are thanked for their assistance. Finally, we thank the several dozen reviewers and experts from whom we received many useful comments and constructive suggestions.

EXECUTIVE SUMMARY

Global climate change will have a wide range of health impacts. Overall, negative health impacts are anticipated to outweigh positive health impacts. Some health impacts would result from changes in the frequencies and intensities of extremes of heat and cold and of floods and droughts. Other health impacts would result from the impacts of climate change on ecological and social systems and would include changes in infectious disease occurrence, local food production and nutritional adequacy, and concentrations of local air pollutants and aeroallergens, as well as various health consequences of population displacement and economic disruption.

There is little published evidence that changes in population health status actually have occurred as yet in response to observed trends in climate over recent decades. A recurring difficulty in identifying such impacts is that the causation of most human health disorders is multifactorial and the “background” socioeconomic, demographic, and environmental context varies constantly. A further difficulty is foreseeing all of the likely types of future health effects, especially because for many of the anticipated future health impacts it may be inappropriate to extrapolate existing risk-function estimates to climatic-environmental conditions not previously encountered. Estimation of future health impacts also must take account of differences in vulnerability between populations and within populations over time.

Research since the Second Assessment Report (SAR) mainly has described the effect of climate variability, particularly daily and seasonal extremes, on health outcomes. Studies of health impacts associated with the El Niño-Southern Oscillation (ENSO) have identified interannual climate-health relationships for some epidemic diseases. The upward trend in worldwide numbers of people adversely affected by weather disasters has been characterized by peak impacts during El Niño events. Meanwhile, there has been an expanded effort to develop, test, and apply mathematical models for predicting various health outcomes in relation to climate scenarios. This mix of epidemiological studies and predictive modeling leads to the following conclusions.

An increase in the frequency or intensity of heat waves will increase the risk of mortality and morbidity, principally in older age groups and the urban poor (high confidence). The greatest increases in thermal stress are forecast for higher latitude (temperate) cities, especially in populations that have limited resources, such as access to air conditioning. The pattern of acclimatization to future climate regimes is difficult to estimate. Recent modeling of heat wave impacts in U.S. urban

populations, allowing for acclimatization, suggests that several U.S. cities would experience, on average, several hundred extra deaths per summer. Poor urban populations in developing countries may be particularly vulnerable to the impacts of increased heat waves, but no equivalent predictions are available. Warmer winters and fewer cold spells, because of climate change, will decrease cold-related mortality in many temperate countries (high confidence). The reduction in winter deaths will vary between populations. Limited evidence indicates that, in at least some temperate countries, reduced winter deaths would outnumber increased summer deaths.

Any regional increases in climate extremes (storms, floods, cyclones, etc.) associated with climate change would cause physical damage, population displacement, and adverse effects on food production, freshwater availability and quality, and would increase the risks of infectious disease epidemics, particularly in developing countries (very high confidence/well-established). Over recent years, several major climate-related disasters have had major adverse effects on human health—including floods in China, Mozambique, Bangladesh, and Europe; famine in Sudan; and Hurricane Mitch, which devastated Central America. Although these events cannot be confidently attributed to climate change, they indicate the susceptibility of vulnerable populations to the adverse effects of such events.

Climate change will cause some deterioration in air quality in many large urban areas, assuming that current emission levels continue (medium to high confidence). Increases in exposure to ozone and other air pollutants (e.g., radon, forest fire particulates) could increase known morbidity and mortality effects.

Vector-borne diseases are maintained in complex transmission cycles involving blood-feeding arthropod vectors (and usually reservoir hosts) that depend on specific ecological conditions for survival. These diseases are sensitive to climatic conditions, although response patterns vary between diseases. In areas with limited or deteriorating public health infrastructure, and where temperatures now or in the future are permissive of disease transmission, an increase in temperatures (along with adequate rainfall) will cause certain vector-borne diseases (including malaria, dengue, and leishmaniasis) to extend to higher altitudes (medium to high confidence) and higher latitudes (medium to low confidence). Higher temperatures, in combination with conducive patterns of rainfall and surface water, will prolong transmission seasons in some endemic locations (medium to high confidence). In other locations, climate change will decrease transmission via reductions in

rainfall or temperatures that are too high for transmission (low to medium confidence). In all such situations, the actual health impacts of changes in potential infectious disease transmission will be strongly determined by the effectiveness of the public health system.

Mathematical models indicate that climate change scenarios over the coming century would modestly increase the proportion of world population living in regions of potential transmission of malaria and dengue (medium to high confidence). These models are limited by their reliance on climate factors, without reference to modulating influences of environmental, ecological, demographic, or socioeconomic factors. Although the most recent of several biologically based model studies suggests that the increase in population living in regions of potential malaria transmission would be on the order of an extra 260–320 million people in 2080 (against a baseline expectation of about 8 billion), a recent statistically based modeling study, which incorporated conservative assumptions, estimated that there would be no net change in actual transmission of malaria by 2080, assuming a business-as-usual climate scenario and adaptation. In the latter study, regional increases and decreases would approximately cancel out.

Changes in climate, including changes in climate variability, would affect many other vector-borne infections (such as various types of mosquito-borne encephalitis, Lyme disease, and tick-borne encephalitis) at the margins of current distributions (medium to high confidence). For some diseases—such as malaria in the Sahel, Western equine encephalitis in North America, and tick-borne encephalitis in Europe—a net decrease may occur. Changes in surface water quantity and quality will affect the incidence of diarrheal diseases (medium confidence). Ocean warming will facilitate transmission of cholera in coastal areas (low confidence; speculative).

Fish and shellfish poisoning is closely associated with marine ecology. There is some evidence that sea-surface warming associated with El Niño increases the risk to humans of ciguatera poisoning and the occurrence of toxic (and ecologically harmful) algal blooms. Climate change will increase the incidence of ciguatera poisoning and shellfish poisoning (low confidence).

Climate change represents an additional pressure on the world's food supply system and is expected to increase yields at higher latitudes and lead to decreases at lower latitudes. These regional differences in climate impacts on agricultural yield are likely to grow stronger over time, with net beneficial effects on yields and production in the developed world and net negative effects in the developing world. This would increase the number of undernourished people in the developing world (medium confidence).

In some settings, the impacts of climate change may cause social disruption, economic decline, and displacement of populations. The ability of affected communities to adapt to such disruptive events will depend on the social, political, and economic situation of the country and its population. The health impacts associated with such social-economic dislocation and population displacement are substantial [high confidence; well-established].

For each anticipated adverse health impact there is a range of social, institutional, technological, and behavioral adaptation options to lessen that impact. There is a basic and general need for public health infrastructure (programs, services, surveillance systems) to be strengthened and maintained. It also is crucial for nonhealth policy sectors to appreciate how the social and physical conditions of living affect population health.

Our scientific capacity to model the various potential health outcomes of climate change is limited. Nevertheless, it is clear that for many health outcomes—especially for those that result indirectly from a sequence of environmental and social impacts—precise and localized projections cannot yet be made. In the meantime, a precautionary approach requires that policy development proceed on the basis of available—though often limited and qualitative—evidence of how climate change will affect patterns of human population health. Furthermore, high priority should be assigned to improving the public health infrastructure and developing and implementing effective adaptation measures.

9.1. Introduction and Scope

This chapter assesses how climatic changes and associated environmental and social changes are likely to affect human population health. Such an assessment necessarily takes account of the multivariate and interactive ecological framework within which population health and disease are determined. This *ecological* perspective recognizes that the foundations of long-term good health lie in the continued stability and functioning of the biosphere's natural systems—often referred to as “life-support systems.”

Deliberate modification of these ecological and physical systems by human societies throughout history has conferred many social, economic, and public health benefits. However, it also has often created new risks to health, such as via mobilization of infectious agents, depletion of freshwater supplies, and reduced productivity of agroecosystems (Hunter *et al.*, 1993; Gubler, 1996). Consider, for example, the chain of consequences from clearance of tropical forests. In the first instance, it typically leads to a warmer and drier local climate. The consequent drying of soil and loss of its organic structure predisposes the area to increased water runoff during heavy rainfall. This, in turn, can endanger human health via flooding, water contamination, impaired crop yields, and altered patterns of vector-borne infectious diseases. Meanwhile, forest clearance also contributes to the atmospheric buildup of carbon dioxide (CO_2) and hence to climate change and its health impacts.

Today, as the scale of human impact on the environment increases, a range of population health impacts can be expected from these large-scale changes in the Earth's life-support systems (Watson *et al.*, 1998). That is the complex context within which actual and potential health impacts of global climate change must be assessed.

9.1.1. Summary of IPCC Second Assessment Report (1996): Potential Health Impacts of Climate Change

The IPCC Second Assessment Report (McMichael *et al.*, 1996a) relied on the relatively limited scientific literature that had emerged during the late 1980s and early 1990s. Most published studies were on health impacts associated with climate variability (e.g., El Niño) and extreme events (natural disasters and heat waves). Predictive modeling of future health impacts was in an early developmental stage.

The SAR noted the many inherent uncertainties in forecasting the potential health impacts of climate change. This included recognition that various other changes in social, economic, demographic, technological, and health care circumstances would unfold over coming decades and that these developments would “condition” the impact of climatic and environmental changes on human health. However, such accompanying changes can be foreseen neither in detail nor far into the future.

The overall assessment was that the likely health impacts would be predominantly adverse. Reflecting the published literature, most of the specific assessments were nonquantitative and relied on expert judgment. They drew on reasoned extrapolations from knowledge of health hazards posed by extreme weather events, increases in temperature-dependent air pollution, summertime increases in certain types of food poisoning, and the spectrum of public health consequences associated with economic disruption and physical displacement of populations. It was noted that the projected effects of climate change on agricultural, animal, and fishery productivity could increase the prevalence of malnutrition and hunger in food-insecure regions experiencing productivity downturns.

For two of the anticipated health impacts, the published literature available by 1995 allowed a more quantitative approach. The relevant conclusions were as follows:

- An increase in the frequency or severity of heat waves would cause a short-term increase in (predominantly cardiorespiratory) deaths and illness. In some very large cities (e.g., Atlanta, Shanghai) by about 2050, this would result in up to several thousand extra heat-related deaths annually. This heat-related mortality increase would be offset by fewer cold-related deaths in milder winters, albeit to an extent that was not yet adequately estimated and likely to vary between populations.
- Climate-induced changes in the geographic distribution and biological behavior of vector organisms of vector-borne infectious diseases (e.g., malaria-transmitting mosquitoes) and infective parasites would alter—usually increase—the potential transmission of such diseases. For example, simulations with global/regional mathematical models indicated that, in the absence of demographic shifts, the proportion of the world's population living within the potential malaria transmission zone would increase from ~45% in the 1990s to ~60% by 2050. Some localized decreases in malaria transmissibility also may occur in response to climate change.

9.1.2. Population Health and its Significance as an Outcome of Climate Change

This is the last of the sector-impact chapters in this volume. This is appropriate because human population health is influenced by an extensive “upstream” range of environmental and social conditions. Indeed, over time, the level of health in a population reflects the quality of social and natural environments, material standards of living, and the robustness of the public health and health service infrastructure. Therefore, population health is an important integrating index of the effects of climate change on ecosystems, biological processes, physical environmental media, and the social-economic environment.

Two other points are important. First, the causation of most human diseases is complex and multifactorial. Second, there is great heterogeneity in the types of disease: acute and chronic;

infectious and noninfectious; physical injury and mental health disorders. These two considerations explain some of the difficulties in fully understanding and quantifying the influences of climate on human health.

Profiles of health and disease vary greatly between regions and countries and over time. Currently, noncommunicable diseases (including mental health disorders) predominate in developed countries, with cardiovascular diseases and cancer accounting for more than half of all deaths. In poorer countries, infectious diseases (especially in childhood) remain important, even as noncommunicable diseases increase in urbanizing populations that are exposed to changes in lifestyle and environmental and occupational exposures. Globally, infectious diseases remain a major cause of human morbidity and are responsible for approximately one-third of all deaths (WHO, 1999a). Many of these water-, food-, and vector-borne infectious diseases are sensitive to climate.

9.2. Research into the Relationship between Climate Change and Health: Caveats and Challenges

9.2.1. New Knowledge about Climate Change Impacts on Health

Since the SAR, much of the additional research on health impacts has examined natural climate variability in relation to interannual variations in infectious diseases—particularly vector-borne diseases—and the relationship between daily weather and mortality in various urban populations. Predictive modeling of the impact of climate scenarios on vector-borne disease transmissibility has undergone further development. Meanwhile, however, data sets that allow study of the effects of the health impacts of observed longer term trends in climate remain sparse.

9.2.2. Characteristics and Methodological Difficulties

The research task of assessing the actual and potential health impacts of climate change has several distinctive characteristics and poses four major challenges to scientists:

- 1) Anticipated anthropogenic climate change will be a gradual and long-term process. This projected change in mean climate conditions is likely to be accompanied by regional changes in the frequency of extreme events. Changes in particular health outcomes already may be occurring or soon may begin to occur, in response to recent and ongoing changes in world climate. Identification of such health effects will require carefully planned epidemiological studies.
- 2) In epidemiological studies (in which associations are observed with or without knowledge of likely causal mechanisms), there often are difficulties in estimating the role of climate *per se* as a cause of change in health status. Changes in climate typically are accompanied by various other environmental changes. Because most diseases have multiple contributory causes, it often is difficult to attribute causation between climatic factors and other coexistent factors. For example, in a particular place, clearing of forest for agriculture and extension of irrigation may coincide with a rise in regional temperature. Because all three factors could affect mosquito abundance, it is difficult to apportion between them the causation of any observed subsequent increase in mosquito-borne infection. This difficulty is well recognized by epidemiologists as the “confounding” of effects.
- 3) It is equally important to recognize that certain factors can modify the vulnerability of a particular population to the health impacts of climate change or variability. This type of effect-modification (or “interaction”) can be induced by endogenous characteristics of the population (such as nutritional or immune status) or contextual circumstances that influence the “sensitivity” of the population’s response to the climate change (such as unplanned urbanization, crowding, or access to air conditioning during heat waves). Deliberate social, technological, or behavioral adaptations to reduce the health impacts of climate change are an important category of effect-modifying factor.
- 4) Simulation of scenario-based health risks with predictive models entails three challenges. These challenges relate to validity, uncertainty, and contextual realism:
 - Valid representation of the main environmental and biological relationships and the interacting ecological and social processes that influence the impact of those relationships on health is difficult. A balance must be attained between complexity and simplicity.
 - There are various sources of (largely unavoidable) uncertainty. There is uncertainty attached to the input scenarios of climate change (and of associated social, demographic, and economic trends). Subsequently, there are three main types of uncertainties in the modeling process itself: “normal” statistical variation (reflecting stochastic processes of the real world); uncertainty about the correct or appropriate values of key parameters in the model; and incomplete knowledge about the structural relationships represented in the model.
 - Climate change is not the sole global environmental change that affects human health. Various large-scale environmental changes now impinge on human population health simultaneously, and often interactively (Watson *et al.*, 1998). An obvious example is vector-borne infectious diseases, which are affected by climatic conditions, population movement, forest clearance and land-use patterns, freshwater surface configurations, human population density, and the population density of insectivorous predators (Gubler, 1998b). In accordance with point 2 above, each change in health outcome must be appropriately apportioned between climate and other influences.

9.3. Sensitivity, Vulnerability, and Adaptation

There are uncertainties regarding the sensitivity (i.e., rate of change of the outcome variable per unit change in the input/exposure variable) of many health outcomes to climate or climate-induced environmental changes. Relatively little quantitative research, with estimation of exposure-response relationships, has been done for outcomes other than death rates associated with thermal stress and changes in the transmission potential of several vector-borne infectious diseases. There has been increased effort to map the current distribution of vectors and diseases such as malaria by using climate and other environmental data (including satellite data).

Continuation of recent climatic trends soon may result in some shifts in the geographic range and seasonality of diseases such as malaria and dengue. In reality, however, such shifts also would depend on local topographical and ecological circumstances, other determinants of local population vulnerability, and the existence and level of adaptive public health defenses. There has been some recent debate in the scientific literature about whether there is any evidence of such shifts yet (Epstein *et al.*, 1997; Mouchet *et al.*, 1998; Reiter, 1998a,b). It is not yet clear what criteria are most appropriate for assessment of climatic influences on such changes in infectious disease patterns. A balance is needed between formal, statistically based analysis of changes within a particular local setting and a more synthesizing assessment of the consistency of patterns across diverse settings and across different systems—physical, biotic, social, and public health. As with climate change itself, there is an inherent difficulty in detecting small climate-induced shifts in population health outcomes and in attributing the shift to a change in climate.

Population vulnerability is a function of the extent to which a health outcome in that particular environmental-demographic setting is sensitive to climate change and the capacity of the population to adapt to new climate conditions. Determinants of population vulnerability to climate-related threats to health include level of material resources, effectiveness of governance and civil institutions, quality of public health infrastructure, access to relevant local information on extreme weather threats, and preexisting burden of disease (Woodward *et al.*, 1998). Thus, vulnerability is determined by individual, community, and geographical factors:

- *Individual factors include:*
 - Disease status (people with preexisting cardiovascular disease, for example, may be more vulnerable to direct effects such as heat waves)
 - Socioeconomic factors (in general, the poor are more vulnerable)
 - Demographic factors (the elderly are more vulnerable to heat waves, for example, and infants are more vulnerable to diarrheal diseases).
- *Community factors may include:*
 - Integrity of water and sanitation systems and their capacity to resist extreme events
 - Local food supplies and distribution systems

- Access to information, including early warnings of extreme climate events
- Local disease vector distribution and control programs.
- *Geographical factors may include:*
 - The influence of El Niño cycle or the occurrence of extreme weather events that are more common in some parts of the world
 - Low-lying coastal populations more vulnerable to the effects of sea-level rise
 - Populations bordering current distributions of vector-borne disease particularly vulnerable to changes in distribution
 - Rural residents often with less access to adequate health care, and urban residents more vulnerable to air pollution and heat island effects
 - Environmentally degraded and deforested areas more vulnerable to extreme weather events.

Understanding a population's capacity to adapt to new climate conditions is crucial to realistic assessment of the potential health impacts of climate change (Smithers and Smit, 1997). This issue is addressed more fully in Section 9.11.

9.4. Thermal Stress (Heat Waves, Cold Spells)

9.4.1. Heat Waves

Global climate change is likely to be accompanied by an increase in the frequency and intensity of heat waves, as well as warmer summers and milder winters (see Table 3-10). The impact of extreme summer heat on human health may be exacerbated by increases in humidity (Gaffen and Ross, 1998; Gawith *et al.*, 1999).

Daily numbers of deaths increase during very hot weather in temperate regions (Kunst *et al.*, 1993; Ando, 1998a,b). For example, in 1995, a heat wave in Chicago caused 514 heat-related deaths (12 per 100,000 population) (Whitman *et al.*, 1997), and a heat wave in London caused a 15% increase in all-cause mortality (Rooney *et al.*, 1998). Excess mortality during heat waves is greatest in the elderly and people with preexisting illness (Sartor *et al.*, 1995; Semenza *et al.*, 1996; Kilbourne, 1997; Ando *et al.*, 1998a,b). Much of this excess mortality from heat waves is related to cardiovascular, cerebrovascular, and respiratory disease. The mortality impact of a heat wave is uncertain in terms of the amount of life lost; a proportion of deaths occur in susceptible persons who were likely to have died in the near future. Nevertheless, there is a high level of certainty that an increase in the frequency and intensity of heat waves would increase the numbers of additional deaths from hot weather. Heat waves also are associated with nonfatal impacts such as heat stroke and heat exhaustion (Faunt *et al.*, 1995; Semenza *et al.*, 1999).

Heat waves have a much bigger health impact in cities than in surrounding suburban and rural areas (Kilbourne, 1997; Rooney *et al.*, 1998). Urban areas typically experience higher—and

nocturnally sustained—temperatures because of the “heat island” effect (Oke, 1987; Quattrochi *et al.*, 2000). Air pollution also is typically higher in urban areas, and elevated pollution levels often accompany heat waves (Piver *et al.*, 1999) (see also Section 9.6.1.2 and Chapter 8).

The threshold temperature for increases in heat-related mortality depends on the local climate and is higher in warmer locations. A study based on data from several European regions suggests that regions with hotter summers do not have significantly different annual heat-related mortality compared to cold regions (Keatinge *et al.*, 2000). However, in the United States, cities with colder climates are more sensitive to hot weather (Chestnut *et al.*, 1998). Populations will acclimatize to warmer climates via a range of behavioral, physiological, and technological adaptations. Acclimatization will reduce the impacts of future increases in heat waves, but it is not known to what extent. Initial physiological acclimatization to hot environments can occur over a few days, but complete acclimatization may take several years (Zeisberger *et al.*, 1994).

Weather-health studies have used a variety of derived indices—for example, the air mass-based synoptic approach (Kalkstein and Tan, 1995) and perceived temperature (Jendritzky *et al.*, 2000). Kalkstein and Greene (1997) estimated future excess mortality under climate change in U.S. cities. Excess summer mortality attributable to climate change, assuming acclimatization, was estimated to be 500–1,000 for New York and 100–250 for Detroit by 2050, for example. Because this is an isolated study, based on a particular method of treating meteorological conditions, the chapter team assigned a medium level of certainty to this result.

The impact of climate change on mortality from thermal stress in developing country cities may be significant. Populations in developing countries (e.g., in Mexico City, New Delhi, Jakarta) may be especially vulnerable because they lack the resources to adapt to heat waves. However, most of the published research refers to urban populations in developed countries; there has been relatively little research in other populations.

9.4.2. Decreased Mortality Resulting from Milder Winters

In many temperate countries, there is clear seasonal variation in mortality (Sakamoto-Momiyama, 1977; Khaw, 1995; Laake and Sverre, 1996); death rates during the winter season are 10–25% higher than those in the summer. Several studies indicate that decreases in winter mortality may be greater than increases in summer mortality under climate change (Langford and Bentham, 1995; Martens, 1997; Guest *et al.*, 1999). One study estimates a decrease in annual cold-related deaths of 20,000 in the UK by the 2050s (a reduction of 25%) (Donaldson *et al.*, 2001). However, one study estimates that increases in heat-related deaths will be greater than decreases in cold-related death in the United States by a factor of three (Kalkstein and Greene, 1997).

Annual outbreaks of winter diseases such as influenza, which have a large effect on winter mortality rates, are not strongly associated with monthly winter temperatures (Langford and Bentham, 1995). Social and behavioral adaptations to cold play an important role in preventing winter deaths in high-latitude countries (Donaldson *et al.*, 1998). Sensitivity to cold weather (i.e., the percentage increase in mortality per 1°C change) is greater in warmer regions (e.g., Athens, southern United States) than in colder regions (e.g., south Finland, northern United States) (Eurowinter Group, 1997). One possible reason for this difference may be failure to wear suitable winter clothing. In North America, an increase in mortality is associated with snowfall and blizzards (Glass and Zack, 1979; Spitalnic *et al.*, 1996; Gorjanc *et al.*, 1999) and severe ice storms (Munich Re, 1999).

The extent of winter-associated mortality that is directly attributable to stressful weather therefore is difficult to determine and currently is being debated in the literature. Limited evidence indicates that, in at least some temperate countries, reduced winter deaths would outnumber increased summer deaths. The net impact on mortality rates will vary between populations. The implications of climate change for nonfatal outcomes is not clear because there is very little literature relating cold weather to health outcomes.

9.5. Extreme Events and Weather Disasters

Major impacts of climate change on human health are likely to occur via changes in the magnitude and frequency of extreme events (see Table 3-10), which trigger a natural disaster or emergency. In developed countries, emergency preparedness has decreased the total number of tropical cyclone-related deaths (see Section 7.2.2). However, in developed countries, studies indicate an increasing trend in the number and impacts (deaths, injuries, economic losses) of all types of natural disasters (IFRC, 1998; Munich Re, 1999). Some of the interannual variability in rates of persons affected by disasters may be associated with El Niño (Bouma *et al.*, 1997a). The average annual number of people killed by natural disasters between 1972 and 1996 was about 123,000. By far the largest number of people affected (i.e., in need of shelter or medical care) are in Asia, and one study reveals that Africa suffers 60% of all disaster-related deaths (Loretti and Tegegn, 1996).

Populations in developing countries are much more affected by extreme events. Relative to low socioeconomic conditions, the impact of weather-related disasters in poor countries may be 20–30 times larger than in industrialized countries. For example, floods and drought associated with the El Niño event of 1982–1983 led to losses of about 10% in gross national product (GNP) in countries such as Bolivia, Chile, Ecuador, and Peru (50% of their annual public revenue) (Jovel, 1989).

Disasters occur when climate hazards and population vulnerability converge. Factors that affect vulnerability to disasters are shown in Figure 9-1. The increase in population vulnerability

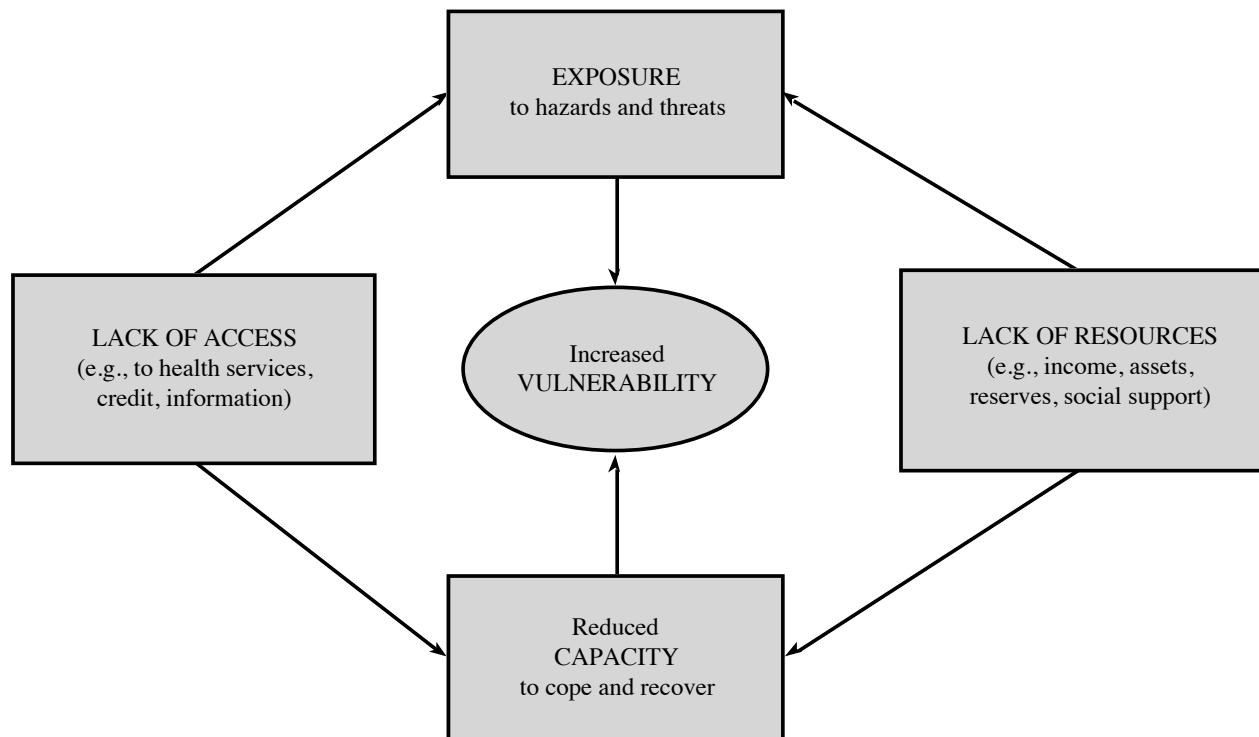

Figure 9-1: Diagrammatic illustration of vulnerability to disasters (McMichael *et al.*, 1996b).

to extreme weather is primarily caused by the combination of population growth, poverty, and environmental degradation (Alexander, 1993). Concentration of people and property in high-risk areas (e.g., floodplains and coastal zones) also has increased. Degradation of the local environment also may contribute to vulnerability (see Chapter 7).

The health impacts of natural disasters include (Noji, 1997):

- Physical injury
- Decreases in nutritional status, especially in children
- Increases in respiratory and diarrheal diseases resulting from crowding of survivors, often with limited shelter and access to potable water
- Impacts on mental health, which in some cases may be long-lasting
- Increased risk of water-related diseases as a result of disruption of water supply or sewage systems
- Release and dissemination of dangerous chemicals from storage sites and waste disposal sites into floodwaters.

Extreme weather events cause death and injury directly. However, substantial indirect health impacts also occur because of damage to the local infrastructure and population displacement (see also Section 9.10). Following disasters, fatalities and injuries can occur as residents return to clean up damage and debris (Philen *et al.*, 1992). Bereavement, property loss, and social disruption may increase the risk of depression and mental health problems (WHO, 1992). For example, cases of post-traumatic stress disorder were reported in the United States up to 2 years after Hurricane Andrew (Norris *et al.*, 1999).

States up to 2 years after Hurricane Andrew (Norris *et al.*, 1999).

9.5.1. Floods

Floods are associated with particular dangers to human populations (Menne *et al.*, 1999). Climate change may increase the risk of river and coastal flooding (see Chapters 4 and 6). The health impacts of floods may be divided into the immediate, medium, and long terms. Immediate effects are largely death and injuries caused by drowning and being swept against hard objects. Medium-term effects include increases in communicable diseases such as those caused by ingestion of contaminated water (e.g., cholera, hepatitis A), contact with contaminated water (e.g., leptospirosis—see Section 9.7.9.1), or respiratory diseases resulting from overcrowding in shelters. A study in populations displaced by catastrophic floods in Bangladesh in 1988 found that diarrhea was the most common illness, followed by respiratory infection. Watery diarrhea was the most common cause of death for all age groups under 45 (Siddique *et al.*, 1991). In rural Bangladesh and Khartoum, Sudan, the proportion of severely malnourished children increased after flooding (Woodruff *et al.*, 1990; Choudhury and Bhuiya, 1993). Also, in the aftermath of flooding, molds and fungi may grow on interior surfaces, providing a potent stimulus to allergic persons (American Academy of Pediatrics, 1998).

In China, floods experienced over the past few years have been particularly severe. In 1996, official national statistics showed

200 million people affected by flooding: There were more than 3,000 deaths, and 363,800 people were injured; 3.7 million houses were destroyed, and 18 million houses were damaged. Direct economic losses exceeded US\$12 billion (IFRC 1997). In 1998, official national statistics showed 200 million people affected by flooding, more than 3,000 deaths, and 4 million houses damaged; direct economic losses exceeded US\$20 billion (National Climate Centre of China, 1998). Nevertheless, the vulnerability of the Chinese population has been reduced by a combination of better preparedness, including sophisticated warning systems, and relief efforts. In the longer term, reforestation may reduce the risk of flooding in these regions.

In developed countries, physical and disease risks from flooding are greatly reduced by a well-maintained flood control and sanitation infrastructure and public health measures, such as monitoring and surveillance activities to detect and control outbreaks of infectious disease. However, the experience of the central European floods of 1997, when more than 100 people died, showed that even in industrialized countries floods can have a major impact on health and welfare. In Poland, 6,000 km² were flooded, and 160,000 people were evacuated from their homes. The cost of the damage was estimated at US\$3 billion [2.7% of 1996 gross domestic product (GDP)]. In the Czech Republic, 50,000 people were evacuated and damage was estimated at US\$1.8 billion (3.7% of GDP) (IFRC, 1998). There was an increase in cases of leptospirosis in the Czech Republic (Kriz *et al.*, 1998). Floods also have an important impact on mental health in the affected community (WHO, 1992; Menne *et al.*, 1999). Increases in suicide, alcoholism, and psychological and behavioral disorders, particularly among children, were reported following floods in Poland in 1997 (IFRC 1998).

9.5.2. Storms and Tropical Cyclones

Impoverished and high-density populations in low-lying and environmentally degraded areas are particularly vulnerable to tropical cyclones (also called hurricanes and typhoons). Many of the most serious impacts of tropical cyclones in the 20th century have occurred in Bangladesh because of the combination of meteorological and topographical conditions, along with the inherent vulnerability of this low-income, poorly resourced population. Tropical cyclones also can cause landslides and flooding. Most deaths are caused by drowning in the storm surge (Alexander, 1993; Noji, 1997). The impacts of cyclones in Japan and other developed countries have been decreasing in recent years because of improved early warning systems. However, the experience of Hurricane Mitch demonstrated the destructive power of an extreme event on a densely populated and poorly resourced region (PAHO, 1999).

9.5.3. Droughts

The health impacts of drought on populations occur primarily via impacts on food production. Famine often occurs when a

preexisting situation of malnutrition worsens. The health consequences of drought include diseases resulting from malnutrition (McMichael *et al.*, 1996b). In times of shortage, water is used for cooking rather than hygiene. In particular, this increases the risk of diarrheal diseases (as a result of fecal contamination) and water-washed diseases (e.g., trachoma, scabies). Outbreaks of malaria can occur during droughts as a result of changes in vector breeding sites (Bouma and van der Kaay, 1996). Malnutrition also increases susceptibility to infection.

In addition to adverse environmental conditions, political, environmental, or economic crises can trigger a collapse in food marketing systems. These factors may have a cumulative or synergistic effect. For example, a breakdown in the reserve food supply system resulting from the sale of grain or livestock reserves might be exacerbated by conflict and breakdown in law and order. The major food emergency in Sudan during 1998 illustrates the interrelationship between climatic triggers of famine and conflict. Land mines made portions of major roads in southern Sudan impassable and contributed to poor access for relief supplies. By July 1998, the World Food Programme's air cargo capacity had increased to more than 10,000 t to overcome the transport difficulties. These air cargoes were supplemented by barge convoys and road repair projects (WFP, 1999). Vulnerability to drought and food shortages can be greatly reduced through the use of seasonal forecasts as part of an early warning system (see Section 9.11.1).

9.6. Air Pollution

9.6.1. Gases, Fine Particulates

Weather conditions influence air pollution via pollutant (or pollutant precursor) transport and/or formation. Weather conditions also can influence biogenic (e.g., pollen production) and anthropogenic (e.g., as a result of increased energy demand) air pollutant emissions. Exposure to air pollutants can have many serious health effects, especially following severe pollution episodes. Studies that are relevant to climate change and air pollution can be divided into two categories: those that estimate the combined impact of weather and air pollutants on health outcomes and those that estimate future air pollution levels. Climate change may increase the concentration of ground-level ozone, but the magnitude of the effect is uncertain (Patz *et al.*, 2000). For other pollutants, the effects of climate change and/or weather are less well studied.

Current air pollution problems are greatest in developing country cities. For example, nearly 40,000 people die prematurely every year in India because of outdoor air pollution (World Bank, 1997). Air quality also is one of the main concerns for environmental health in developed countries (Bertollini *et al.*, 1996; COMEAP, 1998).

Radon is an inert radioactive gas. The rate at which it is emitted from the ground is sensitive to temperature (United Nations, 1982). High indoor exposures are associated with an increased

risk of lung cancer (IARC, 1988). There is some evidence from modeling experiments that climate warming may increase radon concentrations in the lower atmosphere (Cuculeanu and Iorgulescu, 1994).

9.6.1.1. Effects of Air Pollution, Season, and Weather on Health

The six standard air pollutants that have been extensively studied in urban populations are sulfur dioxide (SO_2), ozone (O_3), nitrogen dioxide (NO_2), carbon monoxide (CO), lead, and particulates. The impact of some air pollutants on health is more evident during the summer or during high temperatures (Bates and Sizto, 1987; Bates *et al.*, 1990; Castellsague *et al.*, 1995; Bobak and Roberts, 1997; Katsouyanni *et al.*, 1997; Spix *et al.*, 1998; de Diego Damia *et al.*, 1999; Hajat *et al.*, 1999). For example, the relationship between SO_2 and total and cardiovascular mortality in Valencia (Ballester *et al.*, 1996) and Barcelona, Spain (Sunyer *et al.*, 1996), and Rome, Italy (Michelozzi *et al.*, 1998), was found to be stronger during hot periods than during winter. However, Moolgavkar *et al.* (1995) conclude that, in Philadelphia, SO_2 had the strongest health effects in spring, autumn, and winter. Increases in daily mortality and morbidity (indicated by hospital admissions) are associated with high ozone levels on hot days in many cities (e.g., Moolgavkar *et al.*, 1995; Sunyer *et al.*, 1996; Touloumi *et al.*, 1997).

High temperatures also have acute effects on mortality (see Section 9.4.1). Some studies have found evidence of an interaction between the effects of ozone and the effects of higher temperatures (e.g., Katsouyanni *et al.*, 1993; Sartor *et al.*, 1995). Other studies addressing the combined effects of weather and particulate air pollution have not found evidence

of such an interaction (e.g., Samet *et al.*, 1998). Correlations between climate and site-specific air quality variables must be further evaluated and, in some instances, need to include temperature, pollution, and interaction terms in regression models.

Climate change is expected to increase the risk of forest and rangeland fires (see Section 5.6.2.2.1). Haze-type air pollution therefore is a potential impact of climate change on health. Major fires in 1997 in southeast Asia and the Americas were associated with increases in respiratory and eye symptoms (Brauer, 1999; WHO, 1999b). In Malaysia, a two- to three-fold increase in outpatient visits for respiratory disease and a 14% decrease in lung function in school children were reported. In Alta Floresta, Brazil, there was a 20-fold increase in outpatient visits for respiratory disease. In 1998, fires in Florida were linked to significant increases in emergency department visits for asthma (91%), bronchitis (132%), and chest pain (37%) (CDC, 1999). However, a study of 1994 bushfires in western Sydney showed no increase in asthma admissions to emergency departments (Smith *et al.*, 1996).

9.6.1.2. Future Changes in Air Quality

Weather has a major influence on the dispersal and ambient concentrations of air pollutants. Large high-pressure systems often create an inversion of the normal temperature profile, trapping pollutants in the shallow boundary layer at the Earth's surface. It is difficult to predict the impact of climate change on local urban climatology and, therefore, on average local air pollution concentrations. However, any increase in anticyclonic conditions in summer would tend to increase air pollution concentrations in cities (Hulme and Jenkins, 1998).

Box 9-1. Stratospheric Ozone Depletion and Exposure to Ultraviolet Radiation

Stratospheric ozone destruction is an essentially separate process from greenhouse gas (GHG) accumulation in the lower atmosphere. However, not only are several of the anthropogenic GHGs [e.g., chlorofluorocarbons (CFCs) and N_2O] also ozone-depleting gases but tropospheric warming apparently induces stratospheric cooling, which exacerbates ozone destruction (Shindell *et al.*, 1998; Kirk-Davidoff *et al.*, 1999). Stratospheric ozone shields the Earth's surface from incoming solar ultraviolet radiation (UVR), which has harmful effects on human health. Long-term decreases in summertime ozone over New Zealand have been associated with significant increases in ground-level UVR, particularly in the DNA-damaging waveband (McKenzie *et al.*, 1999). In a warmer world, patterns of personal exposure to solar radiation (e.g., sunbathing in temperate climates) also are likely to change.

Many epidemiological studies have implicated solar radiation as a cause of skin cancer (melanoma and other types) in fair-skinned humans (IARC, 1992; WHO, 1994). The most recent assessment by UNEP (1998) projects significant increases in skin cancer incidence as a result of stratospheric ozone depletion. High-intensity UVR also damages the eye's outer tissue, causing "snowblindness"—the ocular equivalent of sunburn. Chronic exposure to UVR is linked to conditions such as pterygium (WHO, 1994). The role of UV-B in cataract formation is complex. Some cataract subtypes appear to be associated with UVR exposure, whereas others do not. In humans and experimental animals, UVR can cause local and whole-body immunosuppression (UNEP, 1998). Cellular immunity has been shown to be affected by ambient doses of UVR (Garssen *et al.*, 1998). Concern exists that UVR-induced immunosuppression could influence patterns of infectious disease. Nevertheless, no direct evidence exists for such effects in humans, and uncertainties remain about the underlying biological processes.

Formation and destruction of ozone is accelerated by increases in temperature and ultraviolet radiation. Existing air quality models have been used to examine the effect of climate change on ozone concentrations (e.g., Morris *et al.*, 1989; Penner *et al.*, 1989; Morris *et al.*, 1995; Sillman and Samson, 1995). The models indicate that decreases in stratospheric ozone and elevated temperature increase ground-level ozone concentration. An increase in occurrence of hot days could increase biogenic and anthropogenic emissions of volatile organic compounds (e.g., from increased evaporative emissions from fuel-injected automobiles) (Sillman and Samson, 1995). These studies of the impact of climate change on air quality must be considered indicative but by no means definitive. Important local weather factors may not be adequately represented in these models.

9.6.2. Aeroallergens (e.g., Pollen)

Daily, seasonal, and interannual variation in the abundance of many aeroallergens, particularly pollen, is associated with meteorological factors (Emberlin, 1994, 1997; Spieksma *et al.*, 1995; Celenza *et al.*, 1996). The start of the grass pollen season can vary between years by several weeks according to the weather in the spring and early summer. Pollen abundance, however, is more strongly associated with land-use change and farming practices than with weather (Emberlin, 1994). Pollen counts from birch trees (the main cause of seasonal allergies in northern Europe) have been shown to increase with increasing seasonal temperatures (Emberlin, 1997; Ahlholm *et al.*, 1998). In a study of Japanese cedar pollen, there also was a significant increase in total pollen count in years in which summer temperatures had risen (Takahashi *et al.*, 1996). However, the relationship between meteorological variables and specific pollen counts can vary from year to year (Glassheim *et al.*, 1995). Climate change may affect the length of the allergy season. In addition, the effect of higher ambient levels of CO₂ may affect pollen production. Experimental research has shown that a doubling in CO₂ levels, from about 300 to 600 ppm, induces an approximately four-fold increase in the production of ragweed pollen (Ziska and Caulfield, 2000a,b).

High pollen levels have been associated with acute asthma epidemics, often in combination with thunderstorms (Hajat *et al.*, 1997; Newson *et al.*, 1998). Studies show that the effects of weather and aeroallergens on asthma symptoms are small (Epton *et al.*, 1997). Other assessments have found no evidence that the effects of air pollutants and airborne pollens interact to exacerbate asthma (Guntzel *et al.*, 1996; Stieb *et al.*, 1996; Anderson *et al.*, 1998; Hajat *et al.*, 1999). Airborne pollen allergen can exist in subpollen sizes; therefore, specific pollen/asthma relationships may not be the best approach to assessing the risk (Beggs, 1998). One study in Mexico suggests that altitude may affect the development of asthma (Vargas *et al.*, 1999). Sources of indoor allergens that are climate-sensitive include the house dust mite, molds, and cockroaches (Beggs and Curson, 1995). Because the causation of initiation and exacerbation of asthma is complex, it is not clear how climate change would affect this disease. Further research into general

allergies (including seasonal and geographic distribution) is required.

9.7. Infectious Diseases

The ecology and transmission dynamics of infectious diseases are complex and, in at least some respects, unique for each disease within each locality. Some infectious diseases spread directly from person to person; others depend on transmission via an intermediate “vector” organism (e.g., mosquito, flea, tick), and some also may infect other species (especially mammals and birds).

The “zoonotic” infectious diseases cycle naturally in animal populations. Transmission to humans occurs when humans encroach on the cycle or when there is environmental disruption, including ecological and meteorological factors. Various rodent-borne diseases, for example, are dependent on environmental conditions and food availability that determine rodent population size and behavior. An explosion in the mouse population following extreme rainfall from the 1991–1992 El Niño event is believed to have contributed to the first recorded outbreak of hantavirus pulmonary syndrome in the United States (Engelthaler *et al.*, 1999; Glass *et al.*, 2000).

Many important infectious diseases, especially in tropical countries, are transmitted by vector organisms that do not regulate their internal temperatures and therefore are sensitive to external temperature and humidity (see Table 9-1). Climate change may alter the distribution of vector species—increasing or decreasing the ranges, depending on whether conditions are favorable or unfavorable for their breeding places (e.g., vegetation, host, or water availability). Temperature also can influence the reproduction and maturation rate of the infective agent within the vector organism, as well as the survival rate of the vector organism, thereby further influencing disease transmission.

Changes in climate that will affect potential transmission of infectious diseases include temperature, humidity, altered rainfall, and sea-level rise. It is an essential but complex task to determine how these factors will affect the risk of vector- and rodent-borne diseases. Factors that are responsible for determining the incidence and geographical distribution of vector-borne diseases are complex and involve many demographic and societal—as well as climatic—factors (Gubler, 1998b). An increase in vector abundance or distribution does not automatically cause an increase in disease incidence, and an increase in incidence does not result in an equal increase in mortality (Chan *et al.*, 1999). Transmission requires that the reservoir host, a competent arthropod vector, and the pathogen be present in an area at the same time and in adequate numbers to maintain transmission. Transmission of human diseases is dependent on many complex and interacting factors, including human population density, housing type and location, availability of screens and air conditioning on habitations, human behavior, availability of reliable piped water, sewage and waste management

systems, land use and irrigation systems, availability and efficiency of vector control programs, and general environmental hygiene. If all of these factors are favorable for transmission, several meteorological factors may influence the intensity of transmission (e.g., temperature, relative humidity, and precipitation patterns). All of the foregoing factors influence the transmission dynamics of a disease and play a role in determining whether endemic or epidemic transmission occurs.

The resurgence of infectious diseases in the past few decades, including vector-borne diseases, has resulted primarily from demographic and societal factors—for example, population growth, urbanization, changes in land use and agricultural practices, deforestation, international travel, commerce, human and animal movement, microbial adaptation and change, and breakdown in public health infrastructure (Lederberg *et al.*, 1992; Gubler, 1989, 1998a). To date, there is little evidence that climate change has

played a significant role in the recent resurgence of infectious diseases.

The following subsections describe diseases that have been identified as most sensitive to changes in climate. The majority of these assessments rely on expert judgment. Where models have been developed to assess the impact of climate change, these also are discussed.

9.7.1. Malaria

Malaria is one of the world's most serious and complex public health problems. The disease is caused by four distinct species of plasmodium parasite, transmitted between individuals by Anopheline mosquitoes. Each year, it causes an estimated 400–500 million cases and more than 1 million deaths, mostly

Table 9-1: Main vector-borne diseases: populations at risk and burden of disease (WHO data).

Disease	Vector	Population at Risk	Number of People Currently Infected or New Cases per Year	Disability-Adjusted Life Years Lost ^a	Present Distribution
Malaria	Mosquito	2400 million (40% world population)	272,925,000	39,300,000	Tropics/subtropics
Schistosomiasis	Water Snail	500–600 million	120 million	1,700,000	Tropics/subtropics
Lymphatic filariasis	Mosquito	1,000 million	120 million	4,700,000	Tropics/subtropics
African trypanosomiasis (sleeping sickness)	Tsetse Fly	55 million	300,000–500,000 cases yr ⁻¹	1,200,000	Tropical Africa
Leishmaniasis	Sandfly	350 million	1.5–2 million new cases yr ⁻¹	1,700,000	Asia/Africa/ southern Europe/ Americas
Onchocerciasis (river blindness)	Black Fly	120 million	18 million	1,100,000	Africa/Latin America/ Yemen
American trypanosomiasis (Chagas' disease)	Triatomine Bug	100 million	16–18 million	600,000	Central and South America
Dengue	Mosquito	3,000 million	Tens of millions cases yr ⁻¹	1,800,000 ^b	All tropical countries
Yellow fever	Mosquito	468 million in Africa	200,000 cases yr ⁻¹	Not available	Tropical South America and Africa
Japanese encephalitis	Mosquito	300 million	50,000 cases yr ⁻¹	500,000	Asia

^a Disability-Adjusted Life Year (DALY) = a measurement of population health deficit that combines chronic illness or disability and premature death (see Murray, 1994; Murray and Lopez, 1996). Numbers are rounded to nearest 100,000.

^b Data from Gubler and Metzger (1999).

Table 9-2: Effect of climate factors on vector- and rodent-borne disease transmission.

Climate Factor	Vector	Pathogen	Vertebrate Host and Rodents
Increased temperature	<ul style="list-style-type: none"> – Decreased survival, e.g., <i>Culex. tarsalis</i> (Reeves <i>et al.</i>, 1994) – Change in susceptibility to some pathogens (Grimstad and Haramis, 1984; Reisen, 1995); seasonal effects (Hardy <i>et al.</i>, 1990) – Increased population growth (Reisen, 1995) – Increased feeding rate to combat dehydration, therefore increased vector–human contact – Expanded distribution seasonally and spatially 	<ul style="list-style-type: none"> – Increased rate of extrinsic incubation in vector (Kramer <i>et al.</i>, 1983; Watts <i>et al.</i>, 1987) – Extended transmission season (Reisen <i>et al.</i>, 1993, 1995) – Expanded distribution (Hess <i>et al.</i>, 1963) 	<ul style="list-style-type: none"> – Warmer winters favor rodent survival
Decreases in precipitation	<ul style="list-style-type: none"> – Increase in container-breeding mosquitoes because of increased water storage – Increased abundance for vectors that breed in dried-up river beds (Wijesunder, 1988) – Prolonged droughts could reduce or eliminate snail populations 	<ul style="list-style-type: none"> – No effect 	<ul style="list-style-type: none"> – Decreased food availability can reduce populations – Rodents may be more likely to move into housing areas, increasing human contact
Increases in precipitation	<ul style="list-style-type: none"> – Increased rain increases quality and quantity of larval habitat and vector population size – Excess rain can eliminate habitat by flooding – Increased humidity increases vector survival – Persistent flooding may increase potential snail habitats downstream 	<ul style="list-style-type: none"> – Little evidence of direct effects – Some data on humidity effect on malarial parasite development in <i>Anopheline</i> mosquito host 	<ul style="list-style-type: none"> – Increased food availability and population size (Mills <i>et al.</i>, 1999)
Increase in precipitation extremes	<ul style="list-style-type: none"> – Heavy rainfall events can synchronize vector host-seeking and virus transmission (Day and Curtis, 1989) – Heavy rainfall can wash away breeding sites 	<ul style="list-style-type: none"> – No effect 	<ul style="list-style-type: none"> – Risk of contamination of flood waters/runoff with pathogens from rodents or their excrement (e.g., <i>Leptospira</i> from rat urine)

in children (WHO, 1998a). Malaria is undergoing a global resurgence because of a variety of factors, including complacency and policy changes that led to reduced funding for malaria control programs in the 1970s and 1980s, the emergence of insecticide and drug resistance, human population growth and movement, land-use change, and deteriorating public health infrastructure (Lindsay and Birley, 1996). Variation in malaria transmission also is associated with changes in temperature, rainfall, and humidity as well as the level of immunity (Lindsay and Birley, 1996). All of these factors can interact to affect adult mosquito densities and the development of the parasite within the mosquito (see Table 9-2).

Very high temperatures are lethal to the mosquito and the parasite. In areas where mean annual temperature is close to

the physiological tolerance limit of the parasite, a small temperature increase would be lethal to the parasite, and malaria transmission would therefore decrease. However, at low temperatures, a small increase in temperature can greatly increase the risk of malaria transmission (Bradley, 1993; Lindsay and Birley, 1996).

Micro- and macroenvironmental changes can affect malaria transmission. For example, deforestation may elevate local temperatures (Hamilton, 1989). Changes in types of housing may change indoor temperatures where some vectors spend most of the time resting (Garnham, 1945). In Africa, deforestation, vegetation clearance, and irrigation can all provide the open sunlit pools that are preferred by important malaria vectors and thus increase transmission (Chandler and Highton, 1975;

Walsh *et al.*, 1993; Githeko *et al.*, 1996; Lindsay and Birley, 1996).

Malaria currently is present in 101 countries and territories (WHO, 1998a). An estimated 40% (i.e., 2.4 billion people) of the total world population currently lives in areas with malaria. In many malaria-free countries with a developed public health infrastructure, the risk of sustained malaria transmission after reintroduction is low in the near term. Other areas may become at risk as a result of climate change if, for example, malaria control programs have broken down or if transmission currently is limited mainly by temperature. Environmental conditions already are so favorable for malaria transmission in tropical African countries that climate change is unlikely to affect overall mortality and morbidity rates in endemic lowland regions (MARA, 1998). Furthermore, reductions in rainfall around the Sahel may decrease transmission in this region of Africa (Mouchet *et al.*, 1996; Martens *et al.*, 1999). Future climate change may increase transmission in some highland regions, such as in East Africa (Lindsay and Martens, 1998; Mouchet *et al.*, 1998; Cox *et al.*, 1999; see Box 9-2). Studies that map malaria in Africa indicate that, at the broad scale, distribution of the disease is determined by climate, except at the southern limit (MARA, 1998). Malaria transmission currently is well within the climatic limits of its distribution in mid- to high-latitude developed countries because of effective control measures and other environmental changes. However, in South America the southern limits of malaria distribution may be affected by climate change. The southern geographical distribution

limit of a major malaria vector in South America (*An. darlingi*) coincides with the April mean isotherm of 20°C. If temperature and rainfall increase in Argentina, *An. darlingi* may extend its distribution in southern Argentina, whereas if rainfall decreases, conditions may become unfavorable for *An. darlingi* (Carcavallo and Curto de Casas, 1996).

Malaria was successfully eradicated from Australia, Europe, and the United States in the 1950s and 1960s, but the vectors were not eliminated (Bruce-Chwatt and de Zulueta, 1980; Zucker, 1996). In regions where the vectors persist in sufficient abundance, there is a risk of locally transmitted malaria. This small risk of very localized outbreaks may increase under climate change. Conditions currently exist for malaria transmission in those countries during the summer months, but few nonimported cases have been reported (Holvoet *et al.*, 1983; Zucker, 1996; Baldari *et al.*, 1998; Walker, 1998). Malaria could become established again under the prolonged pressures of climatic and other environmental-demographic changes if a strong public health infrastructure is not maintained. A particular concern is the reintroduction of malaria in countries of the former Soviet Union with economies in transition, where public health infrastructure has diminished (e.g., Azerbaijan, Russia).

9.7.1.1 Modeling the Impact of Climate Change on Malaria

Classical epidemiological models of infectious disease use the basic reproduction rate, R_0 . This measure is defined as the

Box 9-2. Have Recent Increases in Highland Malaria been Caused by Climate Warming?

“Highland malaria” usually is defined as malaria that occurs around its altitudinal limit, exhibiting an unstable fluctuating pattern. There has been considerable debate about the causes of the resurgence of malaria in the African highlands. Early in the 20th century, malaria epidemics occurred at elevations of 1,500–2,500 m in Africa, South America, and New Guinea (Mouchet *et al.*, 1998; Reiter, 1998a). Highland malaria in Africa was effectively controlled in the 1950s and 1960s, mainly through the use of DDT and improved medical care. Important changes that have contributed to the subsequent resurgence include changes in land use, decreasing resources for malaria control and treatment, and population growth and movement (Lindsay and Martens, 1998; Malakooti *et al.*, 1998; Mouchet *et al.*, 1998; Reiter, 1998a). There are insufficient historical data on malaria distribution and activity to determine the role of warming, if any, in the recent resurgence of malaria in the highlands of Kenya, Uganda, Tanzania, and Ethiopia (Cox *et al.*, 1999).

That malaria is sensitive to temperature in some highland regions is illustrated by the effect of El Niño. Increases in malaria have been attributed to observed El Niño-associated warming in highland regions in Rwanda (Loevinsohn, 1994) and Pakistan (Bouma *et al.*, 1996). However, increases in rainfall (sometimes associated with El Niño) also trigger highland epidemics (e.g., Uganda—Lindblade *et al.*, 1999). Lindsay *et al.* (2000) found a reduction in malaria infection in Tanzania associated with El Niño when heavy rainfall may have flushed out Anopheline mosquitoes from their breeding sites.

Most increases in malaria transmission entail single epidemics or a sequence of epidemics that occur over a 1- to 2-year period. Although many epidemics are triggered by transient increases in temperature and/or rainfall, the short time scale of events and the difficulty of linking different epidemics in different parts of the world make it difficult to say if long-term climate change is a factor. Furthermore, there has been little work that identifies where malaria transmission currently is limited by temperature and therefore where highland populations are at risk of malaria as a result of climate change. To determine the role of climate in the increase in highland malaria, a comprehensive research effort is required, together with implementation of a sustainable disease surveillance system that combines trend analyses across multiple sites to account for substantial local factors.

number of new cases of a disease that will arise from one current case when introduced into a nonimmune host population during a single transmission cycle (Anderson and May, 1992). The basic reproduction rate—or a related concept, “vectorial capacity”—can provide a relative index of the impact of different climate scenarios on the transmissibility of vector-borne diseases such as malaria. Vectorial capacity, however, is determined by complex interactions of many host, vector, pathogen, and environmental factors. Some of the variables are sensitive to temperature, including mosquito density, feeding frequency, mosquito survival, and the extrinsic incubation period (EIP) of the parasite (*plasmodium*) in the mosquito (Martens *et al.*, 1999). The EIP is especially important, and, within the lower temperature range, it is very temperature-sensitive.

Biological (or process-based) models have been used to estimate the potential transmission of malaria. This is a measure of the extent to which the natural world (the global environment-climate complex) would allow the transmission of malaria if there were no other human-imposed constraints on transmission. However, in some areas where human-imposed constraints have occurred as a result of economic growth, or were put in place purposely, malaria transmission has been successfully controlled, regardless of suitable local temperatures. There has been considerable evolution of models since the SAR (Martens *et al.*, 1995, 1997, 1999; Martin and Lefebvre, 1995). One model (Martens *et al.*, 1999) includes vector-specific information regarding the temperature-transmission relationship and mosquito distribution limits. Recent studies using that revised model applied to the HadCM2 climate scenarios project a global increase of 260–320 million people in 2080 living in the potential transmission zone (against a baseline expectation of about 8 billion—that is, a 2–4% increase in the number of people at risk) (Martens *et al.*, 1999; McMichael *et al.*, 2000a). This projection, by design, does not take into account the fact that much of this additional population at risk is in middle- or high-income countries where human-imposed constraints on transmission are greatest and where potential transmission therefore is unlikely to become actual transmission. The model also projects regional increases and a few decreases in the seasonal duration of transmission in current and prospective areas of malaria transmission. Constraining of GHG emissions to achieve CO₂ stabilization within the range 550–750 ppm would reduce those projected increases by about one-third (Arnell *et al.*, 2001).

On a global scale, all biological models show net increases in the potential transmission zone of malaria and changes in seasonal transmission under various climate scenarios (Martens *et al.*, 1995, 1999; Martin and Lefebvre, 1995). Some local decreases in malaria transmission also are predicted to occur where declines in rainfall would limit mosquito survival. The outputs of these malaria models are very sensitive to assumptions about the minimum rainfall or humidity levels needed for malaria transmission.

Another global modeling study (Rogers and Randolph, 2000) used a statistical-empirical approach, in contrast to the

aforementioned biological models. The outcome variable in this model is the number of people living in an *actual* transmission zone, as opposed to a *potential* transmission zone (as estimated by biological models). Using an IS92a (unmitigated) climate scenario, this study estimated no significant net change by 2080 in the portion of the world’s population living in actual malaria transmission zones; modeled malaria transmission increased in some areas and decreased in others. This study made the assumption that the actual geographic distribution of malaria in today’s world is a satisfactory approximation of its historical distribution prior to modern public health interventions. This assumption is likely to have biased the estimation of the underlying multivariate relationship between climatic variables and malaria occurrence because the sensitive climate-malaria relationship in the lower temperature range in temperate zones (especially Europe and the southern United States) would have been excluded from the empirically derived equation. Hence, the use of that derived equation to predict malaria risk in 2080 would have been relatively inert to marginal climatic changes at the fringes of the current geographic distribution.

Another type of modeling addresses changes in the distribution of mosquito vector species only. The CLIMEX model estimates changes in global and national (Australia) distribution of malaria vectors under a range of climate scenarios, based on the vectors’ temperature and moisture requirements (Bryan *et al.*, 1996; Sutherst, 1998). The distribution of *Anopheles gambiae* complex is projected to undergo a net increase in distribution in southern Africa under three climate change scenarios (Hulme, 1996). However, these models do not address complex ecological interactions, such as competition between species.

None of these models have been adequately validated at global or regional levels. Modeling to date has not satisfactorily addressed regional vulnerability to malaria or changes in risk in highland regions (Lindsay and Martens, 1998). This is principally because it is difficult to obtain sufficiently detailed geographic distribution maps of mosquitoes and malaria occurrence over time. An important criticism of biological models is that undue emphasis is placed on temperature changes, without consideration to other ecological complexities—including those influenced by rainfall, humidity, and host exposure—that influence transmission dynamics. Furthermore, the equations within a global model may be inappropriate for particular local conditions, and there is a need for cross-validation of large-scale and small-scale studies (Root and Schneider, 1995). Some attempts to apply these integrated modeling techniques to smaller scale regional settings have attempted to take account of local/regional conditions (Lindsay and Martens, 1998). None of the modeling to date has incorporated the modulating effect of public health strategies and other social adaptive responses to current or future malaria risk (Sutherst *et al.*, 1998). Nevertheless, it remains a legitimate and important question to estimate, under scenarios of climate change, change in the extent to which the natural world (the global environment-climate complex) would allow transmission of malaria if there were no other human-imposed constraints on transmission.

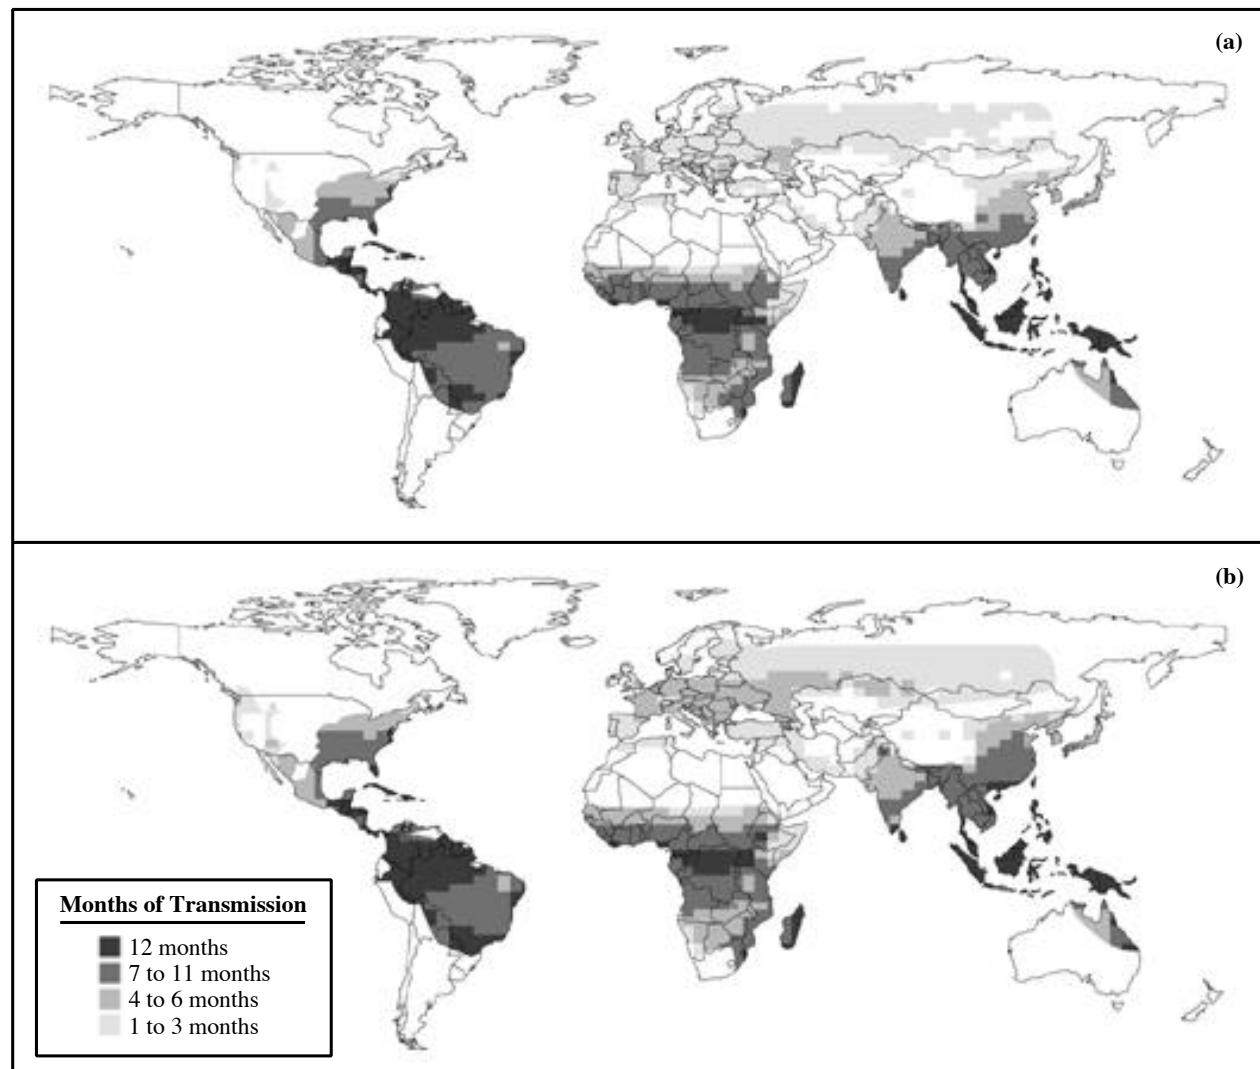

Figure 9-2: Potential impact of climate change on seasonal transmission of falciparum malaria. Output from MIASMA v2.0 malaria model (Martens *et al.*, 1999) indicates the number of months per year when climate conditions are suitable for falciparum transmission and where there is competent mosquito vector: (a) months of potential transmission under current climate (1961–1990); (b) months of potential transmission under a GHG-only climate scenario (HadCM2 ensemble mean) in the 2080s. Future changes in mosquito distributions are not modeled. This model does not take into account control or eradication activities that have significantly limited the distribution of malaria.

9.7.2. Dengue

Dengue is a disease that is caused by four closely related viruses that are maintained in a human-*Aedes aegypti*-human cycle in most urban centers of the tropics (Gubler, 1997). The geographic distribution of the dengue viruses and mosquito vectors (*Aedes aegypti* and *A. albopictus*) has expanded to the point that dengue has become a major tropical urban health problem (Gubler, 1997, 1998b). Dengue is primarily an urban disease; more than half of the world's population lives in areas of risk (Gubler, 1997, 1998b). In tropical areas of the world, dengue transmission occurs year-round but has a seasonal peak in most countries during months with high rainfall and humidity.

Major factors causing epidemics include population growth, rapid urbanization, lack of effective mosquito control, and movement of new dengue virus strains and serotypes between countries (Gubler, 1997, 1998b).

The global resurgence of dengue in recent years has resulted in increased imported dengue and cases of local transmission in the United States and Australia. As with malaria, the number of cases is small and sporadic (Gubler, 1989, 1997, 1998b). By contrast, Mexican states bordering the United States have had repeated large epidemics of dengue (Gubler, 1989, 1998b; Reiter, 1997; Rawlins *et al.*, 1998). The difference in vulnerability may be caused by differences in living standards and human

behavior, which in the United States decrease the probability that vector mosquitoes will feed on humans. It is unlikely that climate change will affect these factors and cause increased epidemic dengue activity in temperate zone developed countries.

9.7.2.1 Modeling the Impact of Climate Change on Dengue

To date, all published studies regarding evaluations of the possible impact of global climate change on dengue transmission have involved modification of the standard equation for vectorial capacity (VC) (Jetten and Focks, 1997; Martens *et al.*, 1997; Patz *et al.*, 1998a). Temperature affects the rate of mosquito larval development, adult survival, vector size, and gonotrophic cycle, as well as the EIP of the virus in the vector (Focks *et al.*, 1993a,b, 1995).

Modeling studies (Jetten and Focks, 1997; Martens *et al.*, 1997; Patz *et al.*, 1998a) suggest that a warming projection of 2°C by 2100 will result in a net increase in the potential latitudinal and altitudinal range of dengue and an increase in duration of the transmission season in temperate locations. However, they also ignore the complex epidemiological and ecological factors that influence transmission of dynamics of dengue. Changes in potential transmission in areas that currently are endemic for dengue are projected to be limited. As with malaria, models indicate that the areas of largest change of potential transmission intensity as a result of temperature rise are places where mosquitoes already occur but where development of the virus is limited by temperature during part of the year. However, these models do not incorporate demographic, societal, and public health factors that have been responsible for eliminating dengue from temperate areas. Transmission intensity in tropical endemic countries is limited primarily by herd immunity, not temperature; therefore, projected temperature increases are not likely to affect transmission significantly. Moreover, in subtropical developed areas, where transmission is limited primarily by demographic and societal factors, it is unlikely that the anticipated temperature rise would affect endemicity (Gubler, 1998b).

9.7.3. Other Mosquito-Borne Viruses

Mosquitoes transmit many viruses, more than 100 of which are known to infect humans—causing illness ranging from acute viral syndrome to severe and sometimes fatal encephalitis and hemorrhagic fever. The natural transmission cycles of these viruses are complex and usually involve birds or rodents as well as several mosquito species; each region of the world has its own unique viruses (Gubler and Roehrig, 1998). These viruses have become important global emergent/resurgent public health problems in recent years, causing widespread epidemics (Gubler 1996, 1998a).

Yellow fever—a virus that occurs naturally in the rain forests of Africa and South America in an enzootic cycle involving lower primates and mosquitoes—also can cause major urban epidemics in a cycle involving *Aedes aegypti* that is identical

to dengue (Monath, 1988). As such, it has similar weather and climate sensitivity to dengue. Yellow fever was effectively controlled in the 1950s and 1960s through vaccination (Africa) and mosquito control (the Americas). With reinvasion of most large American tropical urban centers by *Aedes aegypti* in the past 30 years (Gubler, 1989), the region is at its highest risk for urban epidemics in 50 years (Gubler, 1998c). Once urban epidemics of yellow fever begin to occur in tropical America, it is expected that this virus will move very quickly via modern transportation to Asia and the Pacific, where it has never occurred (Gubler, 1998c).

Several mosquito-borne viruses cause encephalitis, including eastern equine encephalitis (EEE), western equine encephalitis (WEE), St. Louis encephalitis (SLE), La Crosse encephalitis (LAC), and Venezuelan equine encephalitis (VEE) in the Americas; Japanese encephalitis (JE) in Asia; Murray Valley encephalitis (MVE) and Kunin (KUN) in Australia; and West Nile (WN) and Rift Valley fever (RVF) viruses in Africa (Gubler and Roehrig 1998). WN virus also occurs in west and central Asia, the Middle East, and Europe and recently was introduced into the United States, where it caused a major epidemic in New York City (Asnis *et al.*, 2000; Komar, 2000). All of these viruses have birds (EEE, WEE, SLE, JE, MVE, KUN, WN) or rodents (LAC, VEE) as natural reservoir hosts. The natural host for RVF is not known, but large ungulates act as amplifying hosts.

Epidemics of these diseases occur when their natural ecology is disturbed in some way (Gubler and Roehrig, 1998). This could include environmental changes such as meteorological changes or forest clearing, changes in population densities and structure of the mosquito or vertebrate host, or genetic changes in the viruses. All of these diseases are very climate-sensitive, but it is difficult to know how climate change will influence their distribution and incidence because of the complexities of their transmission cycles in nature. For example, in the United States, WEE and SLE could expand their geographic distribution northward, and WEE could disappear from most of the country (Reeves *et al.*, 1994). Climate change also may have an effect on endemic/enzootic arboviruses in Australia (Russell, 1998; Tong *et al.*, 1998; Bi *et al.*, 2000). Thus, there probably would be positive and negative impacts, depending on the disease.

Floods may cause an immediate decrease in mosquito populations because of loss of breeding sites. However, disease risk may rise as floodwaters recede and vector populations increase, but only if the virus is present (Nasci and Moore, 1998). This underscores the need to have effective surveillance systems and prevention strategies in place to monitor disease and control vector activity, as well as the need for more research on the transmission dynamics of vector-borne diseases.

9.7.4. Leishmaniasis

There are two principal clinical types of leishmaniasis—visceral and cutaneous—which is caused by a range of species of *Leishmania* parasites. The parasites are transmitted by sandflies,

Table 9-3: Temperature thresholds of pathogens and vectors. T_{min} is minimum temperature required for disease transmission. T_{max} for the pathogen is upper threshold beyond which temperatures are lethal. T_{max} for vectors are not provided. Temperatures are in degrees Celsius. Note that temperatures assume optimum humidity; vector survival decreases rapidly as dryness increases. There is considerable variation in these thresholds within and between species (Purnell, 1966; Pfluger, 1980; Curto de Casas and Carcavallo, 1984; Molineaux, 1988; Rueda et al., 1990).

Disease	Pathogen	T_{min}	T_{max}	Vector	T_{min} for Vector
Malaria	<i>Plasmodium falciparum</i>	16–19	33–39	<i>Anopheles</i>	8–10 (biological activity)
Malaria	<i>Plasmodium vivax</i>	14.5–15	33–39	<i>Anopheles</i>	8–10 (biological activity)
Chagas' disease	<i>Trypanosoma cruzi</i>	18	38	<i>Triatomine</i> bugs	2–6 (survival) 20 (biological activity)
Schistosomiasis	Cercaria	14.2	>37	Snails (<i>Bulinus</i> and others)	5 (biological activity) 25 ± 2 (optimum range)
Dengue fever	Dengue virus	11.9	not known	<i>Aedes</i>	6–10
Lyme disease	<i>Borrelia burdorferi</i>	Not yet determined		<i>Ixodes</i> ticks	5–8

of which the two most important genera are *Phlebotomus* in Europe and Asia and *Lutzomyia* in the Americas. In central Asia and Europe, leishmaniasis has become an important co-infection with human immunodeficiency virus (HIV) (Alvar et al., 1997; WHO/UNAIDS, 1998). Sandflies are very sensitive to temperature, and increases in temperature also may increase daily mortality rates. *Phlebotominae* are sensitive to sudden temperature changes and prefer regions with small differences between maximum and minimum temperatures. Thomson et al. (1999) mapped *P. orientalis* in Sudan and found that the geographic distribution was best explained by mean annual maximum daily temperature and soil type. One study on leishmaniasis in Italy indicates that climate change may expand the range of one vector (*P. perniciosus*) but decrease the range of another (*P. perfiliewi*) (Kuhn, 1997). A 3°C increase in temperature could increase the geographic and seasonal distribution of *P. papatasi* in southwest Asia, provided other ecological requirements are met (Cross and Hyams, 1996; Cross et al., 1996).

The southern limit of leishmaniasis and vectors in South America is the extreme north of Argentina (Curto de Cassas and Carcavallo, 1995; Marcondes et al., 1997). There have been no systematic studies of the relationship between climate parameters and vectors or human cases in the Americas. Climate change could affect the geographical distribution of these vector species in Brazil, Paraguay, Bolivia, and Argentina (Carcavallo and Curto de Casas, 1996).

9.7.5. Schistosomiasis

Schistosomiasis, which is caused by five species of the trematode (flat worm) *Schistosoma*, requires water snails as an intermediate host. Worldwide prevalence has risen since the 1950s largely as a result of expansion of irrigation systems in hot climates where

viable snail populations can survive and the parasite can find human parasite carriers (Hunter et al., 1993). All three genera of snail hosts (*Bulinus*, *Biomphalaria*, and *Oncomelania*) can tolerate a wide temperature range. At low temperatures, snails are effectively dormant and fecundity is virtually zero, but survival is good. At high temperatures, births (egg production) increase, but so does mortality (Table 9-3). However, snails are mobile and can move to avoid extreme temperatures within their habitats; water can act as an efficient insulator (Hairston, 1973; Gillett, 1974; Schiff et al., 1979). The precise conditions within water bodies that determine transmission depend on a host of environmental factors, including local geology and topography, the general hydrology of the region, the presence or absence of aquatic vegetation, and local agricultural usage (Appleton and Stiles, 1976; Appleton, 1977). In east Africa, colonies of *Biomphalaria* and *Bulinus* spp. persist at altitudes of 2,000 m or more, but transmission—if it occurs at all—is restricted to brief warm seasons. Climate change might allow schistosomiasis transmission to extend its range to higher altitudes. Conversely, increasing temperatures at sea level could decrease transmission unless the snails move to cooler refuges.

Water shortages resulting from climate change could create greater need for irrigation, particularly in arid regions. If irrigation systems expand to meet this need, host snail populations may increase (Schorr et al., 1984), leading to greater risk of human infection with the parasite. However, this impact could be reduced by constructing irrigation systems that are not conducive to snail breeding.

9.7.6. Chagas' Disease

The geographical distribution of American trypanosomiasis (Chagas' disease) is limited to the Americas, ranging from the

southern United States to southern Argentina and Chile (Carcavallo *et al.*, 1998, 1999). Chagas' disease is transmitted by triatomine bugs (see Table 9-3). Temperature affects the major components of VC (reviewed by Zeledón and Rabinovich, 1981; Carcavallo, 1999). If temperatures exceed 30°C and humidity does not increase sufficiently, the bugs increase their feeding rate to avoid dehydration. If indoor temperatures rise, vector species in the domestic environment may develop shorter life cycles and higher population densities (Carcavallo and Curto de Casas, 1996). High temperatures also accelerate development of the pathogen, *Trypanosoma cruzi*, in the vector (Asin and Catalá, 1995). Many vector species are domesticated. Lazzari *et al.* (1998) found that in the majority of structures, differences between inside and outside temperature were small, although differences in humidity were significant. Triatomine dispersal also is sensitive to temperature (Schofield *et al.*, 1992). Population density of domestic vectors also is significantly affected by human activities to control or eradicate the disease (e.g., replastering of walls, insecticide spraying). The southern limits of *Triatoma infestans* and Chagas' disease distributions recently have been moved significantly inside their climatically suitable limits by large-scale control campaigns (Schofield and Dias, 1999).

9.7.7. Plague

Plague is a bacterial disease that is transmitted by the bite of infected fleas (*Xenopsylla cheopis*), by inhaling infective bacteria, and, less often, by direct contact with infected animals (Gage, 1998). Plague exists focally in all regions except Europe. Notable plague outbreaks have occurred in several Asian, African, and South American countries in the past 10 years (John, 1996; WHO, 1997; Gage, 1998; PAHO, 1998). It is unclear whether climate change may affect the distribution and incidence of plague. There does appear to be a correlation between rainfall patterns and rodent populations (Parmenter *et al.*, 1999; see also Section 9.7.9). Prospective field research studies must be conducted to confirm this.

9.7.8. Tick-Borne Diseases

Tick-borne diseases—in particular, Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, and tick-borne encephalitis (TBE)—are the most common vector-borne diseases in temperate zones in the northern hemisphere. Ticks are ectoparasites; their geographical distribution depends on the distribution of suitable host species—usually mammals or birds (Glass *et al.*, 1994; Wilson, 1998). Species that transmit these diseases have complex life cycles that require 3 years and three different hosts species—one for each stage of the cycle (larvae, nymph, and adult). Climate directly and indirectly influences the tick vector, its habitat, host and reservoir animals, time between blood meals, and pathogen transmission. Bioclimatic threshold temperatures set limits for tick distribution and are of importance for the magnitude of disease occurrence (Table 9-3). Temperatures must be sufficiently high for completion of the tick's life cycle.

Humidity must be sufficient to prevent tick eggs from drying out. Temperatures above the optimum range reduce the survival rate of ticks. In temperate countries, tick vectors are active in the spring, summer, and early autumn months.

Over the past 2 decades, marked increases have been reported in the abundance of ticks and the incidence of tick-borne disease in North America and Europe. In North America, these changes have been attributed to an increase in awareness of tick-borne diseases and increased abundance of wild tick hosts (principally deer), as reforestation has expanded areas of suitable habitat (Dennis, 1998). There is some evidence that the northern limit of distribution of the tick vector (*Ixodes ricinus*) and tick density increased in Sweden between the early 1980s and 1994, concurrent with an increased frequency of milder winters (Talleklint and Jaenson, 1998; Lindgren *et al.*, 2000). In New York state, *Ixodes scapularis* has expanded its geographic distribution northward and westward in the past 10 years. The reasons for this expansion are unknown.

9.7.8.1. Lyme Disease

Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi*. It is transmitted by ticks of the *Ixodes ricinus* complex (Dennis, 1998). Lyme disease has a global distribution in temperate countries of North America, Europe, and Asia. The transmission cycle of Lyme disease involves a range of mammalian and avian species, as well as tick species—all of which are affected by local ecology. Under climate change, a shift toward milder winter temperatures may enable expansion of the range of Lyme disease into higher latitudes and altitudes, but only if all of the vertebrate host species required by the tick vector also are able to expand their distribution. A combination of milder winters and extended spring and autumn seasons would be expected to prolong seasons for tick activity and enhance endemicity, but this would not be expected to change disease activity because humans usually are infected by the nymphal stage, which feeds at a specific time during the second year of the cycle.

9.7.8.2. Tick-Borne Encephalitis

Tick-borne encephalitis (TBE) is caused by two closely related but biologically distinct viruses (Gubler and Roehrig, 1998). The eastern subtype is transmitted by *Ixodes persulcatus* and causes Russian spring-summer encephalitis. It occurs from China to eastern Europe and is highly focal in its distribution. The western subtype is transmitted by *Ixodes ricinus* and causes central European encephalitis, a milder form of the disease. It occurs within discrete foci from Scandinavia in the north to Croatia in the south, with only occasional cases further south. A related virus, Powassan, occurs in Canada and the United States and is transmitted by *Ixodes scapularis*. Humans usually become infected when they are exposed to ticks in habitats where the viruses are maintained. The viruses also may be transmitted directly through ingestion of raw goat milk.

It is possible that warming would extend the transmission season for TBE in Europe. The aforementioned study showed a northward extension of the tick population in Sweden in association with warmer winters, accompanied by an increase in the annual number of cases of tick-borne encephalitis reported within Sweden. Most transmission to humans is by the nymphal ticks, each of which feeds for a few days during spring-summer before dropping to the ground and molting to adult ticks, which feed primarily on deer and other large mammals. All tick stages have well-defined seasons of feeding activity, which vary geographically and may be prolonged in regions with mild winters.

Unlike Lyme disease, sustainable transmission of TBE requires a high level of coincident feeding of larval and nymphal ticks. This seasonal synchrony depends on a particular seasonal profile of land surface temperature—specifically, a rapid rate of cooling in the autumn (Randolph *et al.*, 2000). Synchrony may be disrupted by climate change as patterns of overwinter development by ticks are changed. A statistical model, based on the current distribution of TBE, indicates significant net contraction in the geographic distribution of TBE under mid-range climate scenarios by the 2050s (Randolph and Rogers, 2000). The model indicates that although disease foci spread to higher latitudes and altitudes, current foci in central Europe largely disappear as a result of disruption of the tick seasonal dynamic by climate change. Thus, one model suggests that it is unlikely that warming would increase the incidence or net geographic distribution of TBE in Europe.

9.7.9. Rodent-Borne Diseases

Rodent-borne diseases are zoonoses that are transmitted directly to humans by contact with rodent urine, feces, or other body fluids (Mills and Childs, 1998; Peters, 1998). Rodents are principle hosts for arthropod vectors such as fleas (see Section 9.7.7) and ticks (see Section 9.7.8). Environmental factors that affect rodent population dynamics include unusually high rainfall, drought, and successful introduction of exotic plant species. Rodent-borne pathogens are affected indirectly by ecological determinants of food sources that affect rodent population size (Williams *et al.*, 1997; Engelthaler *et al.*, 1999).

9.7.9.1. Leptospirosis

Leptospirosis is an acute febrile disease caused by the bacteria *Leptospira*. It probably is the most widespread zoonotic disease in the world and is particularly common in the tropics (PAHO, 1998). Infection is caused by exposure to water, damp soil, or vegetation contaminated with the urine of infected wild and domestic animals (e.g., rodents and dogs) (Thiermann, 1980). Outbreaks often occur after heavy rainfall and during floods (Kriz *et al.*, 1998; Trevejo *et al.*, 1998). Therefore, any increase in flooding associated with climate change may affect the incidence of this disease.

9.7.9.2. Hantaviruses

Several hantaviruses are capable of causing severe, often fatal, illness in humans (PAHO, 1998). Each has a specific geographic distribution that is determined by that of the primary rodent host (Schmaljohn and Hjelle, 1997). Humans are infected by aerosol exposure to infectious excreta or occasionally by bites. The better known of these diseases are hemorrhagic fever with renal syndrome, caused by Hantaan virus, in China and Korea and hantavirus pulmonary syndrome in the Americas, caused by several viruses that are specific to their rodent host (Schmaljohn and Hjelle, 1997). Outbreaks of disease may be associated with weather that promotes rapid increases in rodent populations, which may vary greatly between seasons and from year to year (Glass *et al.*, 2000). Many hantavirus infections occur in persons of lower socioeconomic status, where poorer housing and agricultural activities favor closer contact between humans and rodents (Schmaljohn and Hjelle, 1997). Arenaviruses (Lassa, Junin, Machupo, etc.), which are ecologically similar to hantaviruses, may respond similarly (Mills and Childs, 1998).

9.7.10. Water-Related Infectious Diseases

There are complex relationships between human health and problems of water quality, availability, sanitation, and hygiene. Predicting the potential impacts of climate change on water-related diseases therefore is difficult because access to a clean safe water supply is determined primarily by socioeconomic factors. Extreme weather—floods or droughts—can increase the risk of disease via contamination of water resources, poor hygiene, or other mechanisms. Currently, the World Health Organization (WHO) estimates that more than 1 billion people worldwide are without access to safe drinking water and that every year as many as 4 million die prematurely because they do not have access to safe drinking water and sanitation. Increases in water stress are projected under climate change in certain countries (see Chapter 4), but it is difficult to translate such indicators directly into the attributable risk for water-related diseases. Water scarcity may necessitate use of poorer quality sources of freshwater, such as rivers, which often are contaminated. Decreases in water supplies could reduce the water available for drinking and washing and lower the efficiency of local sewerage systems, leading to increased concentration of pathogenic organisms in raw water supplies.

Excessive precipitation can transport terrestrial microbiological agents into drinking-water sources. For example, some outbreaks of cryptosporidiosis, giardia, and other infections have been triggered by heavy rainfall events in the UK and United States (Lisle and Rose, 1995; Atherholt *et al.*, 1998; Rose *et al.*, 2000; Curriero *et al.*, 2001). Significant correlation between the cumulative monthly distribution of cholera cases and the monthly distribution of precipitation has been observed in Guam (Borrotto and Haddock, 1998). In many countries, handling of sewage is not separate from the drainage system for stormwaters. It is important that water resource management can adapt to

changes in the frequency of precipitation extremes to minimize the risk of microbiological contamination of the public water supply.

Cholera is a water- and food-borne disease and has a complex mode of transmission. In tropical areas, cases are reported year-round. In temperate areas, cases are reported mainly in the warmest season. The seventh cholera pandemic currently is spreading across Asia, Africa, and South America. A new serogroup (*V. cholerae* O139) appeared in 1992 and is responsible for large epidemics in Asia. During the 1997–1998 El Niño, excessive flooding caused cholera epidemics in Djibouti, Somalia, Kenya, Tanzania, and Mozambique (WHO, 1998b). Birmingham *et al.* (1997) found a significant association between bathing and drinking water from Lake Tanganyika and the risk of infection with cholera. Warming in the African Great Lakes may cause conditions that increase the risk of cholera transmission in the surrounding countries (WHO, 1998b). See Section 9.8 for a discussion of cholera in coastal waters.

9.7.11. Other Infectious Diseases

Water- and food-borne diseases tend to show marked seasonality, with peaks in early spring or summer. Higher temperatures favor microorganism proliferation and often are associated with an increase in gastrointestinal infections. Above-average temperatures in Peru during the 1997–1998 El Niño were associated with a doubling in the number of children admitted to the hospital with diarrhea (Checkley *et al.*, 2000). Higher temperatures also can trigger spore maturation (e.g., *Cyclospora cayetanensis*—Ortega *et al.*, 1993; Smith *et al.*, 1997). In Peru, the incidence of cyclosporiasis peaks in the summer months (Madico *et al.*, 1997). Because climate change is expected to entail warmer springs and summers, additional cases of food-borne disease may occur, if current trends continue (Bentham and Langford, 1995). In most developed countries, food-borne disease incidence is increasing as a result of changes in behavior, consumption patterns, and commerce.

Major epidemics of meningococcal infection usually occur every 5–10 years within the African “meningitis belt;” they usually start in the middle of the dry season and end a few months later with the onset of the rains (Greenwood *et al.*, 1984). Between February and April 1996, the disease affected thousands of people in parts of northern Nigeria, many of whom died (Angyo and Okpeh, 1997). The epidemic spread from the original meningitis belt to Kenya, Uganda, Rwanda, Zambia, and Tanzania (Hart and Cuevas, 1997). One of the environmental factors that predispose to infection and epidemics is low humidity (Tikhomirov *et al.*, 1997). However, a climate-meningitis association was not clear in parts of the Gulf of Guinea (Besancenot, 1997). The fact that this disease has been limited to semi-arid areas of Africa suggests that its transmission could be affected by warming and reduced precipitation.

Warm and humid conditions can promote fungal skin infections such as sporotrichosis (Conti Diaz, 1989). Decreases in

humidity can lead to increased dispersion of particulate fungal spores, thereby increasing the risk of pneumonia caused by coccidioidomycosis (Durry *et al.*, 1997; Schneider *et al.*, 1997).

9.8. Coastal Water Issues

Pathogens often are found in coastal waters; transmission occurs through shellfish consumption or bathing. Coastal waters in developed and developing countries frequently are contaminated with untreated sewage. Higher temperatures encourage microorganism proliferation. The presence of *Vibrio spp.* (some of which are pathogens that cause diarrhea) has been associated with higher sea-surface temperature (SST) (Lipp and Rose, 1997). *Vibrio vulnificus* is a naturally occurring estuarine bacterium that may be more often transmitted to humans under conditions of higher SST (Patz *et al.*, 2000).

Acute poisoning can occur following consumption of fish and shellfish contaminated with biotoxins (WHO, 1984). Phytoplankton organisms respond rapidly to changes in environmental conditions and therefore are sensitive biological indicators of the combined influences of climate change and environmental change (Harvell *et al.*, 1999). Algal blooms are associated with several environmental factors, including sunlight, pH, ocean currents, winds, SSTs, and runoff (which affects nutrient levels) (Epstein *et al.*, 1993; NRC, 1999). Algal blooms can be harmful to fish and other aquatic life, often causing severe economic damage, and are reported to have increased globally in the past several decades (Hallegraef, 1993; Sournia, 1995), although some of the observed increase is attributed to changes in monitoring, effluent, and land use.

There is no straightforward relationship between the presence of an algal bloom and an outbreak of poisoning. Human poisoning can occur in the absence of a bloom. Two main types of biotoxin poisoning are associated with temperate climates and colder coastal waters: paralytic shellfish poisoning and diarrheic shellfish poisoning. If water temperatures rise as a result of climate change, shifts in the distribution of these diseases could follow. Biotoxins associated with warmer waters, such as ciguatera in tropical waters, could extend their range to higher latitudes (Tester, 1994). An association has been found between ciguatera (fish poisoning) and SST in some Pacific islands (Hales *et al.*, 1999a).

Recent evidence suggests that species of copepod zooplankton provide a marine reservoir for the cholera pathogen and facilitate its long-term persistence in certain regions, such as the estuaries of the Ganges and Bramaputra in Bangladesh (Colwell, 1996). The seasonality of cholera epidemics may be linked to the seasonality of plankton (algal blooms) and the marine food chain. Studies using remote-sensing data have shown a correlation between cholera cases and SST in the Bay of Bengal (Lobitz *et al.*, 2000). Interannual variability in cholera incidence in Bangladesh also is linked to ENSO and regional temperature anomalies (Pascual *et al.*, 2000). Epidemiological evidence further suggests a widespread environmental cause of the 1991

epidemic in Peru, rather than point-source contamination (Seas *et al.*, 2001). There is some evidence for a link between warmer sea surfaces and cholera risk in the Bay of Bengal, but it is not possible to extrapolate such findings to cholera incidence inland or in other regions. The potential impact of long-term climate warming on cholera incidence or risk of epidemics remains uncertain.

Climate-related ecological changes may enhance primary and secondary transmission of cholera in developing countries, particularly among populations settled in low-lying coastal areas in the tropics. However, the causal link between sea temperature, plankton blooms, and human disease requires further elucidation and confirmation.

9.9. Food Yields and Nutrition

Background climate and annual weather patterns are key factors in agricultural productivity, despite technological advances such as improved crop varieties and irrigation systems. As temperature, rainfall, and soil moisture change, plant physiology is affected; so too is the much less predictable risk of a change in patterns of plant pests and pathogens. There are many social, economic, and environmental influences on agricultural, horticultural, and livestock productivity. Climate change represents an additional pressure on the world food supply system. That system, which has yielded an overall increase in per capita food supplies over the past 4 decades, has shown signs of faltering over the past decade. There is ongoing scientific debate about the relative importance of economic, technical, and ecological influences on current food yields (Waterlow *et al.*, 1998; Dyson, 1999). Optimists point to falling food prices; pessimists point to falling soil fertility.

Modeling studies (reviewed in Chapter 5) indicate that, under climate change, yields of cereal grains (the world's dominant food commodity) would increase at high and mid-latitudes but decrease at lower latitudes. Furthermore, this disparity would become more pronounced as time progresses. The world's food system may be able to accommodate such regional variations at the global level, with production levels, prices, and the risk of hunger relatively unaffected by the additional stress of climate change. To minimize possible adverse consequences, a dual development program is desirable. Adaptation should be undertaken via continued development of crop breeding and management programs for heat and drought conditions. These will be immediately useful in improving productivity in marginal environments today. Mitigation strategies should be implemented to try to reduce further enhanced global warming. However, recent work suggests that the main benefits of mitigation will not accrue until late in the 21st century (Parry *et al.*, 1998).

The United Nations Food and Agriculture Organization (FAO) estimates that in the late 1990s, 790 million people in developing countries did not have enough to eat (FAO, 1999). The FAO report on food insecurity has identified population groups, countries, and regions that are vulnerable. For example, nearly

half the population in countries of central, southern, and east Africa are undernourished. Environmental factors, including natural factors and those that are a consequence of human activities, can limit agricultural potential. These factors include extremely dry or cold climates, poor soil, erratic rainfall, steep slopes, and severe land degradation. The FAO report further states that undernutrition and malnutrition prevail in regions where environmental, economic, and other factors expose populations to a high risk of impoverishment and food insecurity.

Undernutrition is a fundamental cause of stunted physical and intellectual development in children, low productivity in adults, and susceptibility to infectious disease in everyone. Decreases in food production and increases in food prices associated with climate change would increase the number of undernourished people. Conversely, if food production increases and food prices decrease, the number of undernourished people would fall, but populations in isolated areas with poor access to markets still may be vulnerable to locally important decreases or disruptions in food supply.

9.10. Demographic and Economic Disruption

Health impacts associated with population displacement fall under two general categories: health impacts resulting from the new ecological environment and health impacts resulting from the living environment in refugee camps (Prothero, 1994). Even displacement from longer term cumulative environmental deterioration is associated with such health impacts. Cumulative changes that may cause population displacement include land degradation, salinity, deforestation, waterlogging, desertification, and water scarcity. When pastoralists in west Africa were forced to move because of reduced pasture and water, they were faced with new ecological conditions. They experienced psychological stress and were more at risk of infectious diseases (Stock, 1976; Prothero, 1994). Climate change may affect human security via changes in water supplies and/or agricultural productivity (Lonergan, 1998, 1999). An increase in the magnitude and frequency of extreme events also would be disruptive to political stability.

Immediate environmental catastrophes can force sudden displacement of a population. In these cases, adverse health impacts usually result from living in refugee camps in overcrowded, poor accommodations with inadequate food, water supplies, sanitation, and waste disposal (Shears *et al.*, 1985; Noji, 1997). These conditions predispose people to parasitic and communicable diseases such as malaria and cholera, respiratory infections, intestinal disorders, malnutrition, and psychological stress (Prothero, 1994).

The potential impacts of sea-level rise on the health and well-being of coastal populations are an important consideration (Klein and Nicholls, 1999). Estimates of the potential number of people at risk from sea-level rise are addressed elsewhere in TAR WGI and this volume. For example, a 0.5-m rise in sea level along the Nile delta would flood 32% of urban areas,

resulting in a significant loss of shelter and forced migration (El-Raey *et al.*, 1999; see Chapter 6). In some locations, sea-level rise could disrupt stormwater drainage and sewage disposal and result in salinization of freshwater supplies. It can affect health indirectly by reducing food production—for example, by reducing rice production in low-lying coastal rice paddies. Sea-level rise also could affect the distribution of vector-borne diseases—for example, some of the coastal wetlands of the United States may be flooded, thereby destroying the habitat of the EEE virus. Populations with limited economic, technical, and social resources have increased vulnerability to various infectious, psychological, and other adverse health consequences.

9.11. Adaptation Options

Adaptation measures can be used effectively to greatly reduce many of the potential health impacts of climate change (Gubler, 1998d; McMichael and Kovats, 2000; WHO, 2000). The most important, cost-effective, and urgently needed measure is to rebuild public health infrastructure. In very many countries of the world, this infrastructure has declined in recent years. Many diseases and public health problems that otherwise may be exacerbated by climate change could be prevented substantially or completely with adequate financial and public health resources. These resources would encompass public health training programs, research to develop and implement more effective surveillance and emergency response systems, and sustainable prevention and control programs.

Understanding vulnerability to changes in ranges or rates of diseases is the first step in addressing adaptive capacity. Adaptation involves the ability to change behavior or health infrastructure to reduce these potential negative impacts or increase potential positive impacts of climate change. Interventions early in the causal chain of disease are preferred (e.g., “primary” prevention to remove or reduce risks before any human cases occur). To the extent that this is not always feasible (or the risk factors unknown), “secondary prevention” or surveillance for early warning to prevent any further cases also is important.

Adaptation is a function of several societal systems, including access to financial resources (for individuals and populations), technical knowledge, public health infrastructure, and the capacity of the health care system. Note that there is much similarity in the determinants of adaptive capacity and those of vulnerability (see Section 9.3). Adaptation can occur via two routes: autonomous adaptation, which is the natural or spontaneous response to climate change by affected individuals, and purposeful adaptation, which is composed of planned responses to projected climate change—typically by governmental or other institutional organizations (MacIver and Klein, 1999). Purposeful adaptation also can occur via deliberate modification of personal, family, and community lifestyles, particularly in response to public education programs. Anticipatory adaptations are planned responses that take place in advance of climate change.

Adaptation to the impacts of climate change may occur at the population, community, or personal level (see Table 9-4). The capacity to adapt to potential changes in the climate will depend on many factors, including improving the current level of public health infrastructure; ensuring active surveillance for important diseases; and continuing research to further our understanding of associations between weather, extreme events, and vector-borne diseases. In addition, continuing research into medical advances required for disease prevention, control, and treatment—such as vaccines, methods to deal with drug-resistant strains of infectious agent, and mosquito control—is needed. More generally, research is needed to identify adaptation needs, evaluate adaptation measures, assess their environmental and health implications, and set priorities for adaptation strategies. The following subsections outline adaptive measures that have been developed for two areas of climate change impacts on health.

9.11.1. Extreme Events and Natural Disasters

Major impacts on human health may occur via changes in the magnitude and frequency of extreme events (see Table 3-10 and TAR WGI Chapter 9). Following Hurricanes George and Mitch, a range of policies to reduce the impacts of such extreme events has been identified (PAHO, 1999):

- Undertaking vulnerability studies of existing water supply and sanitation systems and ensuring that new systems are built to reduce vulnerability
- Developing improved training programs and information systems for national programs and international cooperation on emergency management
- Developing and testing early warning systems that should be coordinated by a single national agency and involve vulnerable communities providing and evaluating mental health care, particularly for those who may be particularly vulnerable to the adverse psychosocial effects of disasters (e.g., children, the elderly, and the bereaved).

Adaptation strategies to reduce heat-related mortality in vulnerable cities around the world include weather-based early warning systems (WMO, 1997; Ortiz *et al.*, 1998). A different system must be developed for each city, based on that city’s specific meteorology. Specific weather/health thresholds are determined and used to call health warnings or advisories. Many systems are based on synoptic methodology; specific “offensive” air masses are identified and forecasts are developed to determine if they will intrude into a city within the next 60 hours. Two systems are under construction for Rome, Italy, and Shanghai (WMO, 1997).

Institutional and cultural barriers to the use of seasonal forecast information remain. Decisionmakers should be educated or encouraged to use scientific information that may lead to reduction in losses from natural disasters (Pfaff *et al.*, 1999).

Table 9-4: Options for adaptation to reduce health impacts of climate change.

Health Outcome	Legislative	Technical	Educational-Advisory	Cultural and Behavioral
Thermal stress	– Building guidelines	– Housing, public buildings, urban planning to reduce heat island effects, air conditioning	– Early warning systems	– Clothing, siesta
Extreme weather events	– Planning laws – Building guidelines – Forced migration – Economic incentives for building	– Urban planning – Storm shelters	– Early warning systems	– Use of storm shelters
Air quality	– Emission controls – Traffic restrictions	– Improved public transport, catalytic converters, smokestacks	– Pollution warning	– Carpooling
Vector-borne diseases		– Vector control – Vaccination, impregnated bednets – Sustainable surveillance, prevention and control programs	– Health education	– Water storage practices
Water-borne diseases	– Watershed protection laws – Water quality regulation	– Genetic/molecular screening of pathogens – Improved water treatment (e.g., filters) – Improved sanitation (e.g., latrines)	– Boil water alerts	– Washing hands and other hygiene behavior – Use of pit latrines

9.11.2. Malaria Epidemics

Malaria prevention illustrates approaches to adaptation that also apply to other vector-borne disease threats. To reduce the increased risks of malaria, human populations must take adaptive measures to diminish the impacts. Although malaria epidemics can be triggered by changes in meteorological or socioeconomic conditions, many health services fail to monitor these variables because indicators of risk for epidemic-prone areas have not been determined (Najera *et al.*, 1998). Malaria surveillance and epidemic preparedness may benefit from recently developed tools that predict the seasonality and risks of epidemics by using satellite or ground-based meteorological data (e.g., Hay *et al.*, 1998; Patz *et al.*, 1998b). New approaches to mapping the distribution of malaria vectors over large areas may facilitate species-specific vector control activities. It has been shown in western Kenya that the risk of malaria transmission in the highlands can be predicted with a simple rainfall- and temperature-dependent predictive model (Githko *et al.*, 2000).

Epidemics are focal in nature and often may be controlled by limited application of safe and effective residual insecticides. Parasite resistance to antimalarials is a threat to malaria control

programs; therefore, it is essential that drug sensitivity is reviewed regularly. At the personal level, insecticide-protected fabrics (e.g., bednets) have been shown to be effective against infective mosquito bites (Legeler, 1998).

9.12. Secondary Health Benefits of Mitigation Policies

Actions taken to reduce GHG emissions are very likely to benefit population health (Wang and Smith, 1999; WHO, 1999c; OECD, 2000; see also TAR WGIII Chapter 9). Fossil fuel combustion releases local hazardous air pollutants (especially particulates, ozone, nitrogen oxides, and sulfur dioxide) and GHGs. Hence, policies to reduce GHG emissions via reductions in vehicle exhausts or an increase in the efficiency of indoor household cookstoves would yield great benefits to health (see also TAR WGIII Section 9.2.8.4). Controlling road traffic also would benefit health through reductions in road traffic accidents—a leading cause of death worldwide (Murray and Lopez, 1996).

The benefits to health from mitigation are highly dependent on the technologies and sectors involved. A study by Wang and Smith (1999) indicates that a significant number of premature

Box 9-3. Understanding El Niño Can Help Adaptation to Climate Change: Seasonal Climate Forecasting

There is evidence of an association between El Niño and epidemics of vector-borne diseases such as malaria and dengue in some areas where El Niño affects the climate (Kovats *et al.*, 1999). Malaria transmission in unstable areas is particularly sensitive to changes in climate conditions, such as warming or heavy rainfall (Akhtar and McMichael, 1996; Gupta, 1996; Najera *et al.*, 1998). In Venezuela and Colombia, malaria morbidity and mortality increases in the year following the onset of El Niño (Bouma and Dye, 1997; Bouma *et al.*, 1997b; Poveda *et al.*, 2000). ENSO also has been shown to affect dengue transmission in some Pacific islands (Hales *et al.*, 1999b), though not in Thailand (Hay *et al.*, 2000). However, in many of the studies that have found a relationship between El Niño and disease, the specific climate drivers or mechanisms have not been determined. There also are other climate oscillations that are less well studied. Furthermore, there are other important explanations of cyclic epidemics, such as changes in herd immunity (Hay *et al.*, 2000).

The ENSO phenomenon provides opportunities for early warning of extreme weather, which could improve epidemic preparedness in the future. Seasonal forecasting methods and information have the potential to be used to far greater effect by the health sector (IRI, 1999; Kovats *et al.*, 1999). In addition to these direct applications, attention to the impacts of interannual climate variability associated with the ENSO phenomenon would help countries develop the necessary capacity and preparedness to address longer term impacts associated with global climate change (Hales *et al.*, 2000). On the other hand, there are limitations to using ENSO interannual climate variability to assess potential impacts of long-term climate change.

deaths can be prevented via reductions in particulate emissions in the household sector (i.e., domestic fuel use) in China. The Working Group on Public Health and Fossil Fuel Combustion (1997) estimates that a worldwide reduction in outdoor exposure to particulate matter (PM10), under a Kyoto-level (but global) emissions mitigation scenario, would avert 700,000 premature deaths annually by 2020 compared to a business-as-usual scenario. This figure, however, can be regarded only as indicative, given the broad assumptions and many uncertainties that underlay the estimation. Large numbers of people lack access to clean energy. Renewable energy sources—particularly solar and wind—could help provide this much needed energy while minimizing GHG emissions and maximizing health gain (Haines and Kammen, 2000).

9.13 Research and Information Needs, including Monitoring

Research on the health impacts of global climate change should be conducted within an international network of scientists. Climatic-environmental changes will vary by geographic location, and local populations vary in their vulnerability to such changes. Therefore, the patterns of health gains and losses will be very context-dependent. This type of research requires maximum exchange of information and cross-fertilization of ideas and techniques among scientists, agencies, and institutes. In particular, forecasting the likely health outcomes of exposure to future climate-environmental scenarios requires development of predictive models that can integrate across disparate systems. This will require an interdisciplinary approach. There is an urgent need to focus research efforts more sharply. Particular tasks include:

- Epidemiological studies of ongoing climatic variability and trends in relation to health

- Development of mathematical models to forecast likely health outcomes in relation to projected climatic/environmental changes, accounting for concurrent social and economic circumstances and their projected changes
- Development of monitoring methods and systems to detect early evidence of health-related changes and further inform epidemiological and predictive modeling studies.

Monitoring of the potential impacts of climate change on health is important for several reasons (Campbell-Lendrum *et al.*, 2000; Kovats and Martens, 2000):

- Early detection of the health impacts of climate change
- Improved analysis of relationships between climate and health
- Validation of predictive models
- Increased understanding of vulnerability
- Assessment of effectiveness of adaptation strategies.

Epidemiological data are necessary to inform policymakers about the magnitude of actual or potential impacts of climate change. Most current infection surveillance systems have been designed to detect particular causes, such as food-borne disease, and individual risk factors, such as overseas travel. Monitoring of climate change requires a more comprehensive approach to infection etiology, examining the possible influence of climate on the environmental sources of pathogens and on human behavior (WHO-ECEH, 1998a,b). Another challenge for climate study is the size of data sets required. Although trends in any one country will be a starting point, improved coordination of infection data across regions will be needed. Epidemiological data also would help to determine the requirements for and the effectiveness of preventive actions.

Bioindicators of health risk also need to be developed, to detect early or unanticipated health impacts of climate change and

stratospheric ozone depletion. For example, mapping and monitoring of vector species could be strengthened to detect early changes in their distribution associated with climate change (Campbell-Lendrum *et al.*, 2000). The effect of extreme weather events such as heat waves and floods need to be included in enhanced surveillance for assessment of future impacts.

Populations vary in their vulnerability to health impacts and in the resources available for adaptive responses (McMichael *et al.*, 2000b). These differences in vulnerability, between and within populations, reflect a wide range of demographic, cultural, political, socioeconomic, and technological circumstances. In the future, national impact assessments should describe and identify means by which the vulnerability of populations and subgroups could be reduced and select priorities for monitoring.

9.14. Cross-Cutting Issues

9.14.1 Costing the Health Impacts of Climate Change

Costing the health impacts of climate change is complex and controversial. It is complex because of the great heterogeneity of the health impacts, which include death, infectious disease, nutritional deprivation, and post-traumatic stress disorders. It is controversial because of difficulties in assigning money values to a diverse range of health deficits, doing so across varied cultures and economies, and taking account of the full “stream” of health impacts into the future (with appropriate time-discounting). During the 1990s, an attempt was made to develop a more standardized approach to measurement of the population health deficit by combining chronic illness or disability and premature death, via weighting procedures, into an integrated index—the Disability Adjusted Life Year (Murray, 1994; Murray and Lopez, 1996).

To date, however, there is negligible scientific literature on the population burden of disease attributable to current or future climate change. There is no such literature on the DALY-based impact. Hence, there is no basis for making overall estimates of the direct costs to society of the health impacts of climate change. Nevertheless, some approximate estimations have been published of the impacts on national economies of major infectious disease outbreaks, such as might occur more often under conditions of climate change. For example, the outbreak of plague-like disease in Surat, northwest India, in 1994 cost an estimated US\$3 billion in lost revenues to India alone (John, 1996; WHO, 1997). The cost of the 1994 Dengue Haemorrhagic Fever (DHF) epidemic in Thailand was estimated to be US\$19–51 million (Sornmani, *et al.*, 1995). The cost of the 1994 epidemic of dengue/DHF in Puerto Rico was estimated to be US\$12 million for direct hospitalization costs alone (Rodriguez, 1997; Meltzer *et al.*, 1998).

9.14.2 Development, Sustainability, and Equity

The ideas of development, sustainability, and equity inform much of the content of this chapter. It has been noted repeatedly that health impacts will tend to occur unevenly in the world

and that the impacts in poorer populations, especially in the least-developed countries, often will be augmented by the heightened vulnerability of those populations. That is one of several reasons why—in today’s world in which the gap between rich and poor is widening (UNDP1999), in association with the nonredistributive character of market-dominated global economics (McMichael and Beaglehole, 2000)—new ways of redressing the imbalance in wealth and knowledge should be found.

The chapter also notes that development on a broad front—social, economic, technological, and provision of public health services and capacities—is crucial to a population’s adaptive capacity to lessen the impacts of climate change.

Indeed, the health of a population is a key indicator of “sustainability.” The capacity of the global population to achieve and maintain good health is an index of how well the natural and social environments are being managed. Wealthy local populations can afford to subsidize their health maintenance, drawing on resources imported from elsewhere. At a global level, however, health indicators provide a more valid indication of the extent to which the “carrying capacity” of the biosphere is being maintained.

9.15. Conclusions

The prospect of global climate change affecting patterns of human health poses a central challenge to scientists and policymakers. For scientists, the causation of most of the health outcomes considered in this chapter—from respiratory and cardiovascular disease to various types of infectious diseases—is complex. Various social, technological, demographic, behavioral, and environmental factors influence the risk of occurrence of these diseases. For that reason, it will remain difficult in the near future to identify any early impacts of the current climate trends on health. This complex causation of human disease also means that predictive modeling of future climatic impacts should take realistic account of the coexistent and modulating effects of nonclimate factors.

Over the past 5 years, we have acquired better understanding of direct temperature effects on health (heat and cold), temperature effects on air pollutant production, the seasonality of certain infectious diseases, and the public health consequences (and situational modifiers) of extreme weather events. Predictive modeling of how scenarios of future climate change would affect the patterns and impacts of vector-borne diseases has evolved, as has modeling of impacts on regional agricultural yields and the geography of world hunger.

Policymakers should appreciate that although our scientific capacity to foresee and model these various health outcomes of climate change continues to evolve, it is not possible to make precise and localized projections for many health outcomes—especially those that result indirectly from a sequence of impacts. In the meantime, a precautionary approach requires

that policy development proceed on the basis of the available—though often limited and qualitative—evidence of how climate change will affect patterns of human population health. Furthermore, high priority should be assigned to improving the public health infrastructure and developing and implementing effective adaptation measures.

EXECUTIVE SUMMARY

Africa is highly vulnerable to the various manifestations of climate change. Six situations that are particularly important are:

- Water resources, especially in international shared basins where there is a potential for conflict and a need for regional coordination in water management
- Food security at risk from declines in agricultural production and uncertain climate
- Natural resources productivity at risk and biodiversity that might be irreversibly lost
- Vector- and water-borne diseases, especially in areas with inadequate health infrastructure
- Coastal zones vulnerable to sea-level rise, particularly roads, bridges, buildings, and other infrastructure that is exposed to flooding and other extreme events
- Exacerbation of desertification by changes in rainfall and intensified land use.

The historical climate record for Africa shows warming of approximately 0.7°C over most of the continent during the 20th century, a decrease in rainfall over large portions of the Sahel, and an increase in rainfall in east central Africa. Climate change scenarios for Africa, based on results from several general circulation models using data collated by the Intergovernmental Panel on Climate Change (IPCC) Data Distribution Center (DDC), indicate future warming across Africa ranging from 0.2°C per decade (low scenario) to more than 0.5°C per decade (high scenario). This warming is greatest over the interior of semi-arid margins of the Sahara and central southern Africa.

Projected future changes in mean seasonal rainfall in Africa are less well defined. Under the low-warming scenario, few areas show trends that significantly exceed natural 30-year variability. Under intermediate warming scenarios, most models project that by 2050 north Africa and the interior of southern Africa will experience decreases during the growing season that exceed one standard deviation of natural variability; in parts of equatorial east Africa, rainfall is predicted to increase in December–February and decrease in June–August. With a more rapid global warming scenario, large areas of Africa would experience changes in December–February or June–August rainfall that significantly exceed natural variability.

Water: Africa is the continent with the lowest conversion factor of precipitation to runoff, averaging 15%. Although the equatorial region and coastal areas of eastern and southern Africa are humid, the rest of the continent is dry subhumid to arid. The dominant impact of global warming is predicted to be a reduction in soil moisture in subhumid zones and a reduction

in runoff. Current trends in major river basins indicate a decrease in runoff of about 17% over the past decade. Reservoir storage shows marked sensitivity to variations in runoff and periods of drought. Lake storage and major dams have reached critically low levels, threatening industrial activity. Model results indicate that global warming will increase the frequency of such low storage episodes.

Natural Resources Management and Biodiversity: Land-use changes as a result of population and development pressures will continue to be the major driver of land-cover change in Africa, with climate change becoming an increasingly important contributing factor by mid-century. Resultant changes in ecosystems will affect the distribution and productivity of plant and animal species, water supply, fuelwood, and other services. Losses of biodiversity are likely to be accelerated by climate change, such as in the Afromontane and Cape centers of plant endemism. Projected climate change is expected to lead to altered frequency, intensity, and extent of vegetation fires, with potential feedback effects on climate change.

Human Health: Human health is predicted to be adversely affected by projected climate change. Temperature rises will extend the habitats of vectors of diseases such as malaria. Droughts and flooding, where sanitary infrastructure is inadequate, will result in increased frequency of epidemics and enteric diseases. More frequent outbreaks of Rift Valley fever could result from increased rainfall. Increased temperatures of coastal waters could aggravate cholera epidemics in coastal areas.

Food Security: There is wide consensus that climate change, through increased extremes, will worsen food security in Africa. The continent already experiences a major deficit in food production in many areas, and potential declines in soil moisture will be an added burden. Food-importing countries are at greater risk of adverse climate change, and impacts could have as much to do with changes in world markets as with changes in local and regional resources and national agricultural economy. As a result of water stress, inland fisheries will be rendered more vulnerable because of episodic drought and habitat destruction. Ocean warming also will modify ocean currents, with possible impacts on coastal marine fisheries.

Settlements and Infrastructure: The basic infrastructure for development—transport, housing, services—is inadequate now, yet it represents substantial investment by governments. An increase in damaging floods, dust storms, and other extremes would result in damage to settlements and infrastructure and affect human health.

Most of Africa's largest cities are along coasts. A large percentage of Africa's population is land-locked; thus, coastal facilities are economically significant. Sea-level rise, coastal erosion, saltwater intrusion, and flooding will have significant impacts on African communities and economies.

Desertification: Climate change and desertification remain inextricably linked through feedbacks between land degradation and precipitation. Climate change might exacerbate desertification through alteration of spatial and temporal patterns in temperature, rainfall, solar insolation, and winds. Conversely, desertification aggravates carbon dioxide (CO_2)-induced climate change through the release of CO_2 from cleared and dead vegetation and reduction of the carbon sequestration potential of desertified land. Although the relative importance of climatic and anthropogenic factors in causing desertification remains unresolved, evidence shows that certain arid, semi-arid, and dry subhumid areas have experienced declines in rainfall, resulting in decreases in soil fertility and agricultural, livestock, forest, and rangeland production. Ultimately, these adverse impacts lead to socioeconomic and political instability. Potential increases in the frequency and severity of drought are likely to exacerbate desertification.

Given the range and magnitude of the development constraints and challenges facing most African nations, the overall capacity for Africa to adapt to climate change is low. Although there is uncertainty in what the future holds, Africa must start planning now to adapt to climate change. National environmental action plans and implementation must incorporate long-term changes and pursue “no regret” strategies. Current technologies and approaches—especially in agriculture and water—are unlikely

to be adequate to meet projected demands, and increased climate variability will be an additional stress. Seasonal forecasting—for example, linking sea-surface temperatures to outbreaks of major diseases—is a promising adaptive strategy that will help save lives. It is unlikely that African countries on their own will have sufficient resources to respond effectively.

Climate change also offers some opportunities. The process of adapting to global climate change, including technology transfer, offers new development pathways that could take advantage of Africa's resources and human potential. Examples would include competitive agricultural products, as a result of research in new crop varieties and increased international trade, and industrial developments such as solar energy. Regional cooperation in science, resource management, and development already are increasing.

This assessment of vulnerability to climate change is marked by uncertainty. The diversity of African climates, high rainfall variability, and a very sparse observational network make predictions of future climate change difficult at the subregional and local levels. Underlying exposure and vulnerability to climatic changes are well established. Sensitivity to climatic variations is established but incomplete. However, uncertainty over future conditions means that there is low confidence in projected costs of climate change.

Improvements in national and regional data and capacity to predict impacts is essential. Developing African capacity in environmental assessment will increase the effectiveness of aid. Regional assessments of vulnerability, impacts, and adaptation should be pursued to fill in the many gaps in information.

10.1. Introduction to African Region

10.1.1. Previous Syntheses of African Region

Previous assessments (Hulme, 1996; IPCC, 1998) concluded that the African continent is particularly vulnerable to the impacts of climate change because of factors such as widespread poverty, recurrent droughts, inequitable land distribution, and overdependence on rainfed agriculture. Timely response actions were considered to be beyond the economic means of some countries. Deterioration in terms of trade, inappropriate policies, high population growth rates, and lack of significant investment—coupled with a highly variable climate—have made it difficult for several countries to develop patterns of livelihood that would reduce pressure on the natural resource base. The reports fell short of assigning relative importance to these different factors in Africa's capacity to adapt to climate change. This still is not possible and presents a new challenge for future assessments.

10.1.2. What is Different about Africa?

The main background factors that need to be kept in mind in assessing the vulnerability of the African region to climate change—particularly the capacity of African governments to respond proactively to changes that are largely not of their making or under their control—are as follows:

- *Diversity:* The term “African region” is a geographical convenience only. There is as much diversity of climate, landform, biota, culture, and economic circumstance within the region as there is between it and, say, South America or Asia. Very few statements are valid for the entire continent. The generalities that follow must be read in that context.
- *Climate:* Africa is predominantly tropical, hot, and dry. There are small regions of temperate (cool) climates in the extreme south and north and at high altitudes in between. Parts of west Africa, as well as the western part of central Africa, are humid throughout the year. A large region north and south of this humid core is subhumid, with substantial rainfall during the wet season (or seasons, in the case of east Africa) but almost no rain during the extended dry season. Poleward from this zone is a large area of semi-arid climates, which permit marginal cropping during the wet season but are characterized by extreme unreliability of rainfall and few permanent surface-water sources. Most of the human population occurs in the subhumid and semi-arid zones. Corresponding to the tropics of Capricorn and Cancer are the vast desert regions of the Kalahari-Namib and the Sahara.
- *Development Status:* Measured by almost any index of human well-being, Africa contains the poorest and least-developed nations of the world. Per capita gross domestic product (GDP), life expectancy, infant mortality, and adult literacy are all in the bottom quartile globally when averaged across Africa, although individual nations may perform somewhat better on one or more of these indices. The general weakness of the science and technology infrastructure—in particular, the relatively small numbers of technically trained professionals—limits the rate at which adaptive research can be performed or implemented.
- *Food Supply:* More than half of the African population is rural and directly dependent on locally grown crops or foods harvested from the immediate environment. Per capita food production in Africa has been declining over the past 2 decades, contrary to the global trend. The result is widespread malnutrition, a recurrent need for emergency food aid, and increasing dependence on food grown outside the region.
- *Dependence on Natural Resources:* The formal and informal economies of most African countries are strongly based on natural resources: Agriculture, pastoralism, logging, ecotourism, and mining are dominant. Climatic variations that alter the viability of these activities, for better or for worse, have very high leverage on the economy.
- *Biodiversity:* About one-fifth of the world's plants, birds, and mammals originate or have major areas of present conservation in Africa. There are major “hot spots” of biodiversity within west, east, central, and southern Africa.
- *Low Capacity for State-Initiated Interventions:* Governance structures typically are underfunded and undercapacity. In many instances they have been undermined by military coups, despotism, tribalism, corruption, maladministration, and economic adjustment programs imposed by the international financial community. Communication from capitals to the remotest provinces—by road, rail, air, or telephone—often is unreliable and slow. State-centered political economies in their postcolonial sense are relatively recent over most of Africa, and their boundaries include wide ethnic diversity within single nations and cut across previous political territories.
- *Disease Burden:* Insect-vector diseases such as malaria and trypanosomiasis; water-borne diseases such as typhoid, cholera, and schistosomiasis; and poverty-related diseases such as tuberculosis are prevalent in Africa. Water and food security are closely linked with health. The HIV/AIDS pandemic is placing great strain on the health infrastructure. Heavy mortalities lead to great loss of productive potential.
- *Armed Conflict:* There has been chronic armed conflict in several regions of Africa almost continuously for the past 3 decades. This weakens the ability of the nations involved to respond to climate change and adds large refugee populations to the local population, which must be supported by the environment.
- *High External Trade and Aid Dependence:* Very little industrial beneficiation takes place in Africa. High volumes of relatively low-value goods dominate export economies. In general, there is no strong internal demand

(national or regional) to buffer the economies from changes in global trade. Trade linkages show the pattern established by the former colonial relationships. Many African countries have a negative trade balance, particularly as a result of heavy international debt-servicing burdens, and are chronically dependent on financial aid from the developed world.

10.1.3. Past to Present

10.1.3.1. Climatology

Africa is a vast continent, and it experiences a wide variety of climate regimes. The location, size, and shape of the African continent play key roles in determining climate. The poleward extremes of the continent experience winter rainfall associated with the passage of mid-latitude airmasses. Across the Kalahari and Sahara deserts, precipitation is inhibited by subsidence virtually throughout the year. In contrast, moderate to heavy precipitation associated with the Inter-Tropical Convergence Zone (ITCZ) characterizes equatorial and tropical areas. Because the movement of the ITCZ follows the position of maximum surface heating associated with meridional displacement of the overhead position of the sun, near-equatorial regions experience two rain seasons, whereas regions further poleward experience one distinct rainfall season. The mean climate of Africa is further modified by the presence of large contrasts in topography (Semazzi and Sun, 1995) and the existence of large lakes in some parts of the continent.

10.1.3.2. Interannual and Interdecadal Climate Variability

Humans have adapted to patterns of climate variability through land-use systems that minimize risk, with agricultural calendars that are closely tuned to typical conditions and choices of crops and animal husbandry that best reflect prevailing conditions. Rapid changes in this variability may severely disrupt production systems and livelihoods. Interannual variability of the African climate is determined by several factors. The El Niño-Southern Oscillation (ENSO) is the most dominant perturbation responsible for interannual climate variability over eastern and southern Africa (Nicholson and Entekhabi, 1986). The typical rainfall anomaly associated with ENSO is a dipole rainfall pattern: Eastern Africa is in phase with warm ENSO episodes, whereas southern Africa is negatively correlated with these events (Nicholson and Kim, 1997). The 1997–1998 ENSO event resulted in extreme wet conditions over eastern Africa (see Boxes 10-1 and 10-2), and the 1999–2000 La Niña may have caused devastating floods in Mozambique. Modeling exercises indicate that climate change may increase the frequency of ENSO warm phases by increasing the warm pool in the tropical western Pacific or by reducing the efficiency of heat loss (Trenberth and Hoar, 1997; Timmerman *et al.*, 1999).

In the Sahel and similar regions of west Africa, the problem is more complex. ENSO appears to influence year-to-year variations

Box 10-1. The 1997–1998 ENSO Event

ENSO appears to play a major role in east Africa, but it masks the perhaps more important role of the other oceans, particularly the Indian Ocean. The 1961–1962 rains were spectacularly manifested as rapid rises in the levels of east African lakes. Lake Victoria rose 2 m in little more than a year (Flohn and Nicholson, 1980). This was not an ENSO year, but exceedingly high sea-surface temperatures (SSTs) occurred in the nearby Indian Ocean as well as the Atlantic. Such high SSTs are associated with most ENSO events, and it is probably SSTs in these regions, rather than the Pacific ENSO (Nicholson and Kim, 1997), that have the largest influence on east African rainfall. In another example, the dipole pattern anticipated to occur during ENSO events did not occur during the 1997–1998 event. There was a tremendous increase in rainfall in east Africa, but intense drought conditions did not occur throughout southern Africa. The reason appears to be an unusual pattern of SST in the Indian Ocean.

and reduces rainfall. Its influence appears to be greater within long dry intervals in the Sahel, but it is not the dominant factor controlling rainfall in this region (Ward, 1998).

Over northern Africa, the North Atlantic Oscillation (NAO) is a key factor that is responsible for interannual variability of the climate (Lamb, 1978). Across western Africa, year-to-year changes in seasonal climatic conditions are determined primarily by the Atlantic Ocean, although the rest of the world's oceans also play important roles. Low-lying islands and coastal regions receive significant amounts of rainfall from tropical cyclone activity, which is sensitive to interannual variability of SST conditions over adjacent ocean basins.

Box 10-2. Drought Conditions in the Sahel

One of the most significant climatic variations has been the persistent decline in rainfall in the Sahel since the late 1960s. The trend was abruptly interrupted by a return of adequate rainfall conditions in 1994. This was considered to be the wettest year of the past 30 and was thought to perhaps indicate the end of the drought. However, by the standard of the whole century, rainfall in 1994 barely exceeded the long-term mean. Also, the 1994 rainy season was unusual in that the anomalously wet conditions occurred toward the end of the rainy season and in the months following. Unfortunately, dry conditions returned after 1994. The persistent drying trend has caused concern among development planners regarding how to cope with losses of food production, episodes of food insecurity, displacements of populations, lack of water resources, and constraints on hydroelectricity.

The climate of Africa also exhibits high interdecadal variability. Rainfall variability in the Sahel derives from factors such as SST and atmospheric dynamics (Lamb, 1978; Folland *et al.*, 1986; Hulme and Kelly, 1997; Nicholson and Kim, 1997) and is modulated by land surface effects related to soil moisture, vegetation cover, dust, and so forth (Charney, 1975; Diedhiou and Mahfouf, 1996; Xue, 1997; Zeng *et al.*, 1999). Modeling evidence also suggests that orographic control plays a significant role in promoting climate teleconnections between global SST anomalies and west African interannual climate variability (Semazzi and Sun, 1997).

Besides ENSO, the NAO, and west African climate anomaly patterns, other continental-scale and subcontinental climate anomalies play significant roles in determining interannual and longer climate variability time scales (Nicholson *et al.*, 2000). For instance, the decade 1950–1959 was characterized by above-normal precipitation over most of Africa, although rainfall deficiencies prevailed over the near-equatorial region. Later, during the period 1960–1969, this rainfall anomaly pattern dramatically reversed in sign, with rainfall deficits observed for most of Africa while the equatorial region experienced widespread abundance of rainfall. These two time periods also coincide with a reversal in the sign of the Sahelian rainfall anomalies (Lamb and Peppler, 1992). More recently, the pattern has been one of increased aridity throughout most of the continent. Mean rainfall decreased by 20–49% in the Sahel between the periods 1931–1960 and 1968–1997 and generally 5–10% across the rest of the continent (see Figure 10-1).

In comparison with the period between 1950 and 1970, the average length of the rainy season has not changed significantly during the dry period 1970–1990. Instead, the decrease in rainfall in July and August explains most of the diminution of total annual rainfall over the Sahel since 1970. The average number of rainy events in August was reduced by about 30% (Le Barbé and Lebel, 1997).

There is emerging evidence that aerosols and dust also may be important factors in modulating the variability of the African climate (d'Almeida, 1986; Mohamed *et al.*, 1992; Pinker *et al.*, 1994). These studies provide overwhelming evidence of an extremely dense and deep (reaching up several kilometers) dust layer in the Sahel/Sudan during the main dust season from November to April.

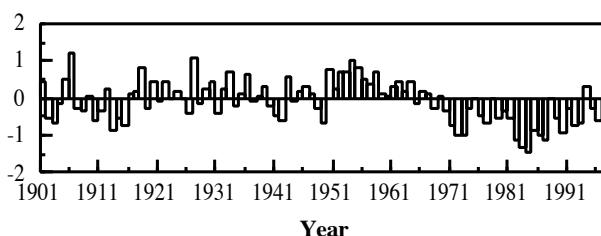

Figure 10-1: Rainfall fluctuations, 1901–1998, expressed as regionally averaged standard deviation (departure from long-term mean divided by standard deviation) for the Sahel.

10.1.3.3. Paleoclimate of Africa

Paleoclimatology and paleoenvironmental changes in Africa have been reconstructed from several lines of sedimentary evidence, such as fossil strand lines, diatom and pollen analyses, evidence of glaciation and fossil moraines on high mountains, sediment lithology, geochemistry and biogeochemistry, and so forth. Most records do not extend beyond 30,000 years before the present (BP), but they capture the climatic extremes of the last glacial-interglacial cycle—the last glacial maximum (22,000 to 14,000 years BP) through to the Holocene period (10,000 years BP to present) (Olago, 2001).

Temperatures during the last glacial maximum are estimated to have been 4–7°C lower than today, and they were coupled with intensive aridity and regression of lakes throughout the African continent, resulting from reduced precipitation as a consequence of weaker monsoons, stronger dry trade winds, and lowered SST (Coetzee, 1967; Flenley, 1979; COHMAP Members, 1988; Bonnefille *et al.*, 1990; Vincens *et al.*, 1993). Highland vegetation was depressed to significantly lower altitudes relative to today, and mountain glaciers were at their maximum extent. Grasslands were more widespread, lowland forests became fragmented, and subtropical desert margins advanced latitudinally by 300–700 km relative to their present positions (Flohn and Nicholson, 1980).

During the Holocene period of the past 10,000 years there was a “warm” climatic optimum roughly 5,000 years ago. At that time, more humid conditions generally were widespread, and deserts were markedly contracted. Lakes existed even in parts of the central Sahara. The current state of climate was reached roughly 3,000 years ago.

10.1.3.4. Recent Historical Record

Observational records show that the continent of Africa is warmer than it was 100 years ago (IPCC, 1996). Warming through the 20th century has been at the rate of about 0.05°C per decade (see Figure 10-2), with slightly larger warming in the June, July, August (JJA) and September–November seasons than in December, January, February (DJF) and March–May (Hulme *et al.*, 2001). The 5 warmest years in Africa have all occurred since 1988, with 1988 and 1995 the two warmest years. This rate of warming is not dissimilar to that experienced globally, and the periods of most rapid warming—the 1910s to 1930s and the post-1970s—occur simultaneously in Africa and the world.

The climate of Africa has experienced wetter and drier intervals during the past 2 centuries. The most pronounced periods were during the 20th century. A very intense dry period, much like the current one, also prevailed for 2 to 3 decades during the first half of the 19th century. Humid conditions reminiscent of the 1950s prevailed around the 1870s or 1880s, but another milder arid interval of roughly 20 years commenced around 1895.

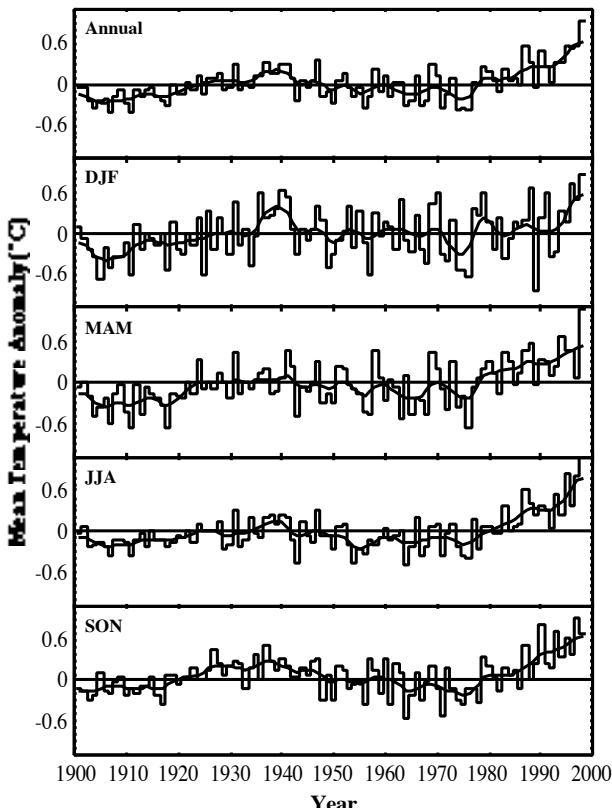

Figure 10-2: Mean surface air temperature anomalies for the African continent, 1901–1998, expressed with respect to 1961–1990 average, annual and four seasons (DJF, MAM, JJA, SON). Smooth curves result from applying a 10-year Gaussian filter.

10.1.4. Climate Change Scenarios

Carter *et al.* (2000) performed a comprehensive characterization of regional climate change projections for the 21st century. They assumed a range of atmospheric greenhouse gas (GHG) loadings according to the four draft marker scenarios developed for the IPCC *Special Report on Emissions Scenarios* (SRES), in combination with the IPCC range of climate sensitivities (1.5–4.5°C—IPCC, 1996). Their method of analysis involved combining simple climate model estimates of the global mean annual temperature response to four combinations of GHG forcing/climate sensitivity (see Table 3-9) with regional patterns of seasonal temperature and precipitation change obtained from 10 general circulation model (GCM) simulations for the end of the 21st century relative to 1961–1990. The GCM patterns of change were scaled up or down so that the global mean temperature change from the GCM coincided with that obtained from the simple climate model. Ten patterns of change were obtained for each emissions/climate sensitivity combination, and each was averaged over subcontinental regions, including five representing the African continent: southern Europe/north Africa, the Sahara, west Africa, east Africa, and southern Africa (Carter *et al.*, 2000; see Chapter 3). Ranges of projected

rates of change in temperature and precipitation over these regions are depicted for each season, and projected changes over southern Africa by the 2050s are compared with modeled natural multi-tridecadal variability from the HadCM2 GCM 1,400-year control simulation (Tett *et al.*, 1997) for the summer (DJF) and winter (JJA) months.

An analysis using the similar methodology also has been conducted specifically for Africa (Hulme *et al.*, 2001). Future annual warming across Africa ranges from 0.2°C per decade (B1—low scenario) to more than 0.5°C per decade (A2—high scenario). This warming is greatest over the interior of semi-arid margins of the Sahara and central southern Africa. The intermodel range (an indicator of the extent of agreement between different GCMs) is smallest over north Africa and the equator and greatest over the interior of southern Africa.

Future changes in mean seasonal rainfall in Africa are less well defined. Under the lowest warming scenario, few areas experience changes in DJF or JJA that exceed two standard deviations of natural variability by 2050. The exceptions are parts of equatorial east Africa, where rainfall increases by 5–20% in DJF and decreases by 5–10% in JJA.

Under the two intermediate warming scenarios, significant decreases (10–20%) in rainfall during March to November, which includes the critical grain-filling period, are apparent in north Africa in almost all models by 2050, as are 5–15% decreases in growing-season (November to May) rainfall in southern Africa in most models.

Under the most rapid global warming scenario, increasing areas of Africa experience changes in summer or winter rainfall that exceed the one sigma level of natural variability. Large areas of equatorial Africa experience increases in DJF rainfall of 50–100% over parts of eastern Africa, with decreases in JJA over parts of the Horn of Africa. However, there are some JJA rainfall increases for the Sahel region.

Hulme *et al.* (2001) also analyzed future rainfall changes for three African regions—the Sahel, east Africa, and southeast Africa—to illustrate the extent of intermodel differences for these regions and to put future modeled changes in the context of past observed changes (see Figure 10-3). Although model results vary, there is a general consensus for wetting in East Africa, drying in southeast Africa, and a poorly specified outcome for the Sahel.

10.2. Key Regional Concerns

10.2.1. Water Resources

10.2.1.1 Overview of Regional Water Resources

Water resources are inextricably linked with climate, so the prospect of global climate change has serious implications for water resources and regional development (Riebsame *et al.*,

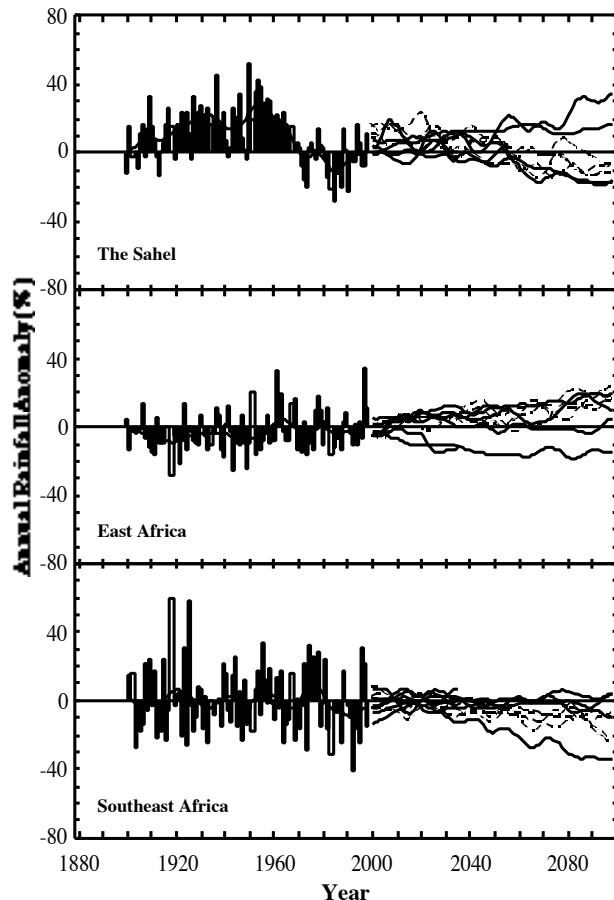

Figure 10-3: Observed annual rainfall anomalies for three African regions, 1900–1998, and model-simulated anomalies for 2000–2099. Model anomalies are for 10 model simulations derived from seven DDC GCM experiments; the four HadCM2 simulations are the dashed curves. All anomalies are expressed with respect to observed or model-simulated 1961–1990 average rainfall. Model curves are extracted directly from GCM experiments, and results are not scaled to SRES scenarios used in Chapter 3. Smooth curves result from applying a 20-year Gaussian filter (Hulme *et al.*, 2001).

1995). Efforts to provide adequate water resources for Africa will confront several challenges, including population pressure; problems associated with land use, such as erosion/siltation; and possible ecological consequences of land-use change on the hydrological cycle. Climate change—especially changes in climate variability through droughts and flooding—will make addressing these problems more complex. The greatest impact will continue to be felt by the poor, who have the most limited access to water resources.

Figure 10-4 shows that the hydrological performance of Africa results in much less runoff yield than in other regions. Apart from the Zambezi/Congo Rivers, the major African rivers (Nile, Niger, Senegal, Senqu/Orange, Rufiji) traverse semi-arid to arid lands on their way to the coast. Of the world's major

rivers, the Nile has the lowest specific discharge (i.e., flow per unit catchment area), even if only the part of the catchment that receives precipitation is considered (Rebsame *et al.*, 1995). Furthermore, because these major rivers originate within the tropics, where temperatures are high, evaporative losses also are high in comparison to rivers in temperate regions. Elevated temperatures will enhance evaporative losses; unless they are compensated by increased precipitation, runoff is likely to be further reduced.

In Morocco, the northward displacement of the Azores high-pressure cell is a subject of study because of its association with a drought cycle that is related to the dipole between the positioning of the Azores high-pressure cell and the Iceland low-pressure cell. These severe droughts seem to manifest themselves in Morocco in periodicities varying between 2 and 13 years (Stockton and Allali, 1992).

The Magreb region is characterized by erratic and variable rainfall, with a high rate of evapotranspiration (almost 80%). In addition, the Magreb region will have water scarcity by 2025, especially in Tunisia and Libya.

Associated with the poor hydrological performance of African river basins is the fact that most of the lakes in Africa have a delicate balance between precipitation and runoff; all of the

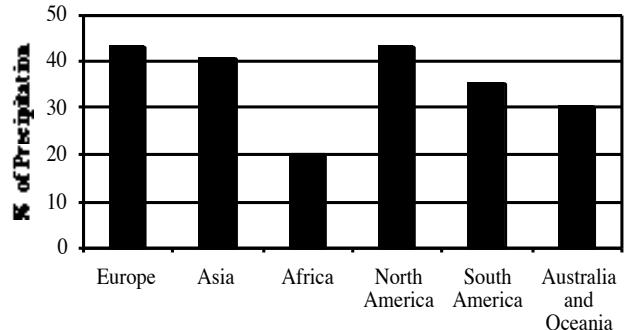

Figure 10-4: Comparative hydrology in world regions—total runoff as percentage of precipitation (GEMS, 1995).

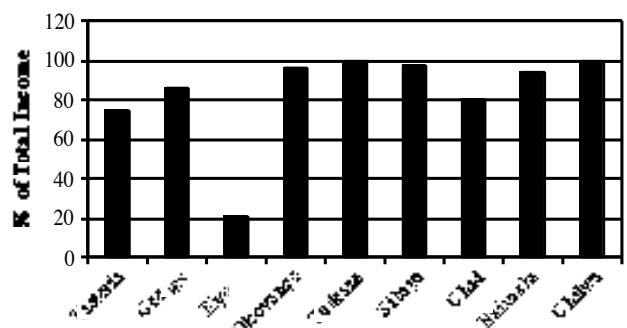

Figure 10-5: Evaporative losses as percentage of total hydrological income in selected African lakes (constructed from Talling and Lemoalle, 1998).

Table 10-1: Estimates of ranges of percentage changes in precipitation, potential evaporation, and runoff in African river basins, constructed from Figure 3 of Arnell (1999). In some basins, estimates given by HadCM3 simulation have been excluded where they appear to be outliers.

Basin	Change in Precipitation (%)	Change in Potential Evaporation (%)	Change in Runoff (%)
Nile	10	10	0
Niger	10	10	10
Volta	0	4 to -5	0 to -15
Schebeli	-5 to 18	10 to 15	-10 to 40
Zaire	10	10 to 18	10 to 15
Ogooue	-2 to 20	10	-20 to 25
Rufiji	-10 to 10	20	-10 to 10
Zambezi	-10 to -20	10 to 25	-26 to -40
Ruvuma	-10 to 5	25	-30 to -40
Limpopo	-5 to -15	5 to 20	-25 to -35
Orange	-5 to 5	4 to 10	-10 to 10

large lakes show less than 10% runoff-to-precipitation ratio (Talling and Lemoal, 1998), and important water basins like Lake Chad and the Okavango Delta have no outflow because evaporation and permiation balance runoff (see Figure 10-5).

In the savanna regions, the incidence of seasonal flow cessation may be on the increase, as shown by some streams in Zimbabwe (Magadza, 2000). Drought periods now translate into critical water shortages for industrial and urban domestic supplies (Magadza, 1996).

10.2.1.2. Major River Basin Systems

The heterogeneity of ground records in Africa imposes serious limitations in constructing future scenarios of water resources. Where consistent long-term climatic data are available, they indicate a trend toward reduced precipitation in current semi-arid to arid parts of Africa. Figure 10.3 of the Hulme *et al.* (2001) publication shows possible scenarios for different climatic regions of Africa. Although there is ambiguity in the Sahel, the simulations appear to indicate possible increases in precipitation in east Africa, whereas most simulations in southern Africa indicate reduced precipitation in the next 100 years.

Table 10-1 shows estimates of ranges of percentage changes in precipitation, potential evaporation, and runoff in African river basins as reconstructed from Arnell (1999, Figure 3). In some basins, estimates given by the HadCM3 simulation have been excluded where they appear to be outliers. A change in the hydrographs of large basins (Niger, Lake Chad, and Senegal) has been observed. Between the mean annual discharge of the humid and drought periods, the percentage of reduction varies from 40 to 60% (Olivry, 1993). Figure 10-6 shows the change in the hydrograph of the Niger River at the Niamey station. This illustrates a clear modification of the Niger River regime at Niamey. Similar situations are observed at the N'djamena station on the Chari at the entrance to Lake Chad. In the Nile basin, Sircoulon (1999) cites a reduction in runoff of 20%

between 1972 and 1987, corresponding to a general decrease in precipitation in the tributary basins calculated by Conway and

Box 10-3. Impact of Drought in the Akosombo Dam (Graham, 1995)

Multiple droughts in recent decades have forced Ghana to reduce the generation of hydroelectricity, provoking a national debate about power supply.

The Akosombo and Kpong generating stations—commissioned in 1965 and 1982, respectively—provide the overwhelming bulk of Ghana's electricity. The two stations account for 1,072 MW of a total national power-generating capacity of 1,160 MW; Akosombo alone provides 833 MW.

Until recently, most of the minority of Ghanaians who use electricity tended to regard the Volta hydroelectric dams as sources of uninterruptible power. The unprecedented drought of 1982–1983, which compelled rationing of electricity until 1986, shattered that illusion. And if that drought's power cuts jolted the nation's complacency about hydroelectricity, the 1994 incident concentrated minds forcefully on the impermanence of power from Akosombo and Kpong and the need for alternative sources.

According to the Volta River Authority (VRA), the statutory power generating body, “cumulative inflow” into Volta Lake by the middle of August 1994 was “the worst...in the 50-year record of Volta river flows—worse than the same period in 1983.” At its lowest, in early August, the level of Volta Lake was 73 m. This was well below the 75.6 m the VRA claims is the minimum level for generating power without risk of damaging the turbines.

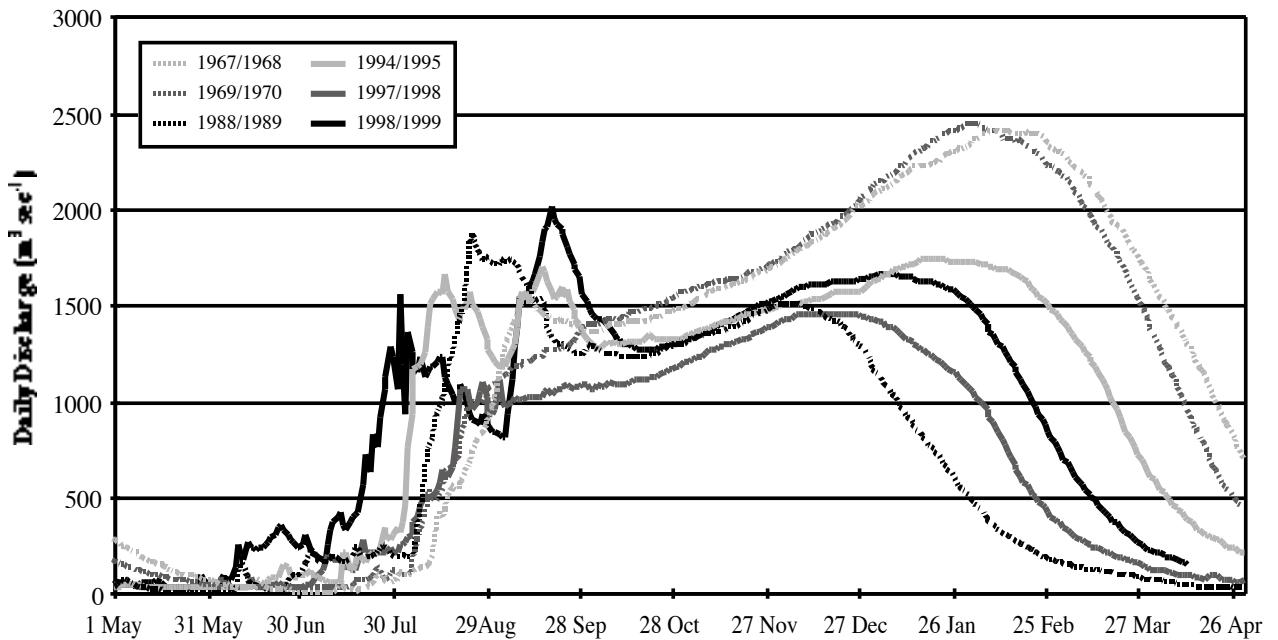

Figure 10-6: Decadal changes in hydrograph of the Niger River at Niamey Station between 1961 and 1999.

Hulme (1993). In recent years there have been significant interruptions in hydropower generation as a result of severe droughts (see Box 10-3).

Instrumental data and climate model simulations cited above indicate imminent water crisis in large parts of Africa. Several seminal works have appeared in the literature that analyze water for Africa, including Falkenmark (1989) and Gleick (1992, 1998).

Large basin-scale analyses often give the wrong impression that many areas of Africa are rich in water reserves, in which case local water problems could be solved easily by technology that would transfer water from the source to areas under stress, assuming that financial resources are available for such enterprises. Although in theory this may be a practical solution to many water problems in most of Africa, the very high costs associated with such projects make them impractical. Political goals such as self-sufficiency in food production and general socioeconomic development cannot be achieved under severe water scarcity (Falkenmark, 1989). Drought-prone zones of Africa already are water-limited, further increasing their vulnerability to water problems.

About 63% of the total land in Africa lies within transboundary river basins. Five major river basins—the Congo, Nile, Niger, Chad, and Zambezi—occupy about 42% of the geographical area and sustain more than 44% of the African population. Other shared basins in the continent are the Senegal, Gambia, Limpopo, Orange/Senqu, and Cunene Basins.

In west Africa, the dependency ratio—defined as the ratio between renewable water produced out of a country and the

total renewable water of the same country—is more than 40% for seven of the nine countries comprising the Permanent Interstate Committee for Drought Control in the Sahel (CILSS). This ratio is nearly 90% for the Niger and the Mauritania. Similar transboundary dependencies are evident in southern Africa and on the Nile basin. The Congo basin is shared by the most countries (13), followed by the Niger and Nile basins (11 countries each) and the Zambezi and Chad basins (9 and 8 countries, respectively).

The impact of changes in precipitation and enhanced evaporation could have profound effects in some lakes and reservoirs. Conway and Hulme (1993) and Calder *et al.* (1995) have discussed the hydrology and paleohydrology of various African Lakes. Magadza (1996) has examined the impact of drought on reservoirs in Zimbabwe. Reports from Ghana (Graham, 1995) indicate severe drought impacts on this large reservoir. Studies show that, in the paleoclimate of Africa and in the present climate, lakes and reservoirs respond to climate variability via pronounced changes in storage, leading to complete drying up in many cases. Furthermore, these studies also show that under the present climate regime several large lakes and wetlands show a delicate balance between inflow and outflow, such that evaporative increases of 40%, for example, could result in much reduced outflow. In the case of Lake Malawi, it has been reported that the lake had no outflow for more than a decade in the earlier part of this century (Calder *et al.*, 1995).

Predictions of response by the Nile to global warming are confounded by the fact that different simulations give conflicting results (Smith *et al.*, 1995), varying from 77% flow reduction in the Geophysical Fluid Dynamics Laboratory (GFDL) simulation to a 30% increase in the Goddard Institute for Space Studies

(GISS) model. Arnell's (1999) model results suggest increased precipitation in the Nile basin, but such gains are offset by evapotranspiration. Gleick (1992) projects that future climatic changes in the Nile basin would be significant and possibly severe. The response of the Nile basin to precipitation change is not linear, though it is symmetric for increased and decreased precipitation. Hulme (1992) shows a decline in total precipitation and overall warming of about 0.5°C over the last half of the 20th century. Conway and Hulme (1993) conclude that the effects of future climate change on Nile discharge would further increase uncertainties in Nile water planning and management, especially in Egypt. Nile precipitation responds more to changes in equatorial circulation, with little influence by the north African monsoon (Sestini, 1993).

Arnell (1999) shows that the greatest reduction in runoff by the year 2050 will be in the southern Africa region, also indicating that as the water use-to-resource ratio changes countries such as Zimbabwe and the Magreb region will shift into the high water-stress category. The Zambezi River has the worst scenario of decreased precipitation (about 15%), increased potential evaporative losses (about 15–25%), and diminished runoff (about 30–40%).

Lake Chad varies in extent between the rainy and dry seasons, from 50,000 to 20,000 km². Precise boundaries have been established between Chad, Nigeria, Cameroon, and Niger. Sectors of the boundaries that are located in the rivers that drain into Lake Chad have never been determined, and several complications are caused by flooding and the appearance or submergence of islands. A similar process on the Kovango River between Botswana and Namibia led to a military confrontation between the two states.

Vorosmarty and Moore (1991) have documented the potential impacts of impoundment, land-use change, and climatic change on the Zambezi and found that they can be substantial. Cambula (1999) has shown a decrease in surface and subsurface runoff of five streams in Mozambique, including the Zambezi, under various climate change scenarios. For the Zambezi basin, simulated runoff under climate change is projected to decrease by about 40% or more.

Growing water scarcity, increasing population, degradation of shared freshwater ecosystems, and competing demands for shrinking natural resources distributed over such a huge area involving so many countries have the potential for creating bilateral and multilateral conflicts (Gleick, 1992). Feddema (1998, 1999) has evaluated the impacts of soil degradation and global warming on water resources for Africa. All major watersheds are affected by global warming; although the trend is toward drying in most locations, there are significant differences in watershed-level responses, depending on timing and distribution of rainfall, as well as soil water-holding capacity. Soil water-holding capacity is modified by the degree of soil degradation.

10.2.1.3. Demography and Water Resources

Availability of water in sub-Saharan Africa (SSA) is highly variable. Only the humid tropical zones in central and west Africa have abundant water. Water availability varies considerably within countries as well, influenced by physical characteristics and seasonal patterns of rainfall. According to Sharma *et al.* (1996), eight countries were suffering from water stress or scarcity in 1990; this situation is getting worse as a consequence of rapid

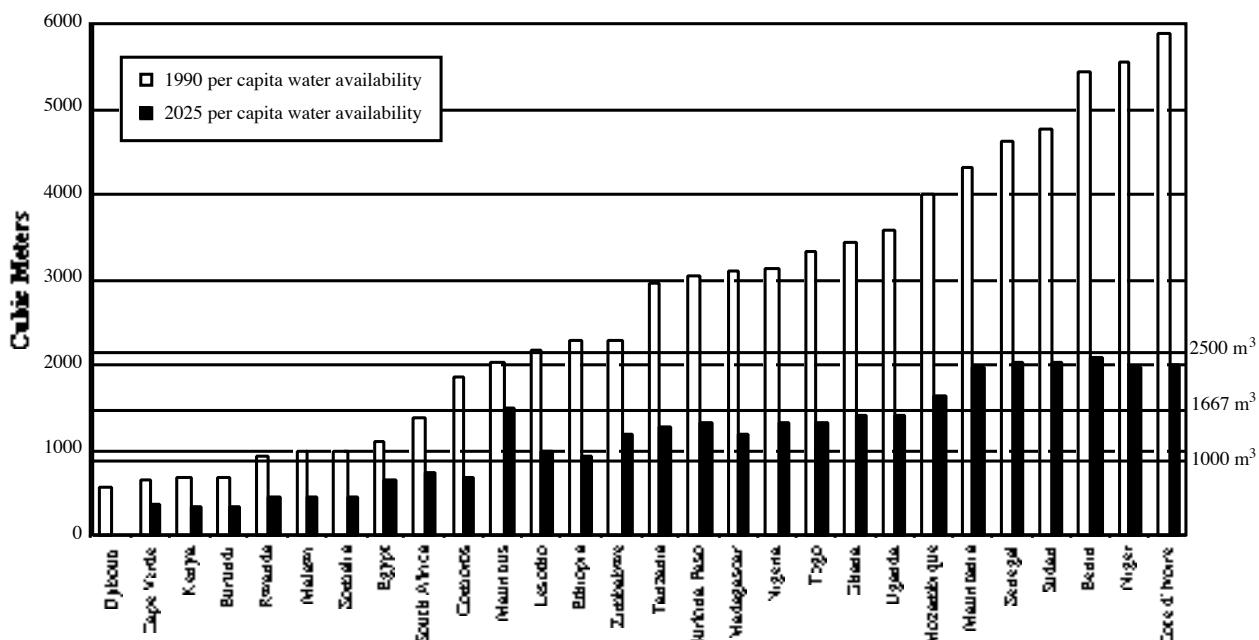

Figure 10-7: Water scarcity and people in Africa (Sharma *et al.*, 1996).

population growth, expanding urbanization, and increased economic development. By 2000, about 300 million Africans risk living in a water-scarce environment. Moreover, by 2025, the number of countries experiencing water stress will rise to 18—affecting 600 million people (World Bank, 1995). Figure 10-7 shows how countries will shift from water surplus to water scarcity as a result of population changes alone between 1990 and 2025, using a per capita water-scarcity limit of $1,000 \text{ m}^3 \text{ yr}^{-1}$. Scarcity statistics also can be associated with challenges to international water resources: Many such basins face water stress or scarcity (Sharma *et al.*, 1996). Long-term precipitation records from the Sahara give a clear indication of declining precipitation in that region (UNEP, 1997). These declines in precipitation register as reduced hydrological discharges in major river basins in the subhumid zones.

Given the climate scenarios discussed in this report, it is apparent that several countries will face water availability restrictions by the middle of the 21st century, if current consumption trends persist. Pottinger (1997) discusses some concerns about future water availability in South Africa. These examples show that the combination of demographic trends and climate change is likely to cause economically significant constraints in some parts of Africa.

10.2.1.4. Impacts and Vulnerability

Sensitivity analyses of major rivers of the continent indicate that these rivers are sensitive to climate change. Magadza (1996) examined changes in water storage in Zimbabwe's main water storage facilities during the 1991–1992 drought cycle. During this period, the mean temperature averaged 2°C above the long-term seasonal mean, and seasonal Penman evaporation exceeded the long-term seasonal mean by more than 30%—peaking at just less than 90% in February at the Kutsaga station. During this drought cycle, stored water resources dwindled to less than 10% of installed capacity.

Urbiztondo (1992) simulated the response of Lake Kariba power-generating capacity to various climate change scenarios. His results indicate that with no significant change in precipitation, the lake would regularly fail to meet installed generating capacity if the temperature rose by 4°C . During dry years, generating capacity would decrease by as much as 50%. Even during wet years, maximum generating capacity would barely exceed 50% of installed capacity.

Economic impacts from curtailment of hydropower generation from Lale Kariba, as a result of the 1991–1992 drought, were estimated to be US\$102 million loss in GDP, US\$36 million loss in export earnings, and loss of 3,000 jobs (Benson and Clay, 1998). The direct impacts on agriculture and the knock-on impacts also were quite severe. These limited estimates provide a window on potential economic impacts of climate change-mediated water resources changes in the medium term (i.e., into the middle of the 21st century—a time span within the planning window of economic development strategies).

With an estimated error of about 8%, the Gambia River flow has been shown to be very sensitive to climate change. Based on the results of river flow responses and vulnerability analysis, climate variables alone can cause a 50% change in runoff in the Gambia River catchment (Jallow *et al.*, 1999). In general, a 1% change in rainfall will result in a 3% change in runoff (Manneh, 1997). On the whole, this translates into saltwater intrusion into the Gambia River by 40 km at times of maximum intrusion. However, the flushing action of freshwater flow of the river will keep the saline/freshwater interface at an equilibrium, oscillating between 90 and 290 km. The rate of saline water intrusion during dry seasons would increase from about 20 km per month in January to about 40 km per month in April and May.

10.2.1.5. Adaptation

Likely changes in precipitation and discharge regimes call for a wide range of adaptations. Broadly, these adaptations would include:

- Refinement of early warning systems to enable timely remedial measures
- Shared basin management, necessitating international agreements
- Water-use strategies—especially demand management—in industry, settlements, and agriculture
- Intensified monitoring to improve data reliability
- Intensive research into energy usage and alternate renewable energy at household and industrial levels
- Intensive research into design of infrastructure facilities, such as roads and telecommunications, to withstand extreme events
- Intensive research into flood control management technology
- Innovation in building designs (e.g., to minimize urban flooding)
- Research into and commencement of coastal defense facilities
- Research into adaptive agricultural startegies
- Research into environmental flow requirements.

Although there are now subregional climate change scenarios for the African region, the quality of such scenarios varies with the intensity of historical data and the spatial distribution of monitoring stations. There is an urgent need to intensify the density of monitoring stations to improve climate change scenarios. The cost of rehabilitating stations that are in disrepair is not beyond the financial capability of African states. Appreciation of the strategic importance of these facilities and a sense of ownership of climate change concerns needs to be reawakened.

It has been noted that practically all of the major river basins of Africa include several states. In recognition of this fact, the past decade has seen the development of international river basin mangement protocols—such as the Southern Africa

Development Community (SADC) Protocol on Shared Waters, the Niger Basin Authority, and several others, including the more recent Lake Victoria Fisheries Authority. The United Nations Environment Programme International Environmental Technology Center (UNEP-ITEC) have emphasized the river basin as the fundamental unit of management (UNEP, 2000). We recommend that these international basin authorities be strengthened in terms of finance and human resources and that their perspectives should embrace near- and long-term climate variability and climate change issues in their work plans. Most important is that the legal framework for such river basin authorities should be robust to ensure equity in access to and accountability for water supply and water quality management. Failure to take these concepts on board could lead to water resources-related conflict.

In general, the African continent lacks technical strategies to optimize water resources. A few countries (e.g., South Africa and Zimbabwe) have begun to develop strategies for optimum use of water resources—using, for example, water pricing and demand management tools. Crop-watering technology is primitive and wasteful in most cases. Few industrial and household water-usage strategies incorporate water reuse. During drought periods, management authorities have resorted to supply restrictions, such as the 3-day supply per week in Mutare during the 1991–1992 drought. Water supply shortages conventionally are addressed through construction of more impoundments. Magadza (1996) remarks that in severe drought periods there would be a multiple failure syndrome of water storage facilities, especially where individual reservoirs are dedicated to defined communities. Although supply structures (banning of garden hoses) and construction of storage reservoirs are practical options, demand management—which reduces consumption per unit of product output—has proved increasingly to be a water-saving strategy that can allow communities to enter a drought cycle with adequate supplies.

Whatever strategies are adopted for optimizing water usage, successful development of such strategies is contingent on reliable meteorological and hydrological information. In many instances, application of hydrological models on a basin-wide scale is restricted by data density. Reliable impacts assessments and near-term predictions depend on robust databases. For example, flood propagation and thus flood warning capability, which are real-time processes, are a function of the density of measuring points. Similarly, crop yield forecasts could be made spatially more accurate by improving the intensity of climatic measurements.

Over the past half-century, Africa has invested heavily in hydroelectric power schemes. Recent drought episodes and demand escalation have highlighted the vulnerability of even the largest hydroelectric plants to climate variability (Magadza, 1996). This assessment has shown that future water resources, especially in the subhumid to semi-arid regions of the African savanna and subtropics, will be more restricted. Research into other forms of renewable energy and energy-use efficiency in industry and households is an essential investment in a more

energy-secure future. At the regional level, energy resource sharing is a necessary strategy. Individual states must have trust and confidence to invest in neighboring countries for overall regional energy security.

Populations that live in flood-prone areas need to consider strategies for early warning procedures for flood events; strategic planning in the location of human habitations to minimize flood impacts; and strategies for robust protocols for alleviating impacts of drought events to minimize loss of human life, economic assets, and societal norms. On the other hand, early warning systems can be effective if impacted areas are accessible in the worst-case scenario, to enable either evacuation or relief supplies delivery.

Although there are major reservoirs on most large African river basins, these reservoirs were not designed for flood control. However, synchronization of operations of reservoirs that are located in the same basin can alleviate flood impacts. Nevertheless, there is a need to consider purposely building flood control facilities in some of the flood-prone areas of Africa, similar to those found on the Danube, which reduce flood crest intensity by sequestering floodwaters into temporary storage facilities along the river. This could be a subject of directed research for each African basin.

Research into coastal defense systems is an immediate need. Several African coastal areas already are experiencing significant coastal impacts. Coastal management infrastructures are likely to entail intergenerational investment programs in which each extent generation must make its contribution to minimize long-term costs. If our generation abrogates our responsibilities to future generations, we will impose immense costs on our posterity.

To minimize sensitivity to climate change, African economies should be more diversified, and agricultural technology should optimize water usage through efficient irrigation and crop development. Considerable advances have been made in agricultural industries of southern Africa, particularly in South Africa and Zimbabwe.

As water resource stresses become acute in future water-deficit areas of Africa as a result of a combination of climate impacts and escalating human demand, there will be intensifying conflict between human and environmental demands on water resources. Because maintenance of healthy ecosystems is an underpinning to economic sustainability, there is need in each water basin management unit to identify and factor into development projects the need for environmental flows.

10.2.2. Food Security

10.2.2.1. Context of Food Security

Present and future prospects for food security are significant determinants of the impacts of climate change. International

agricultural systems and socioeconomic conditions at the household level are major elements of vulnerability. The consequences of present vulnerability for hunger and nutrition are marked. Regional indicators related to food security are shown in Table 10-2.

Food production in most of SSA has not kept pace with the population increase over the past 3 decades. In Africa as a whole, food consumption exceeded domestic production by 50% in the drought-prone mid-1980s and more than 30% in the mid-1990s (WRI, 1998). Food aid constitutes a major proportion of net food trade in Africa, and in many countries it constitutes more than half of net imports. In Kenya and Tanzania, for instance, food aid constituted two-thirds of food imports during the 1990s. Despite food imports, per capita dietary energy supply (DES) remains relatively low (Hulme, 1996); about one-third of the countries in Africa had per capita DES of less than 2,000 kcal day⁻¹ in the 1990s—lower than the minimum recommended intake (data from WRI, 1998).

Agricultural and economic growth must rise—perhaps by 4% yr⁻¹—to realize basic development goals. Today, only a few countries achieve this rate of growth. One consequence of agricultural growth could be a doubling by the year 2050 of cultivated land area—at great cost to the natural environment—unless there is greater investment in agricultural management and technology on existing cropland (Anon, 1999). The scale of food imports fosters dependence on food production in the rest of the world. Africa faces the risk that supplies will fluctuate drastically with the rise and fall of grain reserves and prices on international markets. A major challenge facing Africa is to increase agricultural production and achieve sustainable economic growth; both are essential to improving food security.

Agriculture is not only a vital source of food in Africa; it also is the prevailing way of life. An average of 70% of the population lives by farming, and 40% of all exports are earned from

agricultural products (WRI, 1996). One-third of the national income in Africa is generated by agriculture. Crop production and livestock husbandry account for about half of household income. The poorest members of society are those who are most dependent on agriculture for jobs and income. On average, the poor from developing countries of SSA spend 60–80% of their total income on food (see Odingo, 1990; WRI, 1998; FAO, 1999b). Although industry is significant in a few patches, it still is in its infancy. In many countries, the level of mechanization—including irrigation, processing, and storage facilities—is particularly low.

High-quality land resources per household have shrunk in Africa over the past 2 decades, often dramatically. Traditional, social, and legal status in the sub-Saharan region is responsible for unequal access to land. This, in turn, increases the risk of resource degradation. Lack of land tenure security reduces the motivation to invest in conservation of resources.

Agriculture and household incomes are characterized by large interannual and seasonal variations. The annual flow of income normally rises and peaks during the harvest season. Nonagricultural and migrant, off-farm wage incomes are substitutes during the dry season. The period preceding the harvest is critical: Farmers engage in unemployment-induced migration to urban centers as one of the strategies for coping with scarcity. Fluctuations in annual food production resulting from climate variability place a heavy reliance on food aid, at the national and household levels.

Reduced food supplies and high prices immediately affect landless laborers who have little or no savings. Poverty, population, and sometimes conflicts combine to affect education in many African countries. As a result of population pressure as well as rural and urban economic depression, population mobility sets in. Populations move from the savanna to the forest, from plateaus to drained valleys, from landlocked countries to coastal

Table 10-3: Undernourishment in Africa (FAO, 1999b).

Region	Number of People (millions)		% of Population

Table 10-4: Comparison of indices of human development and food security for regions in developing countries [Human Development Index (UNDP, 1998); data from WRI (1998) and UNDP (1998)].

Human Development Index (HDI)	Food Security			
	Low	Med-Low	Med-High	High
Low	West Africa, South Asia, East and South Africa, Central America, Central Africa			
Medium	South Pacific	Southeast Asia, North Africa		
High	East Asia, Caribbean	West Asia, South America, Central Asia	West Europe, Central and East Europe	Australasia, Indian Ocean, North America

areas and those with infrastructures, and from rural to urban centers within a country in search of better lands and opportunities (Davies, 1996). Internal mobility and its consequences vary from country to country: It is low in Ghana, Madagascar, Malawi, Burundi, and Rwanda but high in Burkina Faso and Kenya and very high in Côte d'Ivoire. Migrations lead to high and rising urban growth across the African region. This translates into increasing pressure on the environment, including social amenities.

The consequences of chronic and episodic food insecurity in Africa are evident in the prevalence of hunger. Nearly 200 million people in Africa are undernourished. In central, eastern, and southern Africa, more than 40% of the population is undernourished, and the number has risen over the past few decades. SSA is home to almost one-quarter of the developing world's food-deprived people, with variations across the continent (FAO, 1999b). Although west Africa has the largest total population of any of the African subregions, it has the fewest undernourished people. By contrast, east Africa has more than twice as many undernourished people. According to anthropometric surveys made between 1987 and 1998, 33% of African children are stunted, underweight, or wasted (FAO, 1999b) (see Table 10-3). Illiteracy and ignorance, along with poor housing and infrastructure, are predisposing conditions to ill health in many countries, which impacts food security.

African food security and potential to adapt to climate change can be portrayed by using national indicators. Of course, local conditions of vulnerability are critical; aggregate indicators are only one way of illustrating the relative risks and potential impacts of climate change. Two indices are shown in Table 10-4. The Human Development Index (HDI) is a composite of measures of life expectancy, literacy, education, and income (GDP per capita), as promoted by the United Nations Development Programme (UNDP). Except for north Africa, African regions score in the lowest group on the HDI. Among other world regions, only Central America is in the lowest group. A similar index of food security has been constructed, using indices of

trends in food production, available food as a percentage of requirements, and arable land per capita (see Downing, 1991); north Africa is in the medium-low group. Relative to other regions, Africa clearly is among the regions with the lowest food security and the lowest ability to adapt to future changes (as indicated by the HDI).

The state of food security is not uniform, and there has been considerable progress in some countries (FAO, 1999b). For example, undernourishment in Ghana has decreased more rapidly than in any other country in the world, fueled by economic growth and consequent improvements in cropped area and yields. Plagued by population growth and conflict, Burundi is in stark contrast: Average daily food intake fell from 2,020 kcal in 1980 to 1,669 kcal in 1996.

The implications of this state of food insecurity in Africa for climate change are significant. The risks of adverse effects on agriculture, especially in semi-arid and subhumid regions and areas with more frequent and prolonged drought, become life-threatening risks. Internal coping mechanisms—through farm improvement, employment, and trade—are not likely to be adequate for many of the vulnerable populations. If food insecurity prevents private investment in agricultural economies (internal and from multinational corporations), resources for adapting to climate change may not keep pace with impacts. However, it also is clear that Africa has enormous resources—natural and human—that can be tapped to make rapid gains in food security and thus reduce the risk of adverse climate change.

10.2.2.2. Marine and Freshwater Fisheries

African nations possess a variety of lacustrine, riverine, and marine habitats with more than 800 freshwater and marine species (as noted in IPCC, 1998). GCMs do not provide direct information on water quality and other hydrological parameters that affect

fisheries (Hlohowskyj *et al.*, 1996). As such, vulnerability assessments must translate projected atmospheric changes into changes in aquatic environments, making it possible for ecological and biological responses to climate change to be identified and evaluated. Most studies on the potential impacts of climate change on fisheries have been done for temperate-zone fisheries. In these studies, the emphasis has been to evaluate the impacts of changes in the availability of thermal habitat on fishery resources and evaluate the effects of temperature on physiological processes of fish.

Temperature increases may affect lake fisheries, although sensitivity across Africa is likely to vary. For example, Ntiba (1998) used empirically derived models to elucidate the relationship between long-term fishery yield data with climatic index value for Lakes Naivasha and Victoria in Kenya. The mean annual temperature is taken as the climatic index because of data availability and close correlation between air and water surface temperatures. The results indicate that in Lake Victoria, mean annual temperature has greater effect on fish yields than morphoedaphic index (MEI); the opposite is the case in Lake Naivasha. For Lake Naivasha, a rise of as much as 2°C above the current mean annual temperature may not even double the yield from the current 12 kg ha⁻¹ yr⁻¹ (yield regressed to temperature only). The additional effect of MEI will double and triple the yield with a rise of 1.5 and 2°C, respectively. For Lake Victoria, the maximum predicted yield under current climatic conditions is estimated to be 81.8 kg ha⁻¹ yr⁻¹ and is predicted to more than triple to 263.7 kg ha⁻¹ yr⁻¹ with a rise in temperature of 0.5°C. However, natural aquatic ecosystems have a finite carrying capacity at which fishery yields will reach a maximum sustainable yield (MSY) (Russell and Yonge, 1975); it is unlikely that the yield will exceed 84.2 kg ha⁻¹ yr⁻¹ in Lake Victoria, considering that the estimated MSY for the entire lake is 74.0 kg ha⁻¹ yr⁻¹ (Turner, 1996).

On Lake Kariba, Magadza (1996) found that drought years were accompanied by decreased fisheries catch. Hart and Rayner (1994) show that the distribution of copepods on the African continent is temperature-dependent, with species examined showing restricted temperature range preferences. In the laboratory, Magadza (1977) found that the optimum temperature for the reproduction of *Moinia dubia* is 24°C, with temperatures exceeding 28°C showing reproductive failure. Chifamba (2000) found negative relationships between catch per unit (CPU) effort and temperature in the pelagic *Limnothrissa miodon* fishery on Lake Kariba, whereas precipitation and river runoff were positively correlated with CPU. These observations indicate possible depression of planktivorous pelagic freshwater fisheries as a result of climate change impacts. Where such fisheries constitute a significant protein source, such impact will bear on food security.

A further consideration in the possible impacts of global warming on inland fisheries is the thermal behaviors of inland waters. In tropical areas, a unit change in temperature elicits a greater density change per unit temperature change. Thus, at the higher tropical temperatures indicated by climate models, thermal

stratifications are likely to be more stable. In eutrophic lakes, anoxia and ammonia intoxication leading to massive fish deaths—as repeatedly witnessed in Lake Chivero—are likely to be significant (Magadza, 1997; Moyo, 1997).

Aquaculture is a food production activity with one of the highest growth rates in the world. Risk management in aquaculture must take into account the level and frequencies of extreme events in assessing available technical options, based on the environment and climatic conditions.

Riverine fisheries will be affected. With a potential warming of 3–5°C projected for the next century, productivity of the Gambia River is estimated to increase by about 13–21% (Jallow *et al.*, 1999). There would be little or no effect on the suitability of the present habitat for some fish and shrimp species. In contrast, warming of more than 3°C will have negative impacts on habitats for catfish, and warming of more than 4°C will reduce the suitability of the present habitat for herring. Shrimp yield is estimated to increase by about 38–54%.

Upwelling of the Canary Current produced by the northeast and southwest tradewinds makes the fishery off the coast of Morocco one of the most productive in the world. Data from the Institut National de Recherche Haleutique du Maroc show that NAO weakens the upwelling, increases temperature, and reduces sardine stocks (Hilmi *et al.*, 1998).

The pelagic fishing industry in the southwest of Africa (based on the Benguela upwelling) contains several migratory species, such as the anchovy (Crawford *et al.*, 1987). These species are an important resource in their own right, but they also are a key element in the food chain of larger fish, seals, and birds. Recruitment in these species is influenced by water temperature, and growth is affected by the state of the upwelling, both of which are linked to global climatic conditions (Shannon *et al.*, 1990; Siegfried *et al.*, 1990). For instance, there is a phenomenon similar to the El Niño effect on the fisheries of Peru that leads to an intrusion of warm, nutrient-poor water from the north in some years, which severely depresses fish yields (Shannon *et al.*, 1990). The net impact of global climate change on southern African fisheries remains unclear because the potential impact on ocean circulation and wind shear in the coastal zone is uncertain. In the event of major reorganization of the circulation of the southern oceans (Hirst, 1999)—which is a possibility at high rates of warming—the impacts most likely would be severe.

10.2.2.3. Crop Production

Major impacts on food production will come from changes in temperature, moisture levels, ultraviolet (UV) radiation, CO₂ levels, and pests and diseases. CO₂ enrichment increases photosynthetic rates and water-use efficiency (WUE) (see Chapter 5). The direct effects are largest on crops with C₃ photosynthetic pathway (wheat, rice, and soybean) compared with C₄ crops (maize, sorghum, millet, and sugarcane). Increases

in local temperatures may cause expansion of production into higher elevations. The grain filling period may be reduced as higher temperatures accelerate development, but high temperatures may have detrimental effects on sensitive development stages such as flowering, thereby reducing grain yield and quality. Crop water balances may be affected through changes in precipitation and other climatic elements, increased evapotranspiration, and increased WUE resulting from elevated CO₂.

Specific examples of impacts on crops are available. Pimentel (1993) notes that global warming is likely to alter production of rice, wheat, corn, beans, and potatoes—staples for millions of people and major food crops in Africa. Staple crops such as wheat and corn that are associated with subtropical latitudes may suffer a drop in yield as a result of increased temperature, and rice may disappear because of higher temperatures in the tropics (Odingo, 1990).

The possible impact of climate change on maize production in Zimbabwe was evaluated by simulating crop production under climate change scenarios generated by GCMs (Muchena and Iglesias, 1995). Temperature increases of 2 or 4°C reduced maize yields at all sites; yields also decreased under GCM climate change scenarios, even when the beneficial effects of CO₂ were included. It is suggested that major changes in farming systems can compensate for some yield decreases under climate change, but additional fertilizer, seed supplies, and irrigation will involve an extra cost. The semi-extensive farming zone was particularly sensitive to simulated changes in

climate, and farmers in this zone would be further marginalized if risk increases as projected.

Analysis of potential impacts, using dynamic simulation and geographic databases, has been demonstrated for South Africa and the southern Africa region by Schulze *et al.* (1993) (see also Schulze *et al.*, 1995; Hulme, 1996; Schulze, 2000). Relatively homogenous climate and soil zones were used to run agrohydrological, primary productivity, and crop yield models. The results reaffirm the dependence of production and crop yield on intraseasonal and interannual variation of rainfall.

Impacts on crops need to be integrated with potential changes in the agricultural economy. Yates and Strzepek (1998) describe an integrated analysis for Egypt (see Figure 10-8). Their model is linked to a dynamic global food trade model, which is used to update the Egyptian sector model and includes socioeconomic trends and world market prices of agricultural goods. Impacts of climatic change on water resources, crop yields, and land resources are used as inputs into the economic model. The climate change scenarios generally had minor impacts on aggregated economic welfare (sum of consumer and producer surplus); the largest reduction was approximately 6%. In some climate change scenarios, economic welfare slightly improved or remained unchanged. Despite increased water availability and only moderate yield declines, several climate change scenarios showed producers being negatively affected by climate change. The analysis supports the hypothesis that smaller food-importing countries are at risk of adverse climate change, and impacts could have as much to do with changes in

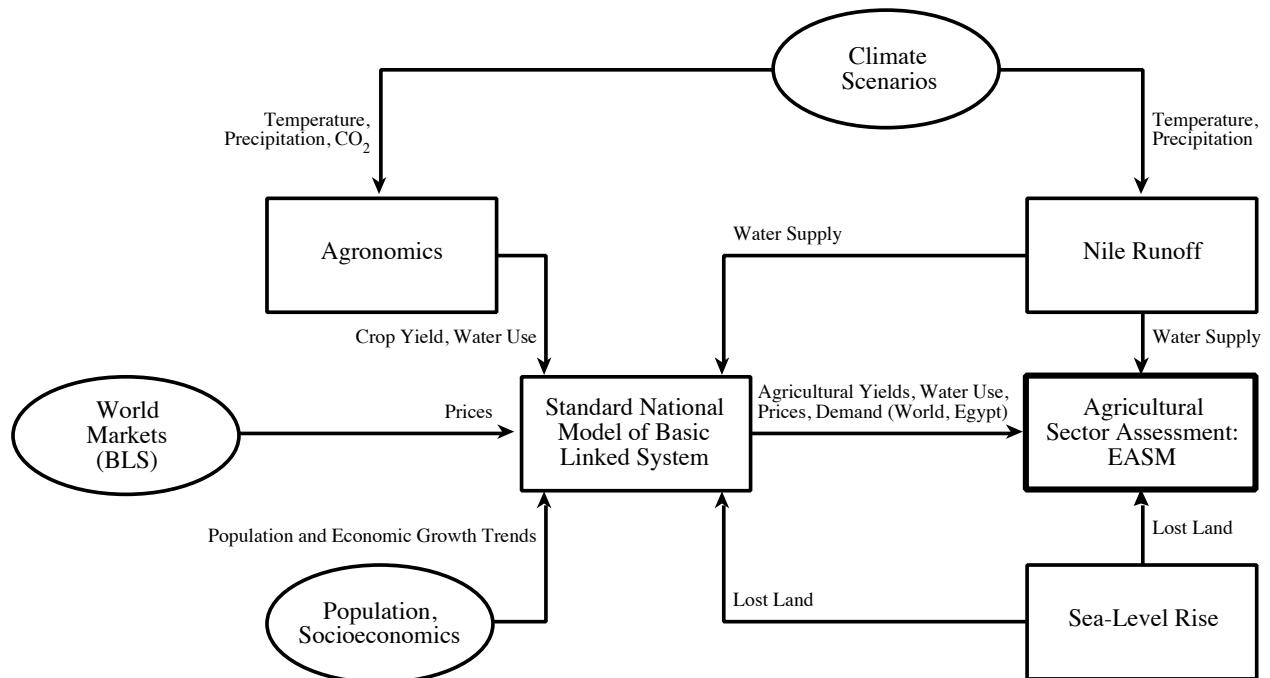

Figure 10-8: Schematic of forward-linkage approach to integrated assessment of climate change impacts on Egypt, using agricultural sector model (Yates and Strzepek, 1998).

world markets as with changes in local and regional biophysical systems and shifts in the national agricultural economy.

10.2.2.4. Livestock

Other than pigs, domestic livestock in Africa are concentrated in the arid and semi-arid zones. This is because the more humid areas were historically prone to livestock diseases such as *nagana* (a trypanosome carried by the tsetse fly—Ford and Katondo, 1977), typically support grasses of low digestibility (Scholes, 1990, 1993), and often are densely settled by crop agriculturalists. The overwhelming majority of these animals feed predominantly off natural grasslands and savannas, although crop residues are an important supplement during the dry season. Many urban and rural families also keep poultry.

Domestic livestock play a central role in many African cultures. Cattle and camels, in particular, have an importance that goes beyond the production of meat. Their value is based on the full set of services they supply (milk, meat, blood, hides, draft power), their asset value as a form of savings, and their cultural symbolism. It would be difficult and damaging for these cultures to abandon pastoralism in the event that it becomes climatically, environmentally, or economically unviable.

Although classical concepts of animal carrying capacity may not be very useful as local management tools in the context of African semi-arid systems with high interannual variability (Behnke *et al.*, 1993), they remain valid as indicators of animal production when they are applied over decadal periods and large areas. Many researchers have demonstrated a strong link between long-term, large-area herbivore biomass (LHB, kg km⁻²) in African wildlife and pastoral systems and mean annual precipitation (MAP, mm) (Coe *et al.*, 1976; van den Berg, 1983). Subsequent studies have shown that this relationship is strongly influenced by soil type or its proxy, the underlying geology (East, 1984; Fritz and Duncan, 1993). These relationships have the form $\log(LHB) = A \times \log(MAP) + B$, where A and B are constants for a particular soil type. Because the values of A lie between 1.45 and 1.55, the relationships are exponentially increasing but approximately linear over the typical range of interannual variation at one site (see also Le Houerou, 1998, for a similar analysis in west Africa and the Mediterranean basin). Thus, in broad terms, changes in range-fed livestock numbers in any African region will be directly proportional to changes in annual precipitation. Given that several GCMs predict a decrease in MAP on the order of 10–20% in the main semi-arid zones of Africa, there is a real possibility that climate change will have a negative impact on pastoral livelihoods. The following additional factors must be considered.

The causal chain between rainfall and animal numbers passes through grass production, which also is approximately linearly related to rainfall (Breman, 1975; Le Houerou and Hoste, 1977; Rutherford, 1995). The slope of this relationship, which can be expressed as WUE, is a function of soil nutrient availability (De Ridder *et al.*, 1982; Scholes, 1993). WUE also is a function

of CO₂ concentration in the atmosphere (Mooney *et al.*, 1999), especially in semi-arid regions. Because the CO₂ concentration will rise in the future, its positive impact on WUE (which is on the order of 20–30% for doubled CO₂, even in C₄-dominated grasslands such as these) will help to offset reduction in rainfall of the same magnitude. Simulations of grassland production in southern Africa indicate an almost exact balancing of these two effects for that region (Scholes *et al.*, 2000).

About 80% of the grazing lands of Africa are in savannas, a vegetation formation that consists of a mix of trees and grasses. Grass production in savannas is strongly depressed by tree cover (see the many references reviewed by Scholes and Archer, 1997). Because domestic livestock, with the exception of goats, predominantly eat the grass in these systems, future changes in tree cover are an important issue from the point of view of carbon sequestration and livestock production. Tree biomass ultimately is related to climate and soil type, but the mechanism appears to be via fire frequency and intensity. If fire frequency and intensity were to decrease—as a result of climate changes (for instance, an increase in dry-season rainfall) or, more likely, changes in land management—woody cover would increase. This has been demonstrated in numerous fire experiments in Africa (Trapnell *et al.*, 1976; Boosy and Tainton, 1984). Given the vast area of the savannas, the carbon sequestration potential is substantial (Scholes and van der Merwe, 1996). In addition, emissions of tropospheric ozone (O₃) precursors would decrease if savanna burning were reduced. The disadvantage would be a more than proportional decrease in livestock carrying capacity, as a result of the nonlinear suppressive effect of trees on grass production.

The bioclimatic limit of savannas in southern Africa is related to winter temperatures. An increase in temperature of 1–2°C—well within the range predicted for next century—would make the montane grasslands (highveld) of southern Africa susceptible to invasion by savanna trees (Ellery *et al.*, 1990).

In moister regions, animal productivity is limited not by the gross availability of fodder but by its protein (nitrogen) content (Ellery *et al.*, 1996). Increasing the CO₂ concentration or the rainfall will not increase the protein availability; thus, livestock in these regions are likely to be less responsive to the direct effects of atmospheric and climate change. Under elevated CO₂, the carbon-to-nitrogen ratio of forage will decrease, but this will not necessarily lead to decreased forage palatability despite the dilution of protein (Mooney *et al.*, 1999). This may be because in grasses, the bulk of the excess carbon is stored in the form of starch, which is readily digestible. Widespread use of protein and micronutrient feed supplements and new technology for the control of veterinary diseases will have a greater impact on livestock numbers and productivity, especially in the “miombo” region of south central Africa.

Domestic livestock, like other animals, have a climate envelope in which they perform optimally. The limits of the envelope are quite broad and can be extended by selecting for heat or cold tolerance, feed supplementation, or providing physical shelter

for the animals. African cattle are mostly from the *Bos indicus* line, which is more heat-tolerant than the European line of *Bos taurus*. In extremely hot areas (mean daily warm-season temperatures greater than body temperature), even the *Bos indicus* breeds are beyond their thermal optimum (Robertshaw and Finch, 1976). Meat and milk production declines, largely because the animals remain in the shade instead of foraging. There is limited potential for extending this limit through breeding. Adaptation would require substitution by a species such as the oryx, which is physiologically equipped for high temperatures and low water supply.

In the higher altitude and higher latitude regions of Africa, livestock (typically sheep) currently are exposed to winter temperatures below their optimum. Mortality often results when cold periods coincide with wet periods, if the animals have not been herded to shelter. These episodes are likely to decrease in frequency and extent in the future.

Livestock distribution and productivity could be indirectly influenced via changes in the distribution of vector-borne livestock diseases, such as *nagana* (trypanosomiasis) and the tick-borne East Coast Fever and Corridor Disease (Hulme, 1996). Simulations of changes in the distribution of tsetse fly (*Glossina spp.*) indicate that with warming it could extend its range southward in Zimbabwe and Mozambique, westward in Angola, and northeast in Tanzania, although in all these simulations there were substantial reductions in the prevalence of tsetse in some current areas of distribution. The tick *Rhipicephalus appendiculatus* was predicted to decrease its range in southern and eastern Africa and increase its range in the central and western part of southern Africa (Hulme, 1996).

One land-use model (IMAGE 2.0—Alcamo, 1994) projects that large parts of Africa will be transformed to pastoral systems during the 21st century. The model logic that leads to this conclusion is that increasing urbanization and a rising standard of living typically are associated with a change in dietary preference toward meat. The area that currently is used for meat production therefore would need to expand, assuming that meat demand was not met by import or by increased productivity of existing herds. These are reasonable but untested assumptions, and their consequences have major implications for biodiversity conservation and atmospheric composition. The areas indicated as being converted to pastures (largely the subhumid tropics) already support cattle to some degree. Increased cattle production would require widespread tree clearing (leading to conversion of a carbon sink into a carbon source), eradication of key cattle diseases, and the use of protein and micronutrient feed supplements. The quantity of fuel consumed by savanna fires would decrease (because it would be grazed), reducing the release of pyrogenic methane (CH_4) and O_3 precursors, but the production of methane from enteric fermentation would increase. Because methane production per unit of grass consumed is higher for enteric fermentation than for savanna fires (Scholes *et al.*, 1996), the result is likely to be a net increase in radiative forcing.

10.2.2.5. Impacts of Drought and Floods

Food security in Africa already is affected by extreme events, particularly droughts and floods (e.g., Kadomura, 1994; Scoones *et al.*, 1996). The ENSO floods in 1998 in east Africa resulted in human suffering and deaths, as well as extensive damage to infrastructure and crops in Kenya (Magadza, 2000). Floods in Mozambique in 2000 and in Kenya in 1997–1998 sparked major emergency relief as hundreds of people lost their lives and thousands were displaced from their homes (Brickett *et al.*, 1999; Ngecu and Mathu, 1999; see also <www.reliefweb.int>). The cost in Kenya alone was estimated at US\$1 billion (Ngecu and Mathu, 1999). Droughts in 1991–1992 and 1997–1998 affected livelihoods and economies and heightened renewed interest in the impacts of climatic hazards (e.g., Kadomura, 1994; Campbell, 1999). For example, the impacts of the 1991–1992 drought in Zimbabwe are estimated to have been 9% of GDP (Benson and Clay, 1998).

Such climatic episodes can serve as an analog of climate change. Irrespective of whether climate change will cause more frequent or more intense extreme events, it is apparent that many aspects of African economies are still sensitive to climatic hazards. At the local level, some coping strategies are less reliable (Jallow, 1995)—for instance, Campbell (1999) notes that plants and trees used as food by pastoralists in southern Kenya declined between 1986 and 1996. National governments often struggle to provide food security during times of crisis (Ayalew, 1997; Gundry *et al.*, 1999). For national and international agencies, the cost of climatic hazards—impacts, recovery, and rehabilitation—may result in a shift in expenditure from reducing vulnerability to simply coping with immediate threats (e.g., Dilley and Heyman, 1995).

10.2.2.6. Adaptation Strategies

The nature and processes of human adaptation to long-range climate change are poorly understood, especially in Africa (but see Chemane *et al.*, 1997; Vogel, 1998). Often, human responses are assumed, or assumed to be rational with foresight and equity. Chapter 18, Smith and Lenhart (1996), and Smithers and Smit (1997) provide overviews; national assessments provide more detail.

A promising approach for much of Africa is to cope with current climate variability through the use of seasonal climate forecasting (e.g., Mason *et al.*, 1996; Matthes and Mason, 1998; Washington *et al.*, 1999; Dilley, 2000). If farmers can adapt to current year-to-year variability through the use of advance information on the future season's climate and institutional systems are in place to respond to short-term changes (such as early warning systems), communities will be in a position to adapt to longer term climate changes. For example, a seasonal maize water-stress forecast for the primary maize-growing regions of South Africa and Zimbabwe anticipates water stress 6 months prior to harvest, with hindcast correlation over 16 seasons of 0.92 for South Africa and 0.62 for Zimbabwe,

based on correlations between water stress and historical global SST and sea-level pressure records (Martin *et al.*, 2000). Similar forecasts are possible in other regions and for other crops; however, seasonal forecasting by itself will not improve food security (e.g., Stack, 1998).

Better soil and water conservation practices, more tolerant crop varieties, improved pest and weed control, and more use of irrigation also are needed to adapt to changes in the weather. Omenda *et al.* (1998) recommend that in areas predicted to have a decline in precipitation, research into the development of maize varieties that are higher yielding, drought-resistant, early maturing, and disease- and pest-tolerant is desirable. They further suggest that methods of improving maize culture be studied, including use of inorganic fertilizers and manure and changes in planting dates. Better adaptation to climate change also will result from the use of improved technologies in agriculture—for example, in irrigation and crop husbandry. It has been suggested (Pinstrum-Anderson and Pandya-Lorch, 1999), for example, that by failing to capitalize on new opportunities that biotechnology offers, SSA may further add to its food insecurity and poverty problems.

Increased meat production can be achieved without massive expansion of area grazed or size of the herds, by application of modern herd and animal diet management. In many situations, this would require a cultural shift from regarding livestock principally as an asset and symbol to regarding them as a production system. Cow-calf systems with supplemental feeding can achieve offtakes of 40% yr⁻¹ (compared to the 10–20% typical of most current herd management in Africa), permitting lower livestock numbers per hectare (Preston and Leng, 1987). This would achieve a reduction in CO₂ and CH₄ emissions. A limited amount of increased heat tolerance can be introduced through breeding programs.

The Senegal River basin (SRB) provides an illustration of sensitivity to climatic variations and opportunities for adaptation. The SRB is undergoing fundamental environmental, hydrologic, and socioeconomic transitions (Venema *et al.*, 1997). Senegal, Mauritania, and Mali—through the river basin development authority, the Organisation pour la Mise en Valeur du Fleuve Senegal (OMVS)—are promoting irrigated rice production for domestic consumption in the river basin to ease the severe foreign exchange shortfalls facing these riparian nations. With the recent completion of Manantali and Diama dams, year-round irrigated agriculture is now possible in the SRB. The full agricultural development potential of the SRB is constrained, however, by the basin's limited water resources, which are sensitive to climatic variations. An alternative approach to the SRB's scarce water resources is an agricultural development policy that is based on village-scale irrigation projects and intensive, irrigated agroforestry projects (Venema *et al.*, 1997). Village-scale irrigation is dedicated to low-water-consumption cereal grain crops and is managed by traditional sociopolitical structures. The proposed agroforestry production system has the dual objectives of using irrigation to reestablish a protective biomass cover in the desertifying river valley and reversing

drought-induced migration from rural to urban areas. A comparative river system simulation was carried out to analyze the effects of the rice production development policy and the natural resources management policy on the SRB's full agricultural development potential. The simulation study compared three alternative hydrologic scenarios, using the pre-drought era, the 1970s-level drought, and the 1980s-level drought. Dynamic programming applied to water allocation in the Manantali reservoir showed that lower overall water demands for the natural resource policy scenarios had higher agricultural development potential than the proposed policy based on rice production.

A significant drawback in combating effects of climate variability is the failure of African governments to devolve power to people who are affected and to link environmental degradation to economic policy (Darkoh, 1998). Consequently, many programs lack local support or are undermined by conflicting trade and agricultural policies pursued by governments. It is contended that, for sustainable development strategies to work, policies should put the welfare of people at the center of the development agenda and give them the rights and power to determine their future. Policies should empower the people to develop adaptive strategies toward sustainable livelihoods. Moreover, threats posed to the environment and development by protection and overconsumption in the north and structural adjustment programs (SAPs) call for the removal of distortions created by the import barriers of developed countries, curbing of overconsumption, and a fundamental revision in the structure of SAPs to help alleviate poverty and protect the environment in these African countries. It is in the interest of the global community that the environment in Africa is protected.

Operational early warning systems in Africa—including the SADC Regional Early Warning Unit, the U.S. Agency for International Development (USAID) Famine Early Warning System Network, and the World Food Program (WFP) Vulnerability Assessment and Mapping unit—assess the vulnerability of rural households in many parts of Africa to food insecurity each year. Vulnerability assessments generally develop a picture of which geographic areas and which social groups will be unlikely to meet their subsistence needs before the next agricultural season, based on a convergence of available environmental and socioeconomic information (USAID, 1999). The USAID Sahel vulnerability assessment for 1999–2000 estimated that 3.8 million people were moderately food insecure in a high-rainfall year (USAID, 2000). This could signify chronic vulnerability resulting from structural weaknesses caused by desertification, climate change, and other long-term environmental and socioeconomic phenomena.

10.2.3. Natural Resource Management and Biodiversity

10.2.3.1. Forest and Woodland Resources

In Africa, forests—as defined and reported by FAO (1999a)—cover 5 million km², one-sixth of the continent's land area. The

moist tropical forests of the Congo constitute the second most extensive rainforest in the world and a globally important reserve of carbon. Trees and shrubs constitute an important component of the more than 12 million km² of agricultural lands, pastures, shrublands, and savannas outside of closed-canopy forest areas.

Trees and shrubs provide ecosystem services of carbon sequestration, storing and transpiring water required for precipitation, maintaining soil fertility, and forming habitats for a diverse array of plant and animal species. Moreover, forest and woodland species also provide firewood, structural timber, traditional medicines, staple foods, and drought emergency foods. Because a large fraction of the population lives in rural areas, they depend on trees and shrubs for many of their subsistence needs. Indeed, firewood and charcoal provide approximately 70% of the energy used in Africa. Moreover, the export of timber, nuts, fruit, gum, and other forest products generates 6% of the economic product of African countries (FAO, 1999a). Thus, climate change renders vulnerable the large part of the African population that is dependent on forest species for subsistence needs and the nontrivial fraction of the economy that is based on forest products.

Because climate change alters the spatial and temporal patterns of temperature and precipitation, the two most fundamental factors determining the distribution and productivity of vegetation—geographical shifts in the ranges of individual species and changes in productivity—constitute the most likely impacts of CO₂-induced climate change on forest species. Research in Senegal (Gonzalez, 1997, 2001) has documented retraction of mesic species to areas of higher rainfall and lower temperature as a result of desertification in the last half of the 20th century. These changes have caused a 25–30 km southwest shift of Sahel, Sudan, and Guinean vegetation zones in half a century, proceeding at an average rate of 500–600 m yr⁻¹—foreshadowing the magnitude of projected vegetation shifts driven by CO₂-induced climate change (Davis and Zabinski, 1992). In northwest Senegal, the human population density is 45 people km⁻², whereas forest species can support only 13 people km⁻² under altered conditions (Gonzalez, 1997).

Dry woodlands and savannas in semi-arid and subhumid areas will be increasingly subjected to drying in the next century, as well as increasing land-use intensity—including conversion to agriculture (Desanker *et al.*, 1997). Moreover, CO₂-induced climate change is very likely to alter the frequency, intensity, seasonality, and extent of vegetation fires that are critical to the maintenance of areas such as the Serengeti grasslands of east Africa, the miombo woodlands of southern Africa, and the fynbos of the Cape. Across the continent, farmers traditionally use fire to clear agricultural fields in forest areas and areas outside closed-canopy forest; pastoralists and hunter-gatherers use fire to improve the quality of plant resources available during the dry season. Satellite remote sensing reveals that more than half of the continent experiences a fire regime with a frequency greater than once per decade (Kendall *et al.*, 1997; Levine *et al.*, 1999).

Although the broad geographical pattern of fire-prone vegetation clearly is climatically related (van Wilgen and Scholes, 1997), the aspect of the fire regime that is most sensitive to the type and degree of climate change suggested for Africa is likely to be fire intensity, rather than its frequency or extent. Fire intensity is related largely to the available dry-season fuel load, which in turn is strongly and positively related to rainfall in the preceding wet season and nonlinearly related to woody plant cover. In the miombo woodlands, it is predicted that increased fire will expand savanna areas at the expense of wooded areas (Desanker *et al.*, 1997). Because emissions of CH₄, tropospheric O₃ precursors, and aerosols from vegetation fires in Africa constitute a significant contribution to the global budgets of these species (Crutzen and Andreae, 1990; Hao *et al.*, 1990; Scholes *et al.*, 1996), changes in the African fire regime could have consequences for global and regional climate.

Modeling of the distribution of forest species on the basis of the Holdridge (1967) life zone classification has projected changes from mesic vegetation to xeric vegetation in Tanzania and The Gambia (Jallow and Danso, 1997) but a shift from arid vegetation to moist vegetation in Mozambique (Bila, 1999). It is not suggested that vegetation formations and their associated fauna (biomes) will migrate as a unit. It is more likely that species will respond to changing climate and disturbance regimes individualistically, with substantial time lags and periods of reorganization. The broad pattern of productive potential of vegetation zones is likely to move with greater spatial integrity because there is a degree of functional redundancy in ecosystems.

The most promising adaptation strategies to declining tree resources include natural regeneration of local species, energy-efficient cookstoves, sustainable forest management, and community-based natural resource management. The most effective adaptation to the decline of trees and shrubs in semi-arid areas is natural regeneration of local species. In addition, the *ban ak suuk* cookstove in Senegal and the *jiko* ceramic stove in Kenya have both produced energy-efficient gains in semi-arid areas (Dutt and Ravindranath, 1993). These practices generally depend on the ability of local people to exercise power to inventory and manage local resources in systems of community-based natural resource management. Decentralization of decisionmaking and revenue allocation authority has promoted efficient forest management in small areas of Niger, Madagascar, and Zimbabwe (FAO, 1999a). All of these practices constitute “no regrets” strategies that society would want to undertake under any climate scenario for their intrinsic environmental and economic benefits.

10.2.3.2. Indigenous Biodiversity and Protected Areas

Africa occupies about one-fifth of the global land surface and contains about one-fifth of all known species of plants, mammals, and birds in the world, as well as one-sixth of amphibians and reptiles (Siegfried, 1989). This biodiversity is concentrated in several centers of endemism. The Cape Floral Kingdom (fynbos), which occupies only 37,000 km² at the southern tip of Africa,

has 7,300 plant species—of which 68% occur nowhere else in the world (Gibbs, 1987). The adjacent Succulent Karoo biome contains an additional 4,000 species, of which 2,500 are endemic (Cowling *et al.*, 1998). These floristic biodiversity hotspots both occur in winter rainfall regions at the southern tip of the continent and are threatened particularly by a shift in rainfall seasonality (for instance, a reduction in winter rainfall amounts or an increase in summer rainfall, which would alter the fire regime that is critical to regeneration in the fynbos). Other major centers of plant endemism are Madagascar, the mountains of Cameroon, and the island-like Afromontane habitats that stretch from Ethiopia to South Africa at altitudes above about 2,000 m (Mace *et al.*, 1998). Montane centers of biodiversity are particularly threatened by increases in temperature because many represent isolated populations with no possibility of vertical or horizontal migration. Several thousand species of plants alone are potentially affected.

The broad patterns of African zoogeography also are climatically linked, but the location of concentrations of biodiversity and endemism, at least in the higher animals, is located in the savannas and tropical forests. World antelope and gazelle biodiversity (more than 90% of the global total of 80 species) is concentrated in Africa (Macdonald, 1987). Changes in climate of the magnitude predicted for the 21st century could alter the distribution range of antelope species (Hulme, 1996).

This biodiversity forms an important resource for African people. Uses are consumptive (food, fiber, fuel, shelter, medicinal, wildlife trade) and nonconsumptive (ecosystem services and the economically important tourism industry).

For a sample of 39 African countries, a median 4% of the continental land surface is in formally declared conservation areas in southern Africa (MacKinnon and MacKinnon, 1986). The fraction of landscape that is conserved varies greatly between countries (from 17% in Botswana to 0% in four countries), as does the degree of actual protection offered within nominally conserved areas (MacKinnon and MacKinnon, 1986). A very large fraction of African biodiversity occurs principally outside of formally conserved areas (especially in central and northern Africa), as a result of a relatively low rate of intensive agricultural transformation on the continent. This will no longer be true if massive extensification of agriculture and clearing of tropical forests occurs in the humid and subhumid zones, as is predicted to occur in the next century by some land-cover change models (Alcamo, 1994). Patterns of human pressure, including grazing by domestic stock, also will be altered and intensified by climate change. Land-use conversion effects on biodiversity in affected areas will overshadow climate change effects for some time to come.

In the medium term (~10–20 years), biodiversity of indigenous plants and animals in Africa is likely to be affected by all of the major environmental changes that constitute climate change. These include changes in ambient air temperature, rainfall and air vapor pressure deficit (which combine to cause altered water balance), rainfall variability, and atmospheric CO₂.

Africa—like the other continents, though perhaps to a greater degree—is characterized by ecosystem control through disturbance, such as fire (Bond and van Wilgen, 1996) and grazing regimes. Changing disturbance regimes will interact with climate change in important ways to control biodiversity—for instance through rapid, discontinuous ecosystem “switches.” For example, changes in the grazing and fire regime during the past century are thought to have increased woody-plant density over large parts of southern Africa. Ecosystem switches are accompanied by drastic species shifts and even species extinction. Subtle changes in species composition of rich ecosystems such as forests will impact biodiversity resources. A significant reduction in rainfall or increase in evapotranspiration in Angola would threaten the Okavango delta wetland in Botswana. Much larger scale ecosystem switches (e.g., savanna to grassland, forest to savanna, shrubland to grassland) clearly occurred in the past (e.g., during the climatic amelioration dating from the last glacial maximum), but diversity losses were ameliorated by species and ecosystem geographical shifts. The geographical range shifts required to preserve biodiversity into the future will be strongly constrained by habitat fragmentation and cannot realistically be accommodated by a static nature reserve network with the low areal coverage evident in Africa.

Theory required to predict the extent and nature of future ecosystem switches and species geographical shifts in Africa is lacking, and case studies are few. The response of major vegetation types to changes such as rising atmospheric CO₂ are almost unstudied, although early evidence (Midgley *et al.*, 1999; Wand *et al.*, 1999) suggests, for example, that these responses may increase WUE in grass species significantly, which may increase grass fuel load or even increase water supply to deeper rooted trees. Recent analysis of tree/grass interactions in savannas suggests that rising atmospheric CO₂ may increase tree densities (Midgley *et al.*, 1999); this kind of ecosystem switch would have major implications for grazing and browsing animal guilds and their predators. For southern Africa, between one-quarter and one-third of current reserves were predicted to experience a biome shift (a major change in the dominant plant functional types) under the equilibrium climate resulting from a twice-preindustrial CO₂ concentration (Hulme, 1996). In South Africa, increased aridity in the interior Bushmanland plateau will introduce a desert-like environment to the country (Rutherford *et al.*, 1999). Analysis for South African conservation areas (Rutherford *et al.*, 1999) shows potentially large losses of plant species diversity in this semi-arid region with low landscape heterogeneity.

Thus, the vegetation and animal communities that many reserves aim to conserve will no longer be within their preferred bioclimatic region. Migration of animals to conserved areas with more suitable climate (if these exist) will be constrained by fragmentation of intervening ecosystems and potentially hostile landscapes. The required rate of migration may be too rapid for unassisted movement of most plant species, especially over relatively flat landscapes (Rutherford *et al.*, 1995). Without adaptive and mitigating strategies, the impact of climate

change will be to reduce the effectiveness of the reserve network significantly, by altering ecosystem characteristics within it and causing species emigrations or extinctions.

At particular risk of major biodiversity loss are reserves on flat and extensive landscapes, those in areas where rainfall regime may change seasonality (e.g., the southern Cape), those where the tree/grass balance is sensitive to CO₂ conditions, and those where the fire regime may be altered. Species most at risk are those with limited distribution ranges and/or poor dispersal abilities, habitat specialists (soil specialists in the case of plants), and those that are responsive to specific disturbance regimes.

Mitigation and adaptation strategies will be greatly strengthened by a risk-sharing approach between countries, which could attempt to share the burden of conserving critical populations in a collaborative way. Part of this risk-sharing approach could include transboundary nature reserves, where this is appropriate for increasing connectivity in areas projected to change significantly. The corridor approach within and between countries would have the added benefit of increasing reserve resilience to current climate variability and would increase attractiveness to the tourism industry. Economic incentives, however, may differ across geographic scales. For the moist tropical forests of Masoala National Park in northeast Madagascar, economic incentives favor conservation at local and global scales, although logging provides more profit at a national scale (Kremen *et al.*, 2000).

A high degree of uncertainty is associated with predictions of the biodiversity effects of climate change. No systematic analysis of mechanisms of ecosystem switches, or areas exposed to them, has been carried out. Although fire and atmospheric CO₂ seem to be important determinants of ecosystem structure and function, little research is available to predict how these factors will interact with other environmental changes. The effects of CO₂ on grass water use may be an important mitigator of negative effects on productivity for grazer guilds in much of subtropical Africa. Effects of shifts of disease-prone areas on animal populations are unstudied.

10.2.3.3. Migratory Species

10.2.3.3.1. Large-mammal migratory systems

The vast herds of migratory ungulates in east and southern Africa remain a distinguishing ecological characteristic of the continent. A major migratory system is located in the Serengeti area of Tanzania and the Masai-Mara region of Kenya. Reduced large-mammal migratory systems persist in the Kalahari (Botswana, South Africa, and Namibia) and Etosha (Namibia) areas of southern Africa.

Migrations typically are regular, and between dry-season and wet-season grazing areas, and to that extent they are sensitive to climate change. There is currently no indication that the broad pattern of seasonality is likely to change in the Serengeti

or the Kalahari, since they are controlled by gross features of the atmospheric circulation (the monsoon system and the position of the Hadley cells). The intensity of seasonality, and the absolute annual rainfall total could change, by about 15% in either direction (Hulme, 1996). This is well within the range of interannual variability. Thus the migratory systems are likely to persist if land-use pressures permit them to.

10.2.3.3.2. Bird migrations

About one-fifth of southern African bird species migrate on a seasonal basis within Africa, and a further one-tenth migrate annually between Africa and the rest of the world (Hockey, 2000). A similar proportion can be assumed for Africa as a whole. One of the main intra-Africa migratory patterns involves waterfowl, which spend the austral summer in southern Africa and winter in central Africa. Palearctic migrants spend the austral summer in locations such as Langebaan lagoon, near Cape Town, and the boreal summer in the wetlands of Siberia. If climatic conditions or very specific habitat conditions at either terminus of these migratory routes change beyond the tolerance of the species involved, significant losses of biodiversity could result. Although the species involved have some capacity to alter their destinations, in an increasingly intensively used world the probability of finding sufficient areas of suitable habitat in the new areas is small. The current system of protected habitats under the Ramsar Convention is based on the present distribution of climate.

10.2.3.3.3. Locust migrations

Aperiodic locust outbreaks characterize the desert/semi-arid fringe in southern Africa and the Sahelian region. The population biology of the outbreak phenomenon is strongly linked to climate, particularly the pattern of soil moisture and temperature (Hanrahan *et al.*, 1992). Outbreaks typically occur when a dry period is followed by good rains—for instance, in southern Africa following an El Niño episode. Changes in El Niño frequency would impact the timing, location, and extent of locust outbreaks in ways that presently are unpredictable.

10.2.3.3.4. Human migratory systems

Semi-arid areas of the Sahel, the Kalahari, and the Karoo historically have supported nomadic societies that respond to intra-annual rainfall seasonality and large interannual variability through migration. Nomadic pastoral systems are intrinsically quite robust to fluctuating and extreme climates (because that is what they evolved to cope with), provided they have sufficient scope for movement and other necessary elements in the system remain in place. The prolonged drying trend in the Sahel since the 1970s has demonstrated the vulnerability of such groups to climate change when they cannot simply move their axis of migration because the wetter end already is densely occupied and permanent water points fail at the drier end. The result has

been widespread loss of human life and livestock and substantial changes to the social system.

10.2.4. Human Health

The IPCC *Special Report on Regional Impacts of Climate Change* (IPCC, 1998) acknowledges that climate will have an impact on vector-borne diseases. The assessment in that report is limited to a qualitative analysis of the impacts. The report identifies the scarcity of disease distribution maps and models as a handicap to establishing current baseline limits. In the case of malaria, however, a continental effort—Mapping Malaria Risk in Africa—is underway. No such parallel efforts, however, are underway for other diseases in the African continent that may be affected by climate change (e.g., arboviruses, trypanosomiasis, schistosomiasis). No specific references are made to water- and food-borne and epizootic/epidemic diseases in Africa.

In recent years it has become clear that climate change will have direct and indirect impacts on diseases that are endemic in Africa. Following the 1997–1998 El Niño event, malaria, Rift Valley fever, and cholera outbreaks were recorded in many countries in east Africa (see Table 10-5 for a summary of disease outbreaks for the 1997–1999 period). The meningitis belt in the drier parts of west and central Africa is expanding to the eastern region of the continent. These factors are superimposed upon existing weak infrastructure, land-use change, and drug resistance by pathogens such as *Plasmodium falciparum* and *Vibrio cholerae*.

10.2.4.1. Vector-Borne Diseases: Malaria

Although the principal causes of malaria epidemics in the African highlands still are a subject of debate in the literature (Mouchet *et al.*, 1998), there is increasing evidence that climate change has a significant role (WHO, 1998). In a highland area of Rwanda, for example, malaria incidence increased by 337%

Table 10-5: Summary of number of countries in Africa reporting diseases/outbreaks from 1997 to July 1999.^a Note that outbreaks indicate above-normal disease prevalence.

Disease	1997	1998	1999 (Jan–July)
Malaria	0	2	2
Rift Valley fever	0	4	1
Yellow fever	1	1	0
Meningitis	3	2	
Plague	2	1	2
Cholera	8	10	7
Dengue	0	0	0

^a (WHO: Outbreak, <http://www.who.int/emc/outbreak_news/n1997/feb>).

No reports were available for schistosomiasis, trypanosomiasis, onchocerciasis, and filariasis.

in 1987, and 80% of this variation could be explained by rainfall and temperature (Loevinsohn, 1994). A similar association has been reported in Zimbabwe (Freeman and Bradley, 1996). Other epidemics in east Africa have been associated largely with El Niño. It can be expected that small changes in temperature and precipitation will support malaria epidemics at current altitudinal and latitudinal limits of transmission (Lindsay and Martens, 1998). Furthermore, flooding could facilitate breeding of malaria vectors and consequently malaria transmission in arid areas (Warsame *et al.*, 1995). The Sahel region, which has suffered from drought in the past 30 years, has experienced a reduction in malaria transmission following the disappearance of suitable breeding habitats. Yet, there are risks of epidemics if flooding occurs (Faye *et al.*, 1995).

10.2.4.2. Cholera

Cholera is a water- and food-borne disease and has a complex mode of transmission. Flood causes contamination of public water supplies, and drought encourages unhygienic practices because of water shortage. The seventh pandemic currently is active across Asia, Africa, and South America.

Colwell (1996) demonstrates the link between cholera and SST. Upwelling of the sea as a result of increased SST increases the abundance of phytoplankton, which in turn supports a large population of zooplankton—which serves as a reservoir of cholera bacteria. Besides other epidemiological factors, the effects of SST on the spread of cholera may be the most profound because they affect large areas of the tropical seas and lakes. During the 1997–1998 El Niño, a rise in SST and excessive flooding (WHO, 1998a) provided two conducive factors for cholera epidemics that were observed in Djibouti, Somalia, Kenya, Tanzania, and Mozambique—all lying along the Indian Ocean.

Cholera epidemics also have been observed in areas surrounding the Great Lakes in the Great Rift Valley region. Birmingham *et al.* (1997) found significant association between bathing, drinking water from Lake Tanganyika, and the risk of infection with cholera. Shapiro *et al.* (1999) have made a similar observation along the shores of Lake Victoria. It is likely that warming in these African lakes may cause conditions that increase the risk of cholera transmission. This is an area that urgently requires research. According to WHO (1998a), Africa accounted for 80% of the total reported number of cholera cases globally in 1997.

10.2.4.3. Meningitis

Major epidemics of meningococcal infections usually occur every 5–10 years within the African “meningitis belt;” they usually start in the middle of the dry season and end a few months later with the onset of the rains (Greenwood, 1984). Between February and April 1996, the disease affected thousands of people in parts of northern Nigeria, many of whom died (Angyo and Okpeh, 1997). This epidemic spread from the original meningitis belt to Kenya, Uganda, Rwanda, Zambia,

and Tanzania (Hart and Cuevas, 1997). One of the environmental factors that predisposes to infection and epidemics is low humidity (Tikhomirov *et al.*, 1997). However, a climate-meningitis association was not clear in parts of the Gulf of Guinea (Besancenot *et al.*, 1997). That this disease has been limited to the semi-arid areas of Africa suggests that its transmission could be affected by warming and reduced precipitation.

10.2.4.4. Rift Valley Fever

From 1931 (when the disease was first described) until the end of the 1970s, Rift Valley fever (RVF) was considered to be a relatively benign zoonoses for humans that periodically developed in domestic animals (especially sheep) following heavy rains (Lefevre, 1997). Recent research indicates that although epizootics in east Africa are associated with an increase in rainfall, a similar association is unknown in west Africa (Zeller *et al.*, 1997). Recent data from west Africa indicate that the risk of a new epizootic is increasing in the region (Fontenille *et al.*, 1995), with significant exposure to the virus among livestock herders and wildlife rangers during the wet season (Olaleye *et al.*, 1996). Following the 1997–1998 El Niño event in east Africa, an RVF outbreak in Somalia and northern Kenya killed as much as 80% of the livestock and affected their owners (WHO, 1998b). Many cases also were reported in Tanzania. In Mauritania, the human epidemic was linked to the epizootic disease (Jouan *et al.*, 1989). Extensive research on mosquito vectors of RVF in Kenya (mainly *Aedes* and *Culex spp.*) has clearly linked the risk of outbreak with flooding (Linthicum *et al.*, 1990). It can be expected that increased precipitation as a consequence of climate change could increase the risk of infections in livestock and people. Such new risks could cause major economic and health problems for herding communities in Africa.

10.2.4.5. Plague

Plague is a flea-borne disease with rodents as reservoirs. The population of rodents can increase suddenly following heavy rains as a result of abundance of food (e.g., grain). During drought, rodents may migrate into human dwellings in search of food. Development of fleas and the pathogens they carry can be accelerated by increased temperature. Plague outbreaks recently have been reported in Mozambique, Namibia, Malawi, Zambia, and Uganda (see WHO Outbreak Web site: <www.who.int/disease-outbreak-news>).

10.2.4.6. Water-Associated Protozoal Diseases

Pollution of streams, wells, and other sources of rural water supplies by flooding could introduce parasites such as giardia, amoeba, and cryptosporidium into drinking water (Alterholt *et al.*, 1998). These parasites assume a new significance in HIV-infected individuals because of the latter's immunocompromised status (Mwachari *et al.*, 1998). Extreme weather events such as

El Niño have been associated with increased episodes of diarrhea.

10.2.4.7. Other Major Parasitic Infections

Shifts in the epidemiology of schistosomiasis, onchocerciasis, and filariasis may take longer to become evident because these parasites are less sensitive to the effects of climate than diseases such as malaria. Changes in the impacts of climate on human trypnosomiasis may require substantial and permanent changes in tsetse fly ecology. Little or no data are available on this subject.

10.2.4.8. Air Pollution-Associated Diseases

Biomass burning and massive importation of badly maintained vehicles could result in increased air pollution—which, combined with increasing temperature, would exacerbate health risks such as respiratory problems and eye and skin infections (Boko, 1988).

10.2.4.9. Vulnerability

Evidence is emerging that many ecosystems on the African continent carry risks of climate-driven threats to human health. Predisposing factors include geographic location, socioeconomic status, and knowledge and attitude toward preventive measures. For example, populations living above 1,500 m in the east African highlands are at risk of epidemic malaria (Lindsay and Martens, 1998); those living along the shores of the Indian Ocean and the Great Lakes are at a risk of cholera infections when conditions for transmission are suitable (Birmingham *et al.*, 1997; Shapiro *et al.*, 1999).

Elsewhere in the Sahel and other arid areas where there are humidity deficits, populations are exposed to meningococcal meningitis (Tikhomirov *et al.*, 1997) and, in flood-prone pastoral areas, RVF (Linthicum *et al.*, 1990). Vulnerability also can be increased by close habitation with animals that are reservoirs of zoonotic diseases such as RVF and plague.

The socioeconomic status of communities may determine whether safe drinking water (piped water, rain-harvested water, and protected wells) is available (Sabwa and Githeko, 1985). The quality of housing is important because simple measures such as screening windows and doors will prevent the entry of disease vectors into human dwellings.

Human factors such as knowledge and attitude and practice will influence health care-seeking behavior of an individual (Karanja *et al.*, 1999). For example, individuals may choose to visit a local healer instead of a clinical facility, and this could affect the progression and outcome of an infection.

At the institutional level, the fragile infrastructure is unable to cope with the impacts of diseases. For example, flood areas

often are inaccessible, and delivery of medical intervention is hampered considerably. Furthermore, pathogens such as those of malaria and cholera are resistant to commonly used medication. In the case of malaria, more than 60% of cases are treated at home (Reubush *et al.*, 1995) with drugs that may not be effective (Karanja *et al.*, 1999), particularly in nonimmune populations. Misdiagnoses of fevers, especially during epidemics of uncommon and unfamiliar diseases, leads to delayed treatment and consequently high morbidity and mortality (CDC, 1998). In many cases, foreign assistance is required, and this assistance may come too late. These factors increase the vulnerability of affected populations.

10.2.4.10. Adaptation

Understanding how climate affects the transmission of these diseases will lead to enhanced preparedness for early and effective interventions. Monitoring drug sensitivity to commonly used anti-malaria drugs and antibiotics will prevent the use of ineffective interventions. Communities that are exposed to water-borne diseases such as cholera could reduce the risk of infections by using safe drinking water technologies.

Several large-scale studies in Africa have demonstrated that insecticide-treated fabrics (e.g., bed-nets and curtains) can significantly reduce the risk of malaria infections (Lengeler, 1998). However, such interventions are not effective against day-biting mosquitoes that are vectors of RVF.

Remote sensing is increasingly becoming an important tool in forecasting the risks of transmission in malaria, RVF, and cholera. Hay *et al.* (1998) have shown that the normalized difference vegetation index (NDVI) correlated significantly with malaria presentation, with a lag period of 1 month. NDVI is a function of climatic factors that are similar to those that affect malaria transmission. Ability to use remote sensing to accurately detect parameters such as ground moisture that determine flooding could provide local officials with sufficient warning to allow for implementation of specific mosquito control measures before a disease (RVF) outbreak (Linthicum *et al.*, 1990, 1999). In the case of cholera, it is now possible to utilize remote sensing and computer processing to integrate ecological, epidemiological, and remotely sensed spatial data for the purpose of developing predictive models of cholera outbreaks (Colwell, 1996).

10.2.4.11. Technology for Safe Drinking Water

Flooding, which can be exacerbated by climate change, often results in increased contamination of drinking water. In other instances, drought and an increase in surface water temperatures have been associated with transmission of cholera. Although *Cryptosporidium parvum* is the more important water-borne pathogen in developed countries, *Vibrio cholerae* is more pervasive in developing countries. *Giardia lumbria*, a water-borne protozoa, has a universal distribution. These pathogens

pose serious threat to individuals whose immune systems are compromised; furthermore, there are numerous records of resistance to antibiotics by cholera bacteria (e.g., Weber *et al.*, 1994). Therefore, it is essential that populations that are vulnerable to water-borne diseases should enhance safe drinking water technology.

Cryptosporidium parvum oocytes are very resistant to chlorine and other drinking-water disinfectants (Venczel *et al.*, 1997). In addition, the cysts have a very low sedimentation rate (Medema *et al.*, 1998); consequently, boiling may be the most appropriate method of disinfecting water where risks of infection exist (Willocks *et al.*, 1998). However, the use of submicron point-of-use water filters may reduce the risk of water-borne cryptosporidiasis (Addis *et al.*, 1996).

Several simple and inexpensive techniques have been found to be effective in reducing the risk of infection with cholera from contaminated water. Huo *et al.* (1996) found that a simple filtration procedure involving the use of domestic sari material can reduce the number of cholera vibrio attached to plankton in raw water from ponds and rivers commonly used for drinking water. In Bolivia, the use of 5% calcium hypochlorite to disinfect water and subsequent storage of treated water in a narrow-mouthed jar produced drinking water from nonpotable sources that met WHO standards for microbiologic quality (Quick *et al.*, 1996). In many cases, boiling water is not possible because of scarcity of firewood and charcoal, particularly in flooded conditions. These examples of low-cost technologies should become widely available to populations that are likely to be impacted by contaminated water supplies, especially following extreme flooding events.

10.2.5. Settlements and Infrastructure

10.2.5.1. Overview of Issues

The main challenges that are likely to face African populations will emanate from the effects of extreme events such as tropical storms, floods, landslides, wind, cold waves, droughts, and abnormal sea-level rises that are expected as a result of climate change. These events are likely to exacerbate management problems relating to pollution, sanitation, waste disposal, water supply, public health, infrastructure, and technologies of production (IPCC, 1996).

The pattern of distribution of human settlements often reflects the uneven nature of resource endowments and availability between regions and within individual communities. In Africa, as elsewhere, there are heavy concentrations of human settlements within 100 km of coastal zones (Singh *et al.*, 1999), in areas of high economic potential, in river and lake basins, in close proximity to major transportation routes, and in places that enjoy hospitable climatic regimes. Changes in climate conditions would have severe impacts not only on the pattern of distribution of human settlements but also on the quality of life in particular areas.

The transport sector is based on long-term, immovable infrastructure such as roads, rails, and water. Road networks have tended to link industrial centers with major areas of agricultural activity; railways have been designed primarily with a sea-route orientation to facilitate international shipments of primary products. Climate change may lead to industrial relocation, resulting either from sea-level rise in coastal-zone areas or from transitions in agroecological zones. If sea-level rise occurs, the effect on the many harbors and ports around the continent will be quite devastating economically for many coastal-zone countries. Excessive precipitation, which may occur in some parts of Africa, is likely to have serious negative effects on road networks and air transport.

10.2.5.2. Coastal Settlements and Sea-Level Rise

More than one-quarter of the population of Africa resides within 100 km of a sea coast (Singh *et al.*, 1999), rendering a significant number of people vulnerable to rises in sea level as a result of climate change. Modeling the effects of a 38-cm mean global sea-level rise in 2080, Nicholls *et al.* (1999) estimate that the average annual number of people in Africa impacted by flooding could increase from 1 million in 1990 to a worst case of 70 million in 2080. Jallow *et al.* (1999) estimate that the capital of The Gambia, Banjul, could disappear in 50–60 years through coastal erosion and sea-level rise, putting more than 42,000 people at risk. El Raey *et al.* (1999) discuss threats to coastal areas of Egypt from sea-level changes. East Africa coastal settlements also are at risk from sea-level rise (Magadza, 2000).

There are three response strategies to rising sea level and its physical impacts: retreat, adapt, or defend. Retreat can involve chaotic abandonment of property and cultural investments, or it can be an ordered, planned program that minimizes losses from rising sea level and maximizes the cost-effectiveness of the operation. The operation also seeks to leave surrendered areas as aesthetic looking as possible and to avoid abandoned structures that are an operational hazard to other social and economic activities.

The capacity of individual states to undertake coastal defense work may be limited. However, if such works are planned on a long-term time scale, it is possible to develop such defenses well before the crisis occurs and thus to spread the total capital costs over many years.

Because the problem of coastal management is regional, such a process would require:

- Regional integration among coastal-zone states
- Recognition by all governments in the region of regional vulnerability to climate change impacts
- Political and institutional stability that allows intergenerational projects to be sustained without interruption from political upheavals.

10.2.5.3. Flooding

Because of their combination of several natural resources, such as fisheries and fertile alluvial soils, wetlands and floodplains often are sites of dense rural settlements as well as urban settlements, such as N'Djamena near Lake Chad and coastal areas of southern Mozambique. The east Africa floods of 1998 and the Mozambique floods in early 2000 caused considerable damage to property and infrastructure. The major infrastructure damage was road and rail network damage. Communications among human settlements in Kenya, Uganda, Rwanda, and Tanzania were seriously disrupted, impeding movement of goods and persons in the region (Magadza, 2000). Many refugees could not be reached by land in Somalia, resulting in significant depletion of their food and medical supplies and leading to mortalities. Road and rail links to seaports were disrupted. In both instances, relief operations were hampered by difficulty of access to affected communities. In Mozambique, the floods of early 2000 caused approximately 2 million people to be displaced or severely affected; about 600 died (<<http://www.reliefweb.int>>, accessed October 10, 2000). By October 2000, the estimated cost of the Mozambique floods stood at more than US\$167 million in terms of emergency aid funds during the flooding and in immediate activities to rehabilitate the infrastructure and relocate displaced persons. The impact on the national economy is still being evaluated but is expected to be significant.

One identifiable adaptive measure against extreme events that are climate related is a state of preparedness to give adequate warning of imminent danger and deliver relief. Facilities to broadcast timely information of developing events such as storms to rural populations remain weak. National disaster plans are available in some countries, but financial resources to respond to emergencies are lacking. The ability to convey impacts quickly to the international media is a factor in the speed and amount of relief. Recent events in Mozambique and other countries of southern and east Africa will provide useful lessons in dealing with similar disasters; there is great value in studying these events not only from the physical point of view—as the Climate Variability and Predictability Program (CLIVAR) is proposing in a new Africa program; see <<http://www.dkrz.de/clivar/hp.html>>—but also from the social point of view.

There is a need for better understanding of the hydrology of river basins to identify vulnerable areas and plan coping mechanisms. Management of early warning systems depends on good understanding of the dynamics of flood systems in real time.

Because river basins sometimes involve more than one state, as in the Somalia floods, an effective flood management protocol will call for international cooperation. A regular bulletin of flood development in Ethiopia would have given the coastal inhabitants of Somalia time to prepare for damage minimization. In the Mozambique floods of 1996–1997, for example, the trigger was heavy rains in the Shire River basin. If the Shire and Zambezi Rivers were managed as one basin system, it

would have been possible to alleviate flooding in the Zambezi delta by manipulating Zambezi river flow, using the flood control capacity of Lakes Kariba and Kabora Bassa.

A further need in formulating adaptive strategies is more refined regional climate change scenarios—especially a better understanding of extreme events. In southern Africa, for example, most of the regional climate change scenarios are rather ambivalent with regard to precipitation (Hulme, 1996). In the 1998–1999 season, the city of Harare suffered damage to its roads because sewer transport could not cope with entrained stormwater. If it were accepted that the frequency of such seasons would increase, future designs of infrastructure amenities would take cognizance of that prediction.

10.2.5.4. Energy

Threats to energy security from climate change impacts are outlined in Section 10.2.1. Disruption of energy supplies will have ripple effects in the social fabric through impacts in economic activity. Some adaptation options for the energy needs of settlements in the African region are in three broad areas:

- Regional cooperation in sharing hydroelectric potential of the continent, especially that of the Zaire River
- More intensive use of renewable energy, such as solar and wind energy and biogas
- Efficient use of biomass.

The countries of the southern and central African region (Democratic Republic of the Congo, Zambia, Zimbabwe, Botswana, South Africa, Mozambique, Namibia) already are networked on an electric power grid system. Climate change models to date indicate minimum changes in the hydrology of the Congo basin, whereas other basins have significant vulnerability to climate change. A regional project to develop the hydropower potential of the Congo basin could significantly increase the energy security of the region without resort to GHG-emitting, coal-driven thermal power plants.

Alternatives to biomass are wind-driven units, either as direct application of wind force—as in water-pumping windmills—or for generation of electricity, as in the windmill farms of Denmark. Biogas units, which utilize livestock dung, have been demonstrated successfully in rural areas of Zimbabwe.

10.2.5.5. Human Comfort

McMichael *et al.* (1996) found a relationship between ambient temperature and heat-related mortalities in Cairo, Egypt. This suggests a need to consider building technology and building materials' thermal properties to produce dwellings that are naturally climatically comfortable for tropical conditions. In Africa, there is a tendency to construct dwellings that do not take account of local climate because of inadequate natural ventilation and use of large decorative glass surfaces. Similarly, urban

planners need to consider landscaping to avoid inner-city congestion that leads to unhealthy microclimate enclaves.

A combination of high temperatures and air pollution leads to increases in respiratory complaints. Clean air policies would not only alleviate health hazards but would be a contribution toward maintenance of the ozone layer in line with the Montreal Protocol. Sudden imposition of stringent air quality standards may cause undue strain to the economy, but graduated improvement of air quality standards, at a pace the economy can absorb, will be beneficial in terms of adaptation to climate change as well as general city health improvement.

10.2.5.6. Water Resources

Section 10.2.1 argues that future water resources for subhumid regions of Africa will be in jeopardy under global warming conditions. The impact of climate change to settlements, through the water resources pathway, will have multiple manifestations in all walks of life.

Adaptive measures include incentives for a water conservation culture, such as water pricing. However, many rural communities are not economically or culturally attuned to commercialization of water resources, which normally are administered in a common access mode. Commoditization of water resources as a strategy for efficient water use is contingent on comparable growth of economic activity and social well-being in all sectors of communities.

Land degradation has resulted in siltation thus disappearance of surface streamwater resources (Magadza, 1984). States are encouraged to consider measures that will rehabilitate streams, paying special attention to wetlands conservation, with an added bonus of biodiversity conservation.

Industrial water cycling in Africa is poorly developed. Processes that maximize water recycling should be encouraged.

At the regional level, there are beginnings of cooperation in interbasin transfers from water-surplus areas to water-deficit areas; the proposed diversion of Zambezi River waters toward the south is an example. Although this development will enhance the status of water and other natural resources as tradable commodities, the groundwork for legal regulation of water sharing between nations of the region must be developed sooner rather than later to avoid situations of water-related political tensions like those in the Middle East and north Africa (Caponera, 1996).

10.2.5.7. Sanitation

Section 10.2.4 draws attention to the possible health implications of climate change and climate variability through vector- and water-borne pathogens. In many African urban settlements, urban drift has outpaced the capacity of municipal authorities

to provide civic works for sanitation and other health delivery services. The outbreak of cholera during recent floods in east Africa and Mozambique underscores the need for adequate sanitation. It should be noted that although the outbreaks were spread from as far north as Mombassa and Nairobi in the north to Beira in the south, incidences remained localized to the outbreak centers because of the isolated nature of the affected urban areas. If settlement conglomerations such as those envisaged for west Africa and the eastern seaboard of South Africa develop—as discussed by Nicholls *et al.* (1999)—vulnerable population and areas will tend to be regional, rather than local. Review of sanitary facilities now rather than later will not only be beneficial to communities now but in the long run will be cost saving for long-term health delivery services.

10.2.5.8. Food Security

Droughts in SSA often translate to famine, which leads to acceleration of urban drift to cities that are not equipped to absorb such migrations. Although maintenance of strategic food reserves is one coping mechanism, development policies increasingly must create other investment opportunities in rural areas besides agriculture, to diversify means of survival and, indeed, create rural wealth (De Latre, 1988).

In semi-arid Africa, pastoralism is the main economic activity. Many pastoral communities include transnational migrants in search of new seasonal grazing. In drought situations, such pastoralists may come into conflict with settled agrarian systems (Anon, 1992; Lado, 1995; Cousins, 1996). Students of pastoralism note the lack of clear policies on pastoralists, who normally are marginalized in state agricultural policies.

10.2.6. Desertification

10.2.6.1. Context

The United Nations Convention to Combat Desertification (UNCCD) defines desertification as “land degradation in arid, semi-arid, and dry subhumid areas resulting from various factors, including climatic variations and human activities” (United Nations, 1994). Furthermore, UNCCD defines land degradation as a “reduction or loss, in arid, semi-arid, and dry subhumid areas, of the biological or economic productivity and complexity of rain-fed cropland, irrigated cropland, or range, pasture, forest, and woodlands resulting from land uses or from a process or combination of processes, including processes arising from human activities and habitation patterns, such as: (i) soil erosion caused by wind and/or water; (ii) deterioration of the physical, chemical, and biological or economic properties of soil; and (iii) long-term loss of natural vegetation.”

Arid, semi-arid, and dry subhumid areas include those lands where the ratio of precipitation to potential evaporation (PET) ranges from 0.05 to 0.65. In Africa, these conditions cover 13 million km² (see Figure 10-9), or 43% of the continent’s land

area—on which 270 million people, or 40% of the continent’s population, live (UNDP, 1997). Areas particularly at risk include the Sahel—a 3.5 million km² band of semi-arid lands stretching along the southern margin of the Sahara Desert—and some nations that consist entirely of drylands (e.g., Botswana and Eritrea). The death of as many as 250,000 people in the Sahel drought of 1968–1973 (UNCOD, 1977) demonstrated the tragic human toll of desertification.

Desertification in Africa has reduced by 25% the potential vegetative productivity of more than 7 million km², or one-quarter of the continent’s land area (UNEP, 1997). Desertification consists more of degradation of the productive capacity of patches well outside open-sand deserts rather than the inexorable encroachment of open sand onto greenlands. Arid lands can respond quickly to seasonal fluctuations. Indeed, analysis of 1980–1990 NDVI data to track the limit of vegetative growth along the Sahara-Sahel margin revealed wide fluctuations: The 1990 limit of vegetative growth lay 130 km south of its 1980 position (Tucker *et al.*, 1991).

Unfortunately, the relative importance of climatic (see Section 10.2.6.3) and anthropogenic (see Section 10.2.6.2) factors in causing desertification remains unresolved. Some scientists have judged that anthropogenic factors outweigh climatic factors (Depierre and Gillet, 1971; Lamprey, 1975; Le Houérou, 1989; Westing, 1994), though others maintain that extended droughts remain the key factor (Mortimore, 1989; Hoffman and Cowling, 1990; Tucker *et al.*, 1991; Dodd, 1994). CO₂-induced climate change and desertification remain inextricably linked because of feedbacks between land degradation and precipitation (see Section 10.2.6.4).

10.2.6.2. Nonclimatic Driving Forces of Desertification

Unsustainable agricultural practices, overgrazing, and deforestation constitute the major anthropogenic factors among the forces that drive desertification. Unsustainable agricultural practices include short rotation of export crops, undisciplined use of fire, and removal of protective crop residues. Overgrazing consists of running livestock at higher densities or shorter rotations than an ecosystem sustainably can support. Finally, deforestation consists of permanent clearing of closed-canopy forests and cutting of single trees outside forests. Forest area in Africa decreased by approximately 37,000 km² yr⁻¹ from 1990 to 1995 (FAO, 1999a). UNEP (1997) attributes two-thirds of the area already desertified in Africa to overgrazing and the remaining third to unsustainable agricultural and forestry practices.

Population growth ultimately can drive desertification if it intensifies agrosylvopastoral exploitation or if it increases the land area subjected to unsustainable agricultural practices, overgrazing, or deforestation. The total population of Africa grew from 220 million in 1950 to 750 million in 1998—a rate of 2.5% yr⁻¹ (United Nations, 1999). Increasing food, wood, and forage needs accompanying this growth place an inordinate burden on the region’s natural resources.

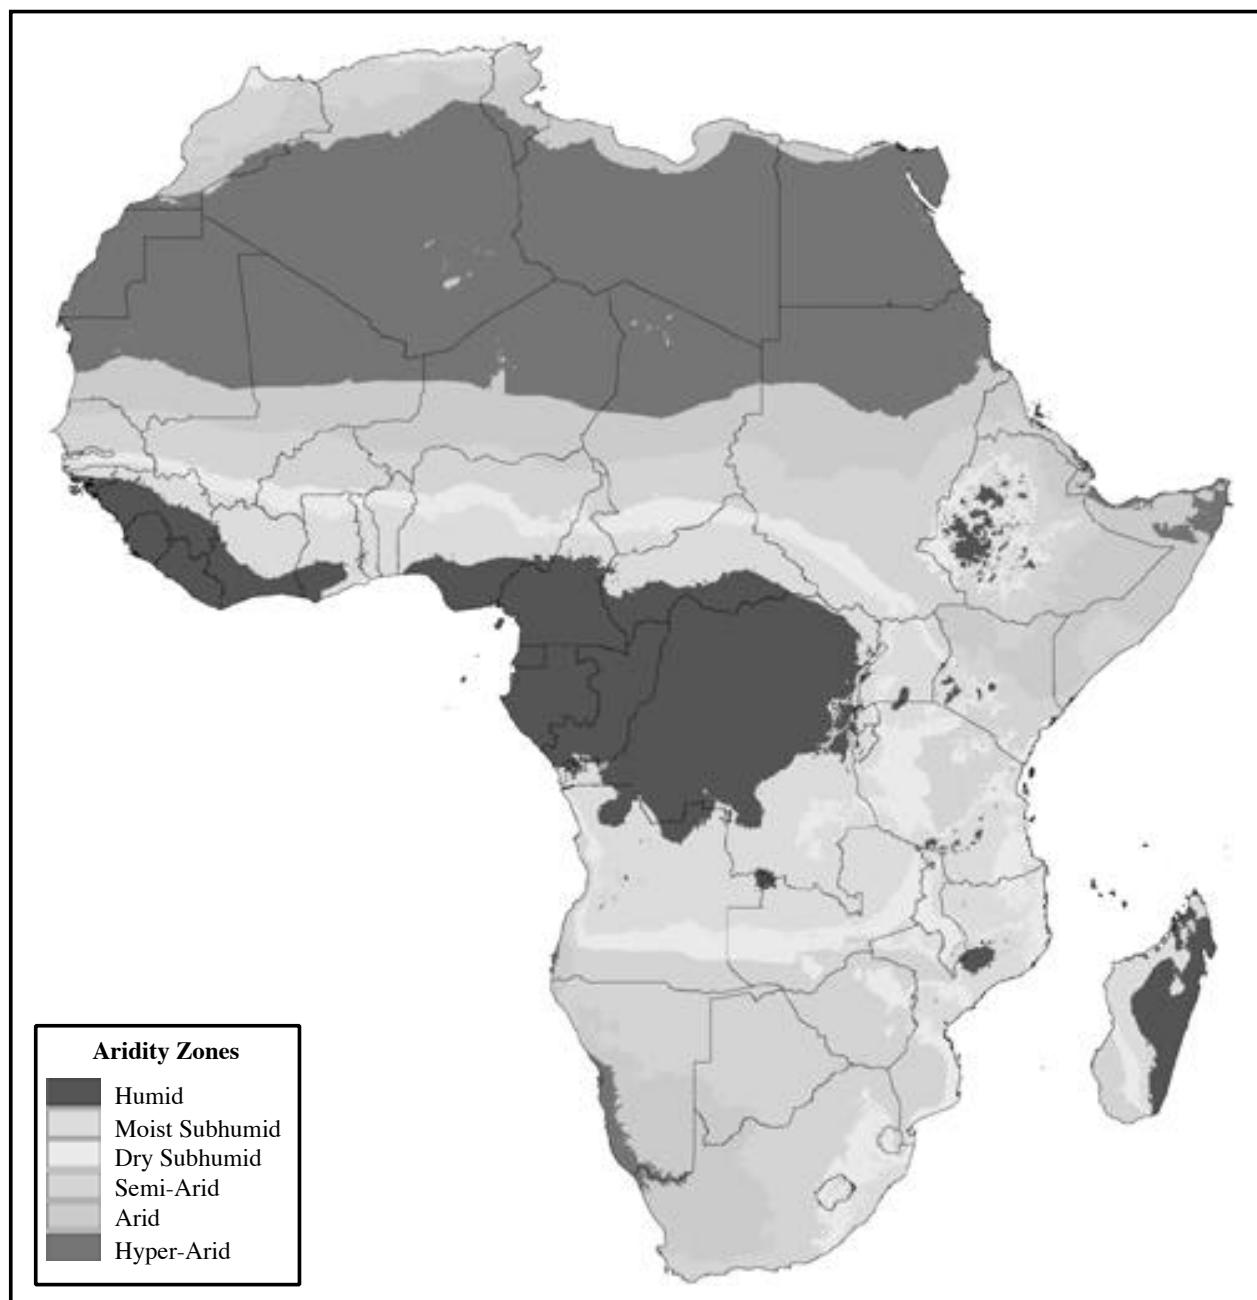

Figure 10-9: Aridity zones for Africa as derived from mean monthly precipitation and potential evapotranspiration surfaces included on *Spatial Characterization Tool for Africa CD-ROM* (UNDP, 1997).

10.2.6.3. Climatic Factors in Desertification

Precipitation and temperature determine the potential distribution of terrestrial vegetation and constitute principal factors in the genesis and evolution of soil. Extended droughts in certain arid lands have initiated or exacerbated desertification. In the past 25 years, the Sahel has experienced the most substantial and sustained decline in rainfall recorded anywhere in the world within the period of instrumental measurements (Hulme and

Kelly, 1997). Linear regression of 1901–1990 rainfall data from 24 stations in the west African Sahel yields a negative slope amounting to a decline of 1.9 standard deviations in the period 1950–1985 (Nicholson and Palao, 1993). Since 1971, the average of all stations fell below the 89-year average and showed a persistent downward trend since 1951.

Because evapotranspiration constitutes the only local input to the hydrological cycle in areas without surface water, reduction

in vegetative cover may lead to reduced precipitation, initiating a positive feedback cycle. Degradation of vegetation cover in moister areas south of the Sahel may have decreased continental evapotranspiration and reduced precipitation in the Sahel (Xue, 1997).

A positive feedback mechanism between vegetation cover and albedo may help to explain the Sahel drought (Charney, 1975). Some research supports an albedo-precipitation feedback mechanism (Otterman, 1974; Cunnington and Rowntree, 1986; Xue *et al.*, 1990; Diedhiou and Mahfouf, 1996; Zheng and Eltahir, 1997; Zeng *et al.*, 1999), although other research disputes the importance of albedo (Jackson and Idso, 1974; Ripley, 1976; Wendler and Eaton, 1983; Gornitz and NASA, 1985; Nicholson *et al.*, 1998; Nicholson, 2000).

Degraded land also may increase atmospheric dust and aerosols, which influence precipitation (see Section 10.1.3.2).

SST anomalies, often related to ENSO or NAO, also contribute to rainfall variability in the Sahel (Lamb, 1978; Folland *et al.*, 1986; Hulme and Kelly, 1997; Nicholson and Kim, 1997; Hulme *et al.*, 1999). Lamb (1978) observes that droughts in west Africa correlate with warm SST in the tropical south Atlantic. Examining oceanographic and meteorological data from the period 1901–1985, Folland *et al.* (1986) found that persistent wet and dry periods in the Sahel were related to contrasting patterns of SST anomalies on a near-global scale. When northern hemisphere oceans were cold, rainfall in the Sahel was low.

Street-Perrott and Perrott (1990) demonstrate that injections of freshwater into the north Atlantic (such as from glacial melt) decrease salinity—stabilizing the water column, inhibiting deep convection, and reducing northern transport of heat by the Atlantic thermohaline circulation, which is driven by a north-south SST gradient. This decreases evaporation from the ocean surface, causing drought in the Sahel and Mexico. From 1982 to 1990, Mynemi *et al.* (1996) found a correlation between ENSO-cycle SST anomalies and vegetative production in Africa. They found that warmer eastern equatorial Pacific waters during ENSO episodes correlated with rainfall of <1,000 mm yr⁻¹ over certain African regions.

A combination of factors—including vegetation cover, soil moisture, and SST—best explains the reduction in rainfall in the Sahel. Diedhiou and Mahfouf (1996) modeled changes in albedo, soil moisture, land surface roughness, and SST anomalies and calculated a rainfall deficit over the Sahel similar to observed patterns. Eltahir and Gong (1996) suggest that a meridional distribution of boundary-layer entropy regulates the dynamics of monsoon circulation over west Africa, explaining observed correlations of SST to rainfall and the sensitivity of monsoon circulation to land-cover changes. A coupled surface-atmosphere model indicates that—whether anthropogenic factors or changes in SST initiated the Sahel drought of 1968–1973—permanent loss of Sahel savanna vegetation would permit drought conditions to persist (Wang and Eltahir, 2000). Zeng *et al.* (1999) compared actual rainfall data from the period 1950–1998 with

the output of a coupled atmosphere-land-vegetation model incorporating SST, soil moisture, and vegetative cover. Their results indicate that actual rainfall anomalies are only weakly correlated to SST by itself. Only when the model includes variations in vegetative cover and soil moisture does it come close to matching actual rainfall data. Modeling the importance of SST, sea ice, and vegetative cover to the abrupt desertification of the Sahara 4,000–6,000 years ago, Claussen *et al.* (1999) show that changes in vegetative cover best explain changes in temperature and precipitation.

10.2.6.4. Linkages and Feedbacks between Desertification and Climate

CO₂-induced climate change might exacerbate desertification through alteration of spatial and temporal patterns in temperature, rainfall, solar insolation, and winds. Conversely, desertification aggravates CO₂-induced climate change through the release of CO₂ from cleared and dead vegetation and through the reduction of the carbon sequestration potential of desertified land.

Areas that experience reduced rainfall and increased temperature as a result of CO₂-induced climate change also could experience declines in agricultural yields, livestock yields, and tree cover, placing local people at risk of famine.

Lower soil moisture and sparser vegetative cover also would leave soil more susceptible to wind erosion. Reduction of organic matter inputs and increased oxidation of soil organic matter (SOM) could reduce the long-term water-retention capacity of soil, exacerbating desertification. Sample plots in Niger lost 46 t ha⁻¹ in just four windstorms in 1993 (Sterk *et al.*, 1996), releasing 180 ± 80 kg ha⁻¹ yr⁻¹ of soil carbon (Buerkert *et al.*, 1996). Moreover, increased wind erosion increases wind-blown mineral dust, which may increase absorption of radiation in the atmosphere (Nicholson and Kim, 1997).

Desertification from anthropogenic and climatic factors in Senegal caused a fall in standing-wood biomass of 26 kg C ha⁻¹ yr⁻¹ in the period 1956–1993, releasing carbon at the rate of 60 kg C cap⁻¹ yr⁻¹ (Gonzalez, 1997).

Although altered surface albedo may increase surface air temperatures locally (Williams and Balling, 1996), the effect of desertification on global mean temperature is unlikely to have exceeded 0.05°C in the past century (Hulme and Kelly, 1997).

10.2.6.5. Impacts of Desertification

Desertification reduces soil fertility, particularly base cation content, organic matter content, pore space, and water-retention capacity. Desertification also reduces vegetative productivity, leading to long-term declines in agricultural yields, livestock yields, plant standing biomass, and plant biodiversity. These changes reduce the ability of the land to support people, often sparking an exodus of rural people to urban areas. Breaking the

strong connection of people to the land produces profound changes in social structure, cultural identity, and political stability.

In Niger, on farmed land where organic carbon in the top 10 cm of the soil has fallen from 0.3 to 0.2% 4 years after coming out of fallow, millet yields fell from 280 to 75 kg ha⁻¹ (Bationo *et al.*, 1993). Modeling of the 4,000 km² Mgeni River watershed in South Africa showed that conversion of more than one-quarter of the watershed from forest and rangeland to agriculture and exotic tree plantations since the area was colonized would double mean annual runoff in urban areas and other areas of reduced land cover (Schulze, 2000).

In the Senegal Sahel, the densities of trees with a height of >3 m declined from 10 trees ha⁻¹ in 1954 to 7.8 trees ha⁻¹ in 1989; the species richness of trees and shrubs fell from 16 species per 4 km⁻² around 1945 to about 11 per 4 km⁻² in 1993 (Gonzalez, 1997, 2001). These changes have caused a 25–30 km shift of the Sahel, Sudan, and Guinean vegetation zones in half a century, proceeding at an average rate of 500–600 m yr⁻¹. Arid Sahel species expanded in the northeast, tracking a concomitant retraction of mesic Sudan and Guinean species toward areas of higher rainfall and lower temperature to the southwest.

In the Senegal Sahel, human carrying capacity in 1993 stood at approximately 13 people km⁻² at observed patterns of resource use, compared to an actual 1988 rural population density of 45 people km⁻² (Gonzalez, 1997, 2001). This means that people with no other alternatives need to cut into their natural resource capital to survive. Such changes across Africa have pushed a rural exodus that may have displaced 3% of the population of Africa since the 1960s (Westing, 1994).

Desertification also will cause conversion of perennial grasslands to savannas dominated by annual grasses. Such changes have occurred in the Kalahari Gemsbok National Park in South Africa, where Landsat imagery showed increases in exposed soil surface (Palmer and van Rooyen, 1998). Such declines often are irreversible (Schlesinger *et al.*, 1990).

10.2.6.6. Vulnerability and Adaptation

The tragic death of as many as 250,000 people in the Sahel drought of 1968–1973 (UNCOD, 1977) demonstrates the vulnerability of humans to desertification. As desertification proceeds, agricultural and livestock yields decline, reducing people's options for survival. Furthermore, not only do local people lose the vital ecosystem services that dead trees and shrubs had provided; the loss of firewood, traditional medicine species, and emergency food species render them more vulnerable to future environmental change.

Adaptations by farmers and herders in Africa to climate change and desertification have involved diversification and intensification of resource use (Davies, 1996; Downing *et al.*, 1997). Resourceful diversification responses by women in Bambara and Fulbe

households in Mali (Adams *et al.*, 1998) reflect the importance of women in guiding adaptation strategies across Africa. In southern Kenya, Maasai herders have adopted farming as a supplement to or replacement for livestock herding (Campbell, 1999). In Kano, Nigeria, peri-urban vegetable gardening has expanded (Adams and Mortimore, 1997), revealing a common diversification trend in small cities across west Africa. In northern Cameroon, Fulbe herders have increased the number of herd displacements between pasture areas and even resorted to long-distance migration, sometimes introducing significant changes to their way of life (Pamo, 1998).

In the future, seasonal climate forecasting (NOAA, 1999; Stern and Easterling, 1999) may assist farmers and herders to know times of higher probability of success of resource diversification or intensification. Seasonal forecasts for Africa currently exhibit moderate skill levels (Thiaw *et al.*, 1999) but skill levels and user communications are not yet high enough to permit users to confidently implement field applications (UNSO, 1999; Broad and Agrawala, 2000). Neither trade nor technology will likely avert the widespread nutritional and economic effects of desertification through the 2020s (Scherr, 1999).

Other adaptations to desertification involve more efficient management of resources. In Niger, farmers with access to credit will adopt low-cost, appropriate technologies for wind erosion control, including windbreaks, mulching, ridging, and rock bunds (Baidu-Forson and Napier, 1998). Across Africa, farmers traditionally have adapted to harsh environmental conditions by promoting natural regeneration of local trees and shrubs. Natural regeneration is a practice whereby farmers and herders seek to reconstitute vegetative cover by setting aside parcels of land or by selecting valued trees in their fields, pruning them, straightening them, and raising them to maturity. The Sereer in Senegal (Lericollais, 1973) and the Mossi in Burkina Faso (Kessler, 1992) have achieved doubling of tree densities in certain semi-arid areas with *Acacia albida* and *Butyrospermum parkii*, respectively.

10.3. Adaptation Potential and Vulnerability

The foregoing assessment highlights the high vulnerability of Africa to climate change as a result of limited adaptive capacity constrained by numerous factors at the national level. The floods of February 2000 in southern Africa (which affected Mozambique, South Africa, Botswana, and Zimbabwe) highlight huge differences in adaptive capacities between countries. Adaptive capacity was influenced largely by the ability to communicate potential risks to vulnerable communities and the ability to react as a result of perceived risks. The ability to mobilize emergency evacuation was critical in reducing adverse impacts. Although there may be high adaptive capacity locally or nationally, overall most countries in Africa have low capacity to adapt to abrupt and extreme events.

Scarce water resources are becoming increasingly critical for Africa; they determine food security as well as human and

ecosystem health, and play a major role in political and socioeconomic development. Although parts of Africa have abundant water, shifting water to stressed areas is not an option in many cases. Groundwater resources are likely to be impacted by prolonged droughts and changes in land cover and land use, in a complex interaction of human activity and population growth rates, climate, and environmental responses. Adaptation will require small actions as well as major national approaches. At the management unit level (e.g., watershed), careful management of rainwater through damming will allow agricultural production. There is vast experience in arid regions of Africa such as Namibia, Botswana, and north Africa (such as Morocco), where brief periods of rain are utilized very efficiently for farming. The constraint will be in finding limits to water extraction that do not adversely impact communities downstream and result in conflicts. Regional bodies set up to negotiate international water rights will play an increasingly crucial role. At the national level, political goals such as self-sufficiency in food production will need to be reevaluated with reference to water resources available to the country and how they can be apportioned between food production, human needs, and ecosystem needs. Countries will need to be more open to fulfilling their food needs through imports and redistribution, using intensified production in areas where it is possible. Good communications within and between countries and major ports are critical to food security. These include roads, rail, and air transportation networks. For inland countries, large corridors being opened up or upgraded (such as the Maputo, Nacala, and Beira corridors between Mozambique and South Africa, Malawi, and Zimbabwe) will greatly enhance access to food and other imported goods. This places greater importance on international relations.

At the subregional scale, Africa is vulnerable to ENSO and related extreme events (drought, floods, changed patterns). As shown by Semazzi and Song (2000), deforestation is likely to alter circulations in distant places through teleconnected feedbacks, increasing the vulnerability of distant populations. Advances in seasonal forecasting, using climate models and satellite observations, has been shown to be a first-order response strategy to changing climate variability. Similar applications of satellite observations (such as for SST) also are useful in predicting disease outbreaks such as RVF. Effective communication of predicted extreme weather events and evaluation of potential risks is critical in minimizing human loss of life, where it is possible to react. Disaster management plans are required and need to be developed jointly with all members of a community.

There is great potential in investing in seasonal forecasting and development of tools (models) such as crop models that can be used to make adjustments in management. Although these models are still experimental, they offer a realistic response to changing climatic patterns. Data must be collected to calibrate and validate these models. In the longer term, governments will need to develop strategic plans that are based on solid foundations. This is an area that is underdeveloped in almost all of Africa.

External funding drives programs in many African countries, so agendas usually align closely with donor agency interests. This situation presents a dilemma for Africa. There is capacity in many countries now to evaluate effective strategies to adapt to adverse effects of climate change. However, these countries are at the mercy of donor agency representatives who often are less informed about issues of climate change. These representatives often regard immediate problems of poverty, erosion, health, and empowerment as the only priority issues for Africa. Longer term planning—for example, land-use planning in areas that are susceptible to flooding under infrequent cyclonic events—never receives the attention it deserves. Most African countries are unlikely to motivate internal funding for climate change; therefore, it is critical that funding agencies award high visibility to issues of climate change.

10.4. Synthesis

Select key impacts over the African continent are highlighted in Figure 10-10. Water resources are a key vulnerability in Africa for water supply for household use and for agricultural and industrial use. In shared river basins, regional cooperation protocols minimize adverse impacts and potential for conflicts. Land use in many of Africa's large and shared basins has long-lasting impacts through modifications of the water budget and through chemical and sediment input into waterways. Water issues in urban and rural areas are likely to become more critical, given increasing and competing demands, as well as rapid population growth. Infrastructure to store and serve water in major urban areas is mostly overstretched in capacity, and extreme events such as floods that cause physical damage add to the problem. Monitoring of water levels and water use is very poor and limits analysis of vulnerability.

There is wide consensus that climate change will worsen food security, mainly through increased extremes and temporal/spatial shifts. The continent already experiences a major deficit in food production in many areas, and potential declines in soil moisture will be an added burden. Food-insecure countries are at greater risk of adverse impacts of climate change.

Irreversible losses of biodiversity could be accelerated with climate change. Climate change is expected to lead to biome shifts, with drastic shifts of biodiversity-rich biomes such as the Succulent Karoo in South Africa, and many losses in species in other biomes. Analysis of potential biome shifts is possible in areas where good spatial databases of vegetation and biophysical variables and land use are available. It is expected that these analyses will improve as more data are available from new and better satellite sensing systems, as well as coordinated field studies in shared resource areas.

Changes in temperature and rainfall will have many negative impacts on human health. Changes in disease vector habitats will expose new populations to diseases such as malaria. Droughts and flooding, where sanitary infrastructure is inadequate,

will result in increased frequency of water-borne diseases. Increased rainfall could lead to more frequent outbreaks of RVF. Many African nations do not have adequate financial resources for public health.

Sea-level rise, coastal erosion, saltwater intrusion, and flooding will have significant impacts for African communities and economies. Most of Africa's largest cities are along coasts and are highly vulnerable to extreme events, sea-level rise, and coastal erosion as a result of inadequate physical planning and escalating urban drift. Rapid unplanned expansion is likely to predispose large populations to infectious diseases from climate-related factors such as flooding.

Desertification is a critical threat to sustainable resource management in arid, semi-arid, and dry subhumid regions of Africa, undermining food and water security.

A diversity of constraints facing many nations limits overall adaptive capacity for Africa. Although there is uncertainty about what the future holds, Africa must start planning now to adapt to climate change. Current technologies and approaches—especially in agriculture and water—are unlikely to be adequate to meet projected demands, and increased climate variability will be an additional stress. It is unlikely that African countries on their own will have sufficient resources to respond effectively.

Climate change also offers some opportunities. The processes of adapting to global climate change, including technology transfer and carbon sequestration, offer new development pathways that could take advantage of Africa's resources and human potential. Regional cooperation in science, resource management, and development already are increasing, and access to international markets will diversify economies and increase food security.

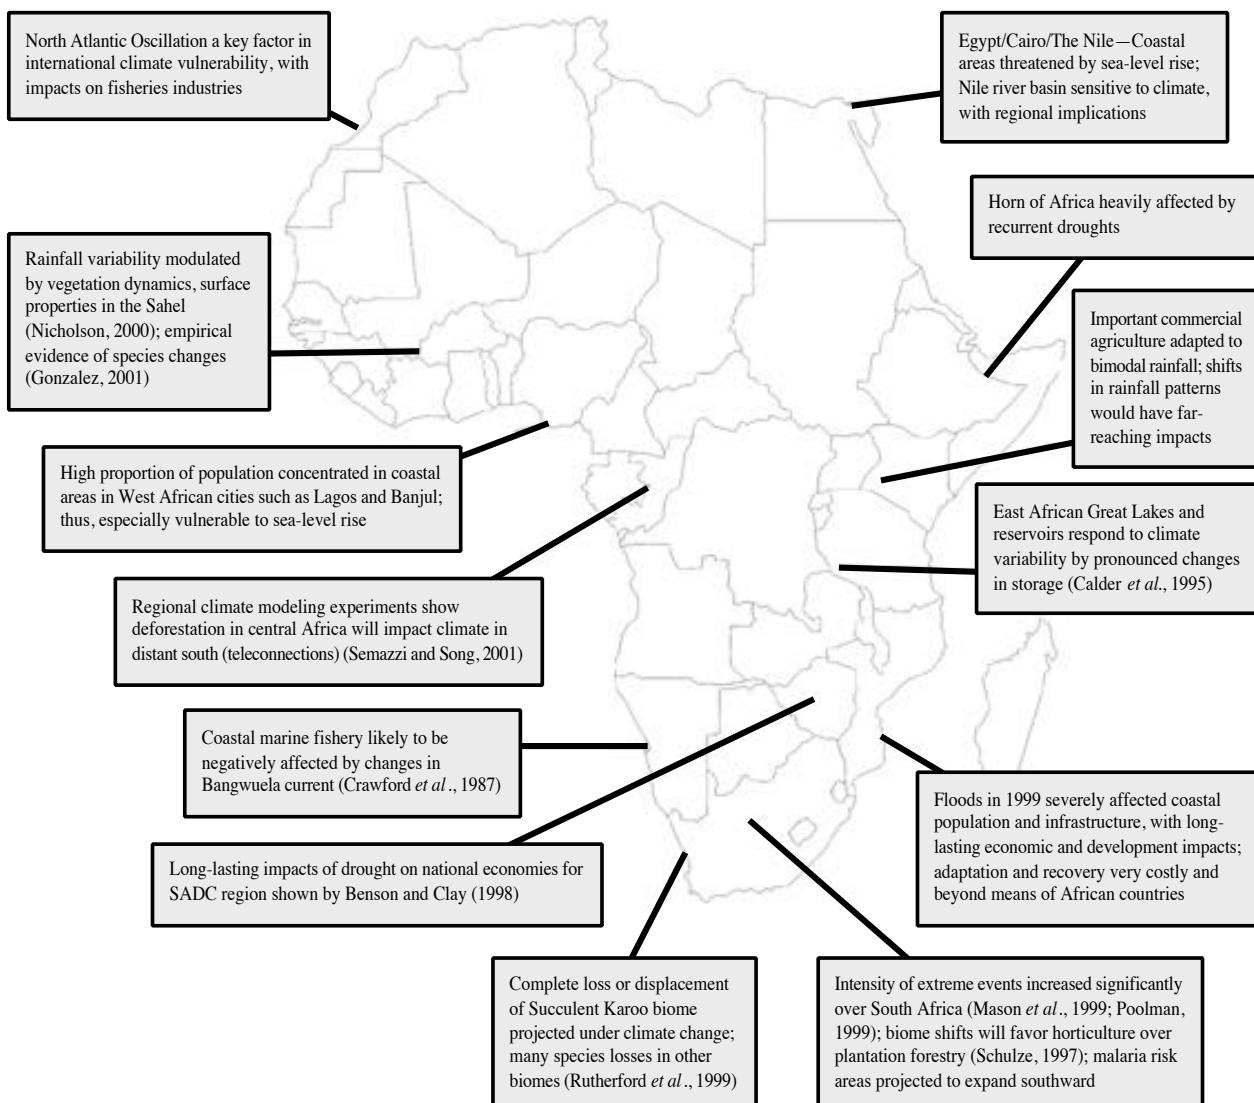

Figure 10-10: Selected key impacts for Africa.

10.4.1. Feedbacks and Interactions

Several integrated studies have looked at feedbacks and complex interactions in African regional systems. In the west African Sahel, land surface-atmosphere interactions have been examined in great detail to explore their role in interannual variability of rainfall since the long drought that started in the late 1960s. Reviews by Nicholson (2000) and Hunt (2000) summarize the state of knowledge for the physical climate of the Sahel. In general, surface processes modulate rainfall variability, along with SST—but in complex ways. The Sahel is likely to remain a major study topic, and field-based observational studies are on the rise. A field campaign in 1992 called the Hydrologic Atmosphere Pilot Experiment (HAPEX)—Sahel was designed to find ways of improving modeling of land surface properties; a series of HAPEX-Sahel papers were published in a special issue of the *Journal of Hydrology* (Goutourbe *et al.*, 1997). More recently, a regional land-atmosphere experiment is underway in southern Africa to study fires and emissions, with modeling studies planned to explore land-atmosphere linkages (see <<http://safari.gecp.virginia.edu>>, accessed October 2000). These studies—and integrated modeling in general—offer comprehensive tools for studying the integrated Earth system. More studies of this kind will assist in our understanding of linkages between land surface processes, regional and global linkages, and human activities.

Biomass burning plays an important role in global atmospheric chemistry (Andreae, 1991), particularly with respect to generation of trace gases that lead to the formation of tropospheric O₃, carbon monoxide (CO), nitrogen oxides, CH₄, volatile organic carbon (VOC, which also is a GHG), and smoke particles (aerosols), which have an anti-greenhouse effect. Africa is a significant location of biomass burning. In Africa, there are three main types of biomass fires: those associated with land clearing for agriculture, which are mostly located in humid tropical forests and the subhumid tropics; burning of wood for domestic energy (either directly or after first converting it to charcoal); and fires in natural and semi-natural vegetation, which are not associated with changes in land cover or use. Emissions from all three types are of broadly comparable magnitude (Scholes and Scholes, 1998), although the last category has received the most attention.

Fires in natural vegetation are not considered to be a net source or sink in the global carbon cycle because when integrated over large regions and over several years, CO₂ (as well as CO, CH₄, and VOC, which ultimately converts to CO₂) emitted by the fire is taken up again by vegetation regrowth. This is true if the overall fire frequency or intensity is not changing, but if fires become more frequent or consume more fuel over time, the result will be a net CO₂ source; conversely, if fire frequency is reduced or the fires burn less fuel, a carbon sink will result, manifested as an increase in woody biomass. There is no evidence that at a continental scale, fires in natural vegetation have increased or decreased in frequency or intensity in the historic period. For some subregions (such as parts of southern and east Africa), where there is clear thickening of the woody

vegetation, it is likely that fire regimes have become less frequent and intense during the 20th century.

During years of regional drought, such as those in southern Africa associated with El Niño events, the area burned decreases by about half (Justice *et al.*, 1996). It is believed that this is caused principally by a decrease in fuel availability.

The potential for teleconnections in impacts of land-use change on distant climates further increases the risk in communities that may be at low risk but will be impacted by actions taken in distant areas. For example, deforestation of the central African basin leads to climatic impacts in the savannas to the south in GCM modeling experiments (Semazzi and Song, 2001).

It is clear that rainfall (e.g., intensity) combined with land-use conversion in watershed areas leads to increased soil erosion. Enhanced siltation in rivers and increased use of chemicals also leaching into the runoff interferes with river chemistry (e.g., eutrophication), with major implications for water quality in lakes and coastal systems. Impacts on biodiversity—hence important economic fisheries, and consequent feedback on national economies—is an area of research that needs elucidation.

10.4.2. Uncertainties and Risks

There is great uncertainty about how climate might change at subregional scales in parts of Africa, especially how this might be influenced by human-driven factors such as deforestation and alternative land uses. Regional climate modeling will help reduce these uncertainties, and there are early results now of such modeling for parts of Africa. For these results to be useful, they will have to incorporate realistic disturbance regimes (e.g., realistic deforestation mechanisms and land-use characterizations).

Climate change will manifest itself through changes in climate variability and hence changes in extreme events. Given its socioeconomic status, Africa is unlikely to respond any better to extreme events than it has in the past. Flooding, droughts, and so forth are increasingly difficult for Africa to cope with given increasing pressures on resources from rapid population growth and dwindling resources. Most African countries remain largely unable to gather adequate data and information in a timely manner to address critical problems and surprises such as droughts and floods. Although progress is being made to design environmental information systems, models for analyzing impacts and policy options are largely nonexistent. Although adequate data probably exist, what is needed is the capacity to access large amounts of data and synthesize it into useful bits of information for decisionmaking. For example, satellite data have been collected over the past 2 to 3 decades, yet their use is largely restricted to mapping and short-term climate predictions. Effective information systems and monitoring have not been achieved.

Evaluation of impacts in monetary or other quantitative terms remains a major obstacle to comprehensive assessment of impacts of climate change for Africa. Regional integrated assessment modeling, such as in Egypt (Yates and Strzepek, 1998), offers a solution, and model development should be accelerated for subregions of Africa where building blocks exist (Desanker *et al.*, 2001).

ENSO-related impacts remain uncertain, given perceived changes in ENSO events in terms of frequency and duration. However, much progress is being reported in prediction of ENSO, and this information should be closely linked with case studies of how different regions and populations respond to specific climate-related events. These studies should document costs and benefits, as well as responses.

10.4.3. Cross-Cutting Issues

10.4.3.1. Costing

In some of the sectors affected by climate change—such as water resources, food security, and natural resources—it may be possible to attach financial values. At this point, there are few if any published data on the economic impacts of climate change on these sectors in Africa. However, there are indications of what it costs to support communities that have been affected by famine and floods. Because most of this is foreign aid, it is difficult to evaluate costs in relation to individual country economies. There are indications that water shortages have a negative impact on power generation and consequently economic activities. It is acknowledged that some elements such as health are difficult to cost. Nevertheless, the financial impacts of dealing with epidemics such as malaria, meningitis, and cholera are known by various governments. Governments may be able to translate the impacts described in this assessment to national costs and begin to plan how to develop adaptive financial measures. As methods for impact assessment involve more integrated modeling, it will be possible to quantify impacts of specific climate change scenarios, either in terms of goods and services or in monetary terms.

10.4.3.2. Development, Sustainability, and Equity

The great uncertainty is the political development of Africa. Africa has had its share of surprises in the political arena. What appeared to be a steady march to economic growth would be shattered by sudden political upheavals and festering corruption among national leadership, which tends to have a trickle-down effect until the process of governance is corrupted at its core. On the other hand, the sudden collapse of apartheid in South Africa brought a fresh wind of hope in southern Africa, with far-reaching impacts on the rest of the continent. The adaptive recommendations made in this assessment assume an underpinning of good governance and social responsibility. Achebe *et al.* (1990) tackle the issue of Africa's future political and economic demise. Using various approaches and assumptions, they conclude that

Africa may not enjoy political and economic stability prior to 2020–2030 at the earliest. According to climate change impact scenarios, this is the period when climate impacts will have significant impacts on the economic and social fabric. Thus, the message is that Africa must get its house in order as a matter of urgency. We challenge the African political leadership to belie the Achebe *et al.* (1990) prognosis.

The impacts of climate change are expected to be severe, yet Africa's contribution to climate change through emissions is minimal. There are strong feelings among some people in the South who would like to see the North implement tangible emissions reductions and find ways of helping the South adapt to adverse impacts of climate change. From this synthesis, it is clear that Africa is highly vulnerable, with very low capacity to adapt. There is great potential to transfer technology to Africa that would help in developing sustainable agriculture, as well as other technologies that would assist in improving welfare and economic development.

Although the relative importance of climatic and anthropogenic factors in causing desertification remains unresolved, evidence shows that certain arid, semi-arid, and dry subhumid areas have experienced declines in rainfall, resulting in decreases in soil fertility and agricultural, livestock, forest, and rangeland production. Ultimately, these adverse impacts lead to political and socioeconomic instability.

Given the range and magnitude of development constraints and challenges facing most African nations, the overall capacity for Africa to adapt to climate change is low. Although there is uncertainty about what the future holds, Africa must start planning now to adapt to climate change. National environmental action plans and their implementation need to incorporate long-term changes and pursue “no regret” strategies. Current technologies and approaches—especially in agriculture and water—are unlikely to be adequate to meet projected demands, and increased climate variability will be an additional stress. Seasonal forecasting—for example, linking SST to outbreaks of diseases—is a promising adaptive strategy that will help to save lives.

Climate change offers some opportunities for development. The process of adapting to global climate change, including technology transfer, offers new development pathways that could take advantage of Africa's resources and human potential. Examples would include competitive agricultural products, resulting from research in new crop varieties and increased international trade, and industrial developments such as solar energy. Regional cooperation in science, resource management, and development already is increasing.

This assessment of vulnerability to climate change is marked by uncertainty. The diversity of African climates, high rainfall variability, and a very sparse observational network make predictions of future climate change difficult at the subregional and local levels. Underlying exposure and vulnerability to climatic changes are well established. Sensitivity to climatic variations is established but incomplete. However, uncertainty

about future conditions means that there is low confidence in projected costs of climate change.

10.4.4. Future Needs

Issues related to Africa's capacity to understand projected impacts include:

- **Data Needs:** The potential exists to develop environmental information systems on the basis of satellite data products and geographic information systems at small management units such as river basins, with socioeconomic and biophysical attributes as required in analyses of impacts and management. Current impact assessment models are limited by input data, limiting their use to fairly general questions. Examples exist where detailed spatial databases have been built and are being used to run integrated agrohydrological models, such as in South Africa (Schulze, 1997; Schulze and Perks, 2000). Monitoring of environmental processes as well as increased weather observation are required. Coordinated collection of integrated data sets for subregions or in connection with an extreme event such as a drought or a flood is highly desirable and would contribute to understanding of adaptation and response strategies and regional integrated modeling.
- **Human Capacity:** There is great need for increased African capacity to study the more fundamental science issues of global change and its impacts. There is great capacity at the applied management level in Africa, and this must be strengthened by a strong science capacity. The increasing number of international environmental treaties and agreements will require an even greater capacity for analysis and delivery of timely reports. There also is great need to apply science findings in policy analysis and international negotiations.
- **Integrated Analysis:** It is becoming increasingly clear that most environmental problems such as climate change require integration of many disciplines and methods of analysis. There also is a shift in interest and focus from global scales to regional and local scales. Models that help to integrate science findings with management and policy issues are needed. These models, called integrated assessment models, are required at regional and subregional levels and should include all important linkages between the socioecological and economic sectors. Given the unique combinations of factors in subregions of Africa (climate, economics, infrastructure), it will be necessary in future assessments to develop and apply regional assessment models that reflect key factors for each subregion, and these models will need to be built around issues of sustainable development rather than emissions reduction. Linking climate change (and other environmental issues) to sustainable development is not going to be easy, but it should spawn a rich body of research to define methods and approaches that will work.

- **Literature Written in French:** It is recognized that there is a rich body of literature that is written in French, and although efforts were made to capture these studies, it simply was not possible to conduct an exhaustive synthesis of that body of work. This represents a major challenge for Africa-wide assessments.

EXECUTIVE SUMMARY

Will the Climate in Asia Change?

Continuing emissions of greenhouse gases from human activities are likely to result in significant changes in mean climate and its intraseasonal and interannual variability in the Asian region. Given the current state of climate modeling, projections of future regional climate have only limited confidence. Currently available general circulation models (GCMs) suggest that the area-averaged annual mean warming would be about 3°C in the decade of the 2050s and about 5°C in the decade of the 2080s over the land regions of Asia as a result of future increases in atmospheric concentration of greenhouse gases. Under the combined influence of greenhouse gas and sulfate aerosols, surface warming would be restricted to about 2.5°C in the 2050s and about 4°C in the 2080s. In general, projected warming over Asia is higher during Northern Hemisphere (NH) winter than during summer for both time periods. The rise in surface air temperature is likely to be most pronounced over boreal Asia in all seasons. GCM simulations project relatively more pronounced increases in minimum temperature than in maximum temperature over Asia on an annual mean basis, as well as during winter, hence a decrease in diurnal temperature range (DTR). During summer, however, an increase in DTR is projected, suggesting that the maximum temperature would have more pronounced increases relative to the minimum temperature. The summertime increase in DTR over central Asia is likely to be significantly higher relative to that in other regions.

In general, all GCMs simulate an enhanced hydrological cycle and an increase in area-averaged annual mean rainfall over Asia. An annual mean increase in precipitation of approximately 7% in the 2050s and approximately 11% in the 2080s over the land regions of Asia is projected from future increases in atmospheric concentration of greenhouse gases. Under the combined influence of greenhouse gases and sulfate aerosols, the projected increase in precipitation is limited to about 3% and 7% in the 2050s and 2080s, respectively. The projected increase in precipitation is greatest during NH winter for both time periods. The increase in annual and winter mean precipitation is projected to be highest in boreal Asia; as a consequence, the annual runoff of major Siberian rivers is expected to increase significantly. Although area-averaged annual mean precipitation is projected to increase in temperate Asia, a decline in summer precipitation is likely over the central parts of arid and semi-arid Asia. Because the rainfall over this region is already low, severe water-stress conditions—leading to expansion of deserts—are quite possible, with rises in surface air temperature and depletion of soil moisture. GCMs show high uncertainty in future projections of winter and summer

precipitation over south Asia (with or without aerosol forcings). Because much of tropical Asia is intrinsically linked with the annual monsoon cycle, research into a better understanding of the future behavior of the monsoon and its variability is warranted.

Is Asia Vulnerable to Projected Climate Change?

Climate change-induced vulnerabilities in Asia have to be understood against the backdrop of the physical, economic, and social environment of the countries in the region. They not only provide benchmarks against which vulnerabilities are to be assessed but also the potential for adaptation to them. The socioeconomic environment of many countries in Asia is characterized by high population density and relatively low rates of economic growth. Surface water and groundwater resources in Asian countries play vital roles in forestry, agriculture, fisheries, livestock production, and industrial activity. The water and agriculture sectors are likely to be most sensitive to climate change-induced impacts in Asia. Forest ecosystems in boreal Asia would suffer from floods and increased volume of runoff associated with melting of permafrost regions. The dangerous processes of permafrost degradation resulting from global warming strengthen the vulnerability of all relevant climate-dependent sectors affecting the economy in high-latitude Asia. Although the frequency and severity of floods eventually would increase in many countries of Asia, arid and semi-arid regions of Asia could experience severe water-stress conditions. The stresses of climate change are likely to disrupt the ecology of mountain and highland systems in Asia. Major changes in high-elevation ecosystems of Asia can be expected as a consequence of the impacts of climate change. Many species of mammals and birds and a large population of many other species in Asia could be exterminated as a result of the synergistic effects of climate change and habitat fragmentation. Glacial melt also is expected to increase under changed climate conditions, which would lead to increased summer flows in some river systems for a few decades, followed by a reduction in flow as the glaciers disappear.

Agricultural productivity in Asia is likely to suffer severe losses because of high temperature, severe drought, flood conditions, and soil degradation; food security of many developing countries in the region would be under tremendous threat. There are likely to be large-scale changes in productivity of warmwater and coolwater fish in many countries in Asia. Sea-level rise would cause large-scale inundation along the vast Asian coastline and recession of flat sandy beaches. The ecological security of mangroves and coral reefs around Asia would be put at risk.

The monsoons in tropical Asia could become more variable if El Niño-Southern Oscillation (ENSO) events become stronger and more frequent in a warmer atmosphere. Countries in temperate and tropical Asia are likely to have increased exposure to extreme events, including forest die-back and increased fire risk, typhoons and tropical storms, floods and landslide, and severe vector-borne diseases.

Major Risks in Asia from Climate Change

Based on present scientific research, the following risks linked to changes in climate and its variability for Asia are identified:¹

- The dangerous processes of permafrost degradation resulting from global warming would increase the vulnerability of many climate-dependent sectors affecting the economy in boreal Asia. ***
- Surface runoff increases during spring and summer periods would be pronounced in boreal Asia. ***
- The frequency of forest fires is expected to increase in boreal Asia. ***
- The large deltas and coastal low-lying areas of Asia could be inundated by sea-level rise. ****
- The developing countries of temperate and tropical Asia already are quite vulnerable to extreme climate events such as droughts and floods; climate change and its variability could exacerbate these vulnerabilities. ****
- Increased precipitation intensity, particularly during the summer monsoon, could increase flood-prone areas in temperate and tropical Asia. There is a potential for drier conditions in arid and semi-arid Asia during summer, which could lead to more severe droughts. ***
- Freshwater availability is expected to be highly vulnerable to anticipated climate change. ****
- Tropical cyclones could become more intense. Combined with sea-level rise, this impact would result in enhanced risk of loss of life and properties in coastal low-lying areas of cyclone-prone countries of Asia. ***
- Crop production and aquaculture would be threatened by a combination of thermal and water stresses, sea-level rise, increased flooding, and strong winds associated with intense tropical cyclones. ****
- Warmer and wetter conditions would increase the potential for a higher incidence of heat-related and infectious diseases in tropical and temperate Asia. ***
- Climate change would exacerbate threats to biodiversity resulting from land-use/cover change and population pressure in Asia. ***

¹Uncertainties in observations, mechanisms, and scenarios are identified with a five-point scale, from “very low confidence” (*) to “very high confidence” (****). The confidence scale has the following probability range: VL = Very Low (<5% probability); L = Low (5–33%); M = Medium (33–67%); H = High (67–95%); and VH = Very High (>95%).

Adaptation to Climate Change in Asia

The impacts of climate change are likely to be felt most severely in the majority of developing countries of Asia because of resource and infrastructure constraints (e.g., disparities in income level, technological gaps). These countries must develop and implement incremental adaptation strategies and policies to exploit “no regret” measures and “win-win” options. Detailed and reliable regional scenarios of climate change must be developed and used in rigorous vulnerability analysis (e.g., low-probability/high-consequence events vs. high-probability/high-consequence events, risk perceptions). To understand which adaptation opportunities will be most cost-effective and have the greatest value, emphasis must be given to characteristics of system vulnerability such as resilience, critical thresholds, and coping ranges, which are highly dependent on regions and nations.

It is important to consider climate change in planning, designing, and implementing development activities in climate-sensitive resources for Asia, particularly where:

- Climate change may cause irreversible or catastrophic impacts
- Decisions with a long lifetime, such as building of infrastructure, are being made
- Development trends such as development of low-lying coastal areas increase vulnerability to climate change.

Two general strategies on adaptation can be used. The first is a macro strategy that involves rapid development. Sustainable and equitable development will increase income levels, education, and technical skills and improve public food distribution, disaster preparedness and management, and health care systems in developing countries of Asia. All of these changes could substantially enhance social capital and reduce the vulnerability of these countries to climate change.

The second strategy is a micro strategy that involves modifying the management of sectors that are most sensitive to climate change. This approach entails developing new institutions or modifying existing institutions related to these sectors that promote rather than discourage adaptation to climate change. It also involves modifying climate-sensitive infrastructures that are already planned or implemented or other long-term decisions that are sensitive to climate to incorporate the risks of climate change.

Based on the foregoing principles, specific adaptation strategies for countries in the Asian region have been identified in the relevant sectors (e.g., water resources, agriculture and food security, coastal resources, human health, and ecosystems and biodiversity). These strategies are summarized in Box 11-1.

Each subregion has its priority adaptation sector for its own situation. Food security, disaster preparedness and management, soil conservation, and human health sectors also appear to be crucial for countries with large populations (e.g., China, India,

Box 11-1. Summary of Potential Sector-Wide Adaptation Options for Subregions of Asia

Agriculture

- *Boreal Asia:* Adopt suitable crops and cultivars; make optimum use of fertilizers and adaptation of agro-technologies.
- *Arid and Semi-Arid Asia:* Shift from conventional crops to intensive greenhouse agriculture/aquaculture; protect against soil degradation.
- *Temperate Asia:* Adopt heat-resistant crops, water-efficient cultivars with resistance to pests and diseases, soil conservation.
- *Tropical Asia:* Adjust cropping calendar and crop rotation; develop and promote use of high-yielding varieties and sustainable technological applications.

Water Resources

- *Boreal Asia:* Develop flood-protection systems in north Asia (required because of permafrost melting and increased streamflow volume/surface runoff); enhance management of international rivers.
- *Arid and Semi-Arid Asia:* Enhance conservation of freshwater supply as option for extreme water-stress conditions.
- *Temperate Asia:* Flood and drought control measures required; improve flood warning and forecasting systems, including disaster management.
- *Tropical Asia:* Develop flood- and drought-control management systems; reduce future developments in floodplains; use appropriate measures for protection against soil erosion; conserve groundwater supply, water impoundments, and efficient water resource systems.

Ecosystems and Biodiversity

- Assess risks to endemic species and ecosystems.
- Introduce integrated ecosystem planning and management.
- Reduce habitat fragmentation and promote development of migration corridors and buffer zones.
- Encourage mixed-use strategies.
- Prevent deforestation and conserve natural habitats in climatic transition zones inhabited by genetic biodiversity of potential for ecosystem restoration.

Coastal Resources

- *Boreal Asia:* Modify infrastructures to accommodate sea-level rise.
- *Arid and Semi-Arid Asia:* Protect lakes and water reservoirs; develop aquaculture farming techniques.
- *Temperate Asia:* Follow setback examples for new coastal development; evaluate coastal subsidence rates in sensitive coastal regions; prepare contingency plans for migration in response to sea-level rise; improve emergency preparedness for weather extremes (e.g., typhoons and storm surges).
- *Tropical Asia:* Protect wetlands and allow for migration; prepare contingency plans for migration in response to sea-level rise; improve emergency preparedness for weather extremes (e.g., cyclones and storm surges); evaluate coastal subsidence rates in sensitive coastal regions.
- *Common Adaptation:* Implement coastal zone management; protect marine resources.

Human Health

- Build heat-resistant urban infrastructures and take additional measures to reduce air and water pollution.
- Adapt technological/engineering solutions to prevent vector-borne diseases/epidemics.
- Improve health care system, including surveillance, monitoring, and information dissemination.
- Improve public education and literacy rate in various communities.
- Increase infrastructure for waste disposal.
- Improve sanitation facilities in developing countries.

Cross-Cutting Issues

- Continue monitoring and analysis of variability and trends in key climatic elements.
- Improve weather forecasting systems in the region.
- Improve and implement reforms on land-use planning.
- Apply new techniques for confident projection of regional climate change and its variability, including extreme events.
- Improve coordination of climate change adaptation activities among countries in the region.
- Keep the nongovernmental organization (NGO) community and the public aware of developments on risks of climate change and involve them in planning, adaptation, and mitigation strategies.
- Take advantage of traditional knowledge in planning for the future.

Bangladesh). Adaptations proposed for human health, which essentially involve improving the health care system, are changes that are needed anyway to address the current human health situation in many Asian countries. Adaptations to deal with sea-level rise, potentially more intense cyclones, and threats to ecosystems and biodiversity should be considered high priority in temperate and tropical Asian countries.

The design of an optimal adaptation program in any country would have to be based on comparison of damages avoided with costs of adaptation. Other factors also should enter the decisionmaking process, such as the impacts of policies on society in terms of employment generation and opportunities, improved air and water quality, and the impacts of policies on broader concerns for equitable and sustainable development.

11.1. The Asian Region

11.1.1. Background

Following publication of its Second Assessment Report (SAR) and on recommendation of the Subsidiary Body for Scientific and Technological Advice of the Conference of the Parties, the Intergovernmental Panel on Climate Change (IPCC) published its *Special Report on the Regional Impacts of Climate Change* in early 1998, providing assessments of the vulnerability of natural ecosystems, socioeconomic sectors, and human health to climate change for 10 regions of the globe (IPCC, 1998). That Special Report served as guidance material, illustrating for the first time the potential character and magnitude of region-specific impacts—though often in qualitative sense only, based on a diverse range of methods and tools.

A key message of the regional assessments in that report was that “many systems and policies are not well adjusted even to today’s climate and climate variability.” Several examples cited, based on information gathered during country study and other projects, demonstrate current vulnerability in the Asian region as a result of increasing risks to human life and property from floods, storms, and droughts in recent decades. The report suggests that, as a consequence of climate change, there could be a large reduction in the area and productivity of forests in boreal Asia. In arid and semi-arid regions of Asia, water shortage—already a limiting factor for ecosystems, food and fiber production, human settlements, and human health—may be exacerbated by climate change. Limited water supplies and land degradation problems are likely to threaten the food security of some countries in this region. Major changes in the composition and distribution of vegetation types of semi-arid areas—for example, grasslands, rangelands, and woodlands—are anticipated. In temperate Asia, changes in temperature and precipitation may result in altered growing seasons and boundary shifts between grasslands, forests, and shrublands. An increase in temperature could lead to oxygen depletion in aquatic ecosystems, fish diseases, and introduction of unwanted species, as well as potential negative factors such as changes in established reproductive patterns, migration routes, and ecosystem relationships in temperate Asia. Arise in sea level will endanger sandy beaches in the coastal zones and add further to the problems of tectonically and anthropogenically induced land subsidence in deltaic regions of temperate Asia. Substantial elevational shifts of ecosystems in the mountains and uplands of tropical Asia are projected. Increases in temperature and seasonal variability in precipitation are expected to result in more rapid recession of Himalayan glaciers. Climate change impacts could result in significant changes in crop yields, production, storage, and distribution in this region. Densely settled and intensively used low-lying coastal plains, islands, and deltas in Asia are extremely vulnerable to coastal erosion and land loss, inundation and sea flooding, and upstream movement of saline water fronts as a result of sea-level rise. The incidence and extent of vector-borne diseases, which are significant causes of mortality and morbidity in tropical Asia, are likely to spread into new regions on the margins of present endemic areas as a result of climate change.

The 1998 Special Report underscores that, in many countries of Asia, economic policies and conditions (e.g., taxes, subsidies, and regulations) that shape decisionmaking, development strategies, and resource-use patterns (hence environmental conditions) hinder implementation of adaptation measures. For example, water is subsidized in most developing countries of Asia, encouraging overuse (which draws down existing sources) and discouraging conservation measures that may be elements of future adaptation strategies. Other examples are inappropriate land-use zoning and subsidized disaster insurance, which encourage infrastructure development in areas that are prone to flooding or other natural disasters—areas that could become even more vulnerable as a result of climate change. Adaptation and better incorporation of the long-term environmental consequences of resource use can be brought about through a range of approaches, including strengthening legal and institutional frameworks, removing pre-existing market distortions (e.g., subsidies), correcting market failures (e.g., failure to reflect environmental damage or resource depletion in prices or inadequate economic valuation of biodiversity), and promoting public participation and education. These types of actions would adjust resource-use patterns to current environmental conditions and better prepare systems for potential future changes.

The 1998 Special Report emphasizes that the challenge lies in identifying opportunities that would facilitate sustainable development by making use of existing technologies and developing policies that make climate-sensitive sectors resilient to today’s climate variability. This strategy will require developing countries of Asia to have access to appropriate technologies, information, and adequate financing. In addition, adaptation will require anticipation and planning; failure to prepare systems for projected change in climate means, variability, and extremes could lead to capital-intensive development of infrastructure or technologies that are ill-suited to future conditions, as well as missed opportunities to lower the costs of adaptation.

Subsequent to publication of the 1998 Special Report, some advances in our ability to better understand the likely future state of social, economic, and environmental factors controlling the emission and concentration of greenhouse gases (GHGs) and aerosols that alter the radiative forcings of climate have been made. Details on future projections of climatic and environmental changes on finer scales also are now better understood. This chapter presents an update on the climate change projections for Asia and examines how projected changes in climate could affect social, environmental, and economic sectors in the region.

11.1.2. Physical and Ecological Features

11.1.2.1. Regional Zonation

The Asian continent is bounded on the north by the Arctic Ocean, on the east by the Pacific Ocean, and on the south by the Indian Ocean; the western boundary, with Europe, runs roughly north-south along the eastern Ural Mountains, the

Zhem River, the Caspian Sea, the Kuma-Manych Depression, the Black Sea, the Aegean Sea, the Mediterranean Sea, the Suez Canal, and the Red Sea. The world's largest plateau—the Tibetan Plateau, with an average elevation of more than 4,000 m—is located in Asia. Mt. Everest, the highest peak in the world (8,848 m), lies near the southern border of this plateau. The islands of Sri Lanka and Taiwan (China) and the archipelagoes of Indonesia, the Philippines, and Japan also are part of Asia. Asia is the most populous of the continents. Its total population in 1998 is estimated to be about 3,589 million, of which almost 65% is rural. The coastline of Asia is 252,770 km long.

Based on broad climatic and geographical features, the Asian region can be divided into four subregions: boreal Asia, arid and semi-arid Asia, temperate Asia, and tropical Asia (Figure 11-1). This chapter discusses key climatological, ecological, and socioeconomic features of each of these subregions and the countries falling within them, as well as various aspects of vulnerability, impacts, and adaptation in relation to climate change for each of these regions.

Boreal Asia is located on the northern margins of the Eurasian continent between 50°N and the Arctic Circle. Boreal forests

cover most of this region. Siberia, which is a part of Russia (the main country in the region), has a mean monthly temperature of about -50°C in January and is the coldest region of the northern hemisphere in winter. Three Siberian rivers—the Ob, the Yenissei, and the Lena—contribute about 42% of total runoff from all rivers of the Arctic basin (CAFW, 1998). In the heart of this region is one of the world's largest and oldest lakes, Baikal, the age of which is estimated to be about 25–30 million years (Kuzmin *et al.*, 1997). Lake Baikal contains as much as 85% of Russian surface freshwaters (Izrael *et al.*, 1997a; Anokhin and Izrael, 2000). There is evidence of recession of permafrost in recent decades (ICRF, 1998).

Arid and semi-arid Asia extends from 22°N to 50°N and from 30°E to 105°E; it includes more than 20 countries of the Middle East and central Asia. Many of the countries in the region are landlocked. Many storms develop locally (*in situ*) over central Asia; some move into the region from the west. The maximum frequency of cyclones occurs in January and March. Despite this cyclonic activity, very little precipitation is recorded over most of the region because of the lack of moisture. Most of the region has a precipitation-to-potential evapotranspiration ratio of less than 0.45, which is typical of a semi-arid and arid

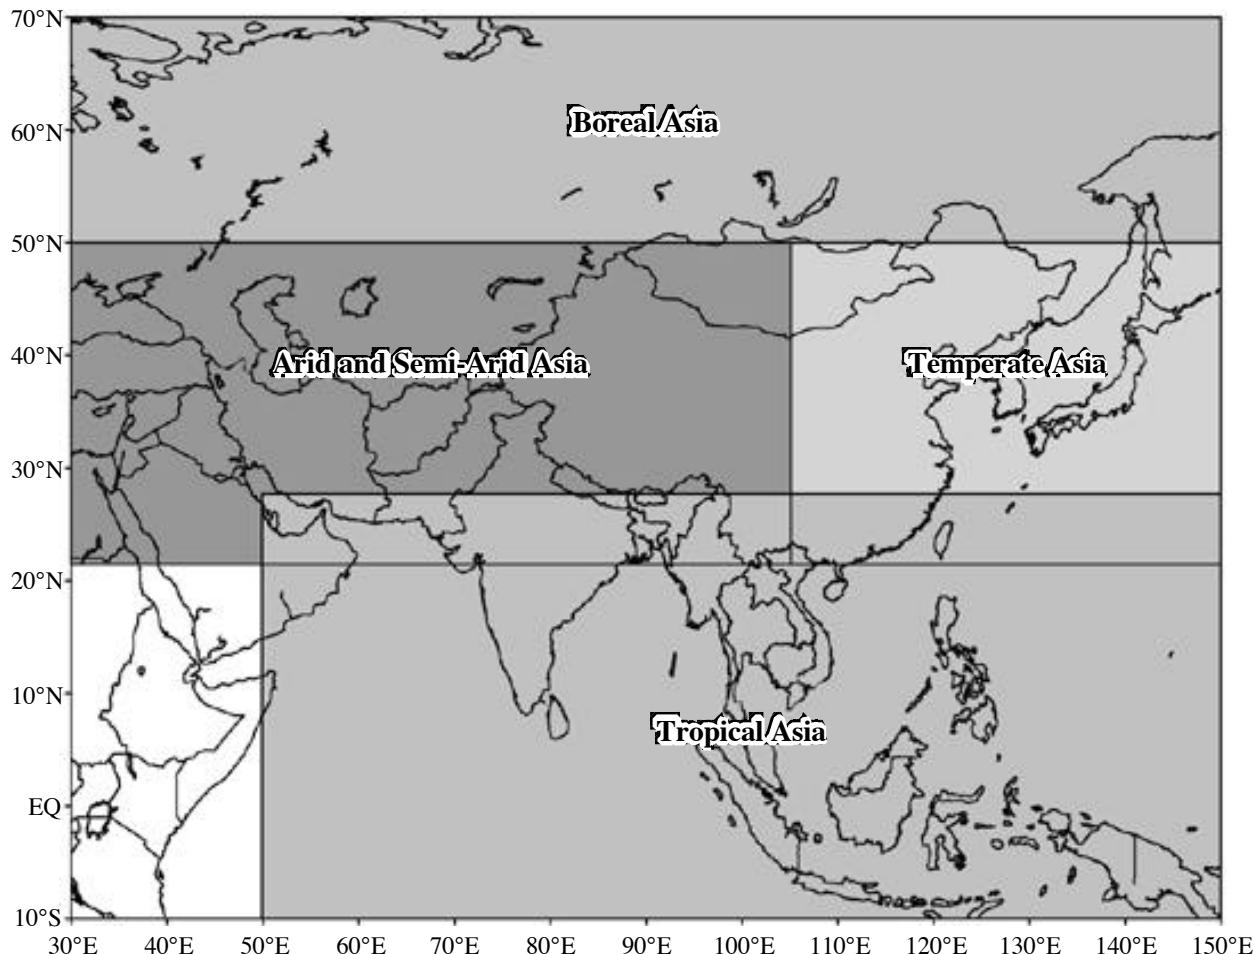

Figure 11-1: Geographical domain of Asia and its subregions.

climate. Grasslands, rangelands, and deserts dominate most of arid and semi-arid Asia.

Temperate Asia extends from 22°N to 50°N and from 105°E to 150°E; it includes eastern China, the Japanese islands, the Korean peninsula, Mongolia, and Taiwan (China). Geographically, the region is located on the eastern part of the Eurasian continent—the world's largest continent—and borders the Pacific, the world's largest ocean. The east-west distance of the area is about 5,000 km; its north-south extent is about 3,000 km. Much of the natural forest in the region has long been destroyed. Broad plains have been cultivated and irrigated, and natural grasslands have been used for animal husbandry for centuries.

Tropical Asia extends from 10°S to 28°N and from 50°E to 150°E; it includes several countries of south Asia, which are influenced predominantly by the monsoons. The region is physiographically diverse and ecologically rich in natural and crop-related biodiversity. Although the present population of the region is principally rural, the region includes seven of the 25 largest cities in the world. Agriculture is the main industry in several countries of this region. Exploitation of natural resources associated with rapid urbanization, industrialization, and economic development has led to increasing air and water pollution, land degradation, and other environmental problems in countries of this region. Climate change represents a further stress. Over the long period of human occupation in the region, human use systems have developed some resilience to a range of environmental stresses (IPCC, 1998).

Table 11-1 lists the total population, gross domestic product, total land area and land area classified under cropland, forest cover, annual internal water resources, and annual production of cereals, as well as per capita availability of fish and seafood in some of the countries of Asia.

11.1.2.2. Trends and Variability in Key Climate Variables

11.1.2.2.1. Surface air temperature

Climate differs widely within Asia. In boreal Asia, the climate generally is humid and cool; it is classified as continental type. Permafrost covers as much as 90% of boreal Asia. An average annual mean increase in surface air temperature of about 2.9°C in the past 100 years has been observed in boreal Asia. Warming was more pronounced during the period 1951–1995 in all of boreal Asia region except for the coast of the Arctic Ocean and Chukotka (Rankova, 1998). The mean surface air temperature increase is most pronounced in the winter, at a rate of approximately 4.4°C over the past 100 years (Gruza *et al.*, 1997). Summer temperatures in central Siberia have exhibited decreasing trends, however.

The climate of arid and semi-arid Asia is the warm temperate type, with hot and wet or dry summers. The highest value of DTR (on the order of 20°C) is experienced in this region. A mean maximum temperature of >45°C in July is not uncommon

in some parts of arid Asia. In most of the Middle East, the long time series of surface air temperature shows a warming trend. An increasing tendency in spatially averaged seasonal and annual air temperatures has been observed in Kazakhstan over the past century. Maximal warming has occurred in spring. The mean annual surface temperature has risen by about 1.3°C during 1894–1997 (Pilifosova *et al.*, 1997); in the arid regions of China, air temperature has obviously increased since the 1970s (Chen, 1995). In Pakistan, annual mean surface temperature has a consistent rising trend since the beginning of 20th century (Chaudhari, 1994).

In temperate Asia, the average annual mean surface temperature in Mongolia has increased by approximately 0.7°C over the past 50 years; consequently, noticeable changes have taken place in the length of the cold and warm seasons (Khulidorj *et al.*, 1998). Surface temperature in northeast China has increased in winter but decreased in summer since 1905 (Ren and Zhou, 1994; Ren, 1998); observations also reveal a 1–2°C decrease in temperature in some parts of southeastern China. In Japan, the surface air temperature has shown a warming trend during the past century (Yoshino, 1998a; Japan Meteorological Agency, 1999).

Tropical Asia has a unique climatological distinction because of the pervasive influence of the monsoon. In tropical Asia, climate uniformity is differentiated by three factors: latitude, relief, and continentality. The entire tropical Asia region stretches over 38° in latitude, so the differences resulting from this factor are pronounced. In spite of some differences, the climates of countries have one factor in common: The Asian monsoon modulates them all to a large extent. For countries near the Equator, only small seasonal variations occur, although most countries in this region experience clearly marked cold and warm seasons. The spatial range of temperature in this region is significantly large during winter. Extreme temperatures of over 45°C occur over the northwest part of the region during May–June. Several countries in this region have reported increasing surface temperature trends in recent decades. In Vietnam, annual mean surface temperature has increased over the period 1895–1996, with mean warming estimated at 0.32°C over the past 3 decades. Annual mean surface air temperature anomalies over Sri Lanka during the period 1869–1993 suggest a conspicuous and gradually increasing trend of about 0.30°C per 100 years (Rupakumar and Patil, 1996). The warming trend over India has been reported to be about 0.57°C per 100 years (Rupakumar *et al.*, 1994).

11.1.2.2.2. Precipitation

Rainfall in boreal Asia is highly variable on seasonal and interannual as well as spatial scales. The time series of annual mean precipitation in Russia suggests a decreasing trend; these tendencies have amplified during 1951–1995, especially in warm years (Rankova, 1998). In long-term mean precipitation, a decreasing trend of about -4.1 mm/month/100 years has been reported in boreal Asia. During the past 10–15 years, however,

precipitation has increased, mostly during the summer-autumn period (Izrael *et al.*, 1997b). As a result of this increase in precipitation, water storage in a 1-m soil layer has grown by 10–30 mm (Robock *et al.*, 2000). The large upward trends in soil moisture (of more than 1 cm/10 years) have created favorable conditions for infiltration into groundwater. The levels of major aquifers have risen by 50–100 cm; the growth of groundwater storage has resulted in increasing ground river recharge and considerable low-water runoff.

Annual mean rainfall is considerably low in most parts of the arid and semi-arid region of Asia. Moreover, temporal variability is quite high: Occasionally, as much as 90% of the annual total is recorded in just 2 months of the year at a few places in the region. Rainfall observations during the past 50 years in some countries in the northern parts of this region have shown an increasing trend on annual mean basis. A decreasing trend in annual precipitation for the period 1894–1997 has been observed in Kazakhstan. The precipitation in spring, summer, and autumn, however, has shown slight increasing trends. In Pakistan, seven of 10 stations have shown a tendency toward increasing rainfall during monsoon season (Chaudhari, 1994).

In temperate Asia, the East Asian monsoon greatly influences temporal and spatial variations in rainfall. Annual mean rainfall in Mongolia is 100–400 mm and is confined mainly to summer. Summer rainfall seems to have declined over the period 1970–1990 in Gobi; the number of days with relatively heavy rainfall events has dropped significantly (Rankova, 1998). In China, annual precipitation has been decreasing continuously since 1965; this decrease has become serious since the 1980s (Chen *et al.*, 1992). The summer monsoon is reported to be stronger in northern China during globally warmer years (Ren *et al.*, 2000). On the other hand, drier conditions have prevailed over most of the monsoon-affected area during globally colder years (Yu and Neil, 1991).

In tropical Asia, hills and mountain ranges cause striking spatial variations in rainfall. Approximately 70% of the total annual rainfall over the Indian subcontinent is confined to the southwest monsoon season (June–September). The western Himalayas get more snowfall than the eastern Himalayas during winter. There is more rainfall in the eastern Himalayas and Nepal than in the western Himalayas during the monsoon season (Kripalani *et al.*, 1996). The annual mean rainfall in Sri Lanka is practically trendless; positive trends in February and negative trends in June have been reported, however (Chandrapala and Fernando, 1995). In India, long-term time series of summer monsoon rainfall have no discernible trends, but decadal departures are found above and below the long time averages alternatively for 3 consecutive decades (Kothyari and Singh, 1996). Recent decades have exhibited an increase in extreme rainfall events over northwest India during the summer monsoon (Singh and Sontakke, 2001). Moreover, the number of rainy days during the monsoon along east coastal stations has declined in the past decade. A long-term decreasing trend in rainfall in Thailand is reported (OEPP, 1996). In Bangladesh, decadal departures were below long-term averages until 1960;

thereafter they have been much above normal (Mirza and Dixit, 1997).

11.1.2.3. Extreme Events and Severe Weather Systems

Apart from intraseasonal and interannual variability in climate, extreme weather events such as heat waves associated with extreme temperatures, extratropical and tropical cyclones, prolonged dry spells, intense rainfall, tornadoes, snow avalanches, thunderstorms, and dust storms are known to cause adverse effects in widely separated areas of Asia. There is some evidence of increases in the intensity or frequency of some of these extreme weather events on regional scales throughout the 20th century, although data analyses are relatively poor and not comprehensive (Balling and Idso, 1990; Bouchard, 1990; Agee, 1991; Yu and Neil, 1991; Chen *et al.*, 1992; Ostby, 1993; Bardin, 1994; Born, 1996). For example, increases in climate extremes in the western Siberia-Baikal region and eastern parts of boreal Asia have been reported in recent decades (Gruza and Rankova, 1997; Gruza *et al.*, 1999). There also are reports of an increase in thunderstorms over the land regions of tropical Asia (Karl *et al.*, 1995). The frequency and severity of wildfires in grasslands and rangelands in arid and semi-arid Asia have increased in recent decades (Pilifosova *et al.*, 1996).

Some mountains in Asia have permanent glaciers that have vacated large areas during the past few decades, resulting in increases in glacial runoff. As a consequence, an increased frequency of events such as mudflows and avalanches affecting human settlements has occurred (Rai, 1999). As mountain glaciers continue to disappear, the volume of summer runoff eventually will be reduced as a result of loss of ice resources. Consequences for downstream agriculture, which relies on this water for irrigation, will be unfavorable in some places. For example, low- and mid-lying parts of central Asia are likely to change gradually into more arid, interior deserts.

Countries in temperate Asia have been frequented by many droughts in the 20th century. In China, droughts in 1972, 1978, and 1997 have been recorded as the most serious and extensive. A large number of severe floods also have occurred in China, predominately over the middle and lower basins of the Yangtze (Changjiang), Huanghe, Huaihe, and Haihe Rivers (Ji *et al.*, 1993). Severe flooding with daily rainfall exceeding 25 cm struck during July and August 1998 in Korea. In Japan, drought disasters are significantly more frequent during years following ENSO warm events than in normal years.

Floods, droughts, and cyclones are the key natural disasters in tropical Asia. The average annual flood covers vast areas throughout the region: In Bangladesh, floods cover 3.1 Mha; the total flood-prone area in India is about 40 Mha (Mirza and Erickson, 1996). In India, chronically drought-affected areas cover the western parts of Rajasthan and the Kutch region of Gujarat. However, drought conditions also have been reported in Bihar and Orissa States in India. In Bangladesh, about 2.7

Mha are vulnerable to drought annually; there is about 10% probability that 41–50% of the country is experiencing drought in a given year (Mirza, 1998). Drought or near-drought conditions also occur in parts of Nepal, Papua New Guinea, and Indonesia, especially during El Niño years. In India, Laos, the Philippines, and Vietnam, drought disasters are more frequent during years following ENSO events. At least half of the severe failures of the Indian summer monsoon since 1871 have occurred during El Niño years (Webster *et al.* 1998). In the event of enhanced anomalous warming of the eastern equatorial Pacific Ocean, such as that observed during the 1998 El Niño, a higher frequency of intense extreme events all across Asia is possible.

11.1.3. Scenarios of Future Climate Change

Increases in atmospheric concentrations of GHGs from anthropogenic activities would warm the earth-atmosphere system. The radiative forcing inferred from likely future increases in GHGs and sulfate aerosols as prescribed under IS92a emission scenarios (Leggett *et al.*, 1992; IPCC, 1995) has been used in recent numerical experiments performed with coupled atmosphere-ocean global climate models (AOGCMs). Projections of future regional climate change and also most of the impact assessment studies for Asia cited herein are based on these numerical experiments (see Chapter 3 for further details).

To develop climate change scenarios on regional scales, it is first necessary to examine if the coupled AOGCMs are able to simulate the dynamics of present-day regional climate. The multi-century control integrations of AOGCMs unforced by anthropogenic changes in atmospheric composition offer an excellent opportunity to examine the skill of individual models in simulating the present-day climate and its variability on regional scales (Giorgi and Francisco, 2000; Lal *et al.*, 2000). A model validation exercise carried out for Asia and its subregions has indicated that each of these models shows large seasonal variations in surface air temperature over boreal Asia and only small seasonal variations over southeast tropical Asia (Figure 11-2). However, many of the AOGCMs have only limited ability for realistic portrayal of even large-scale precipitation distribution over Asia. Seasonal variations in observed precipitation over the South Asia region as a consequence of summer monsoon activity are poorly simulated by most of the models (Figure 11-3). Moreover, none of the seven models can reproduce the observed precipitation climatology over the Tibetan Plateau (Figure 11-4). Based on the pattern correlation coefficients and root mean square errors between the observed and model-simulated seasonal mean sea-level pressure, surface air temperature, and rainfall patterns over land regions of Asia and other relevant considerations in this validation exercise, the HadCM2, ECHAM4, CSIRO, and CCSR/NIES AOGCMs (developed at U.K. Hadley Climate Centre, German Climate Research Centre, Australian Commonwealth Scientific and Industrial Research Organisation, and Japanese Center for Climate System Research/National Institute for Environmental Studies, respectively) are rated to have some skill in simulating the

broad features of present-day climate and its variability over Asia (Lal and Harasawa, 2000).

11.1.3.1. Surface Air Temperature

Climate change scenarios that are based on an ensemble of results as inferred from skilled AOGCMs for Asia and its subregions on annual and seasonal mean basis are presented in Table 11-2. Three future time periods centered around the 2020s (2010–2029), the 2050s (2040–2069), and the 2080s (2070–2099) have been considered here for developing scenarios of changes in surface air temperature and precipitation relative to the baseline period of 1961–1990. The projected area-averaged annual mean warming is $1.6 \pm 0.2^\circ\text{C}$ in the 2020s, $3.1 \pm 0.3^\circ\text{C}$ in the 2050s, and $4.6 \pm 0.4^\circ\text{C}$ in the 2080s over land regions of

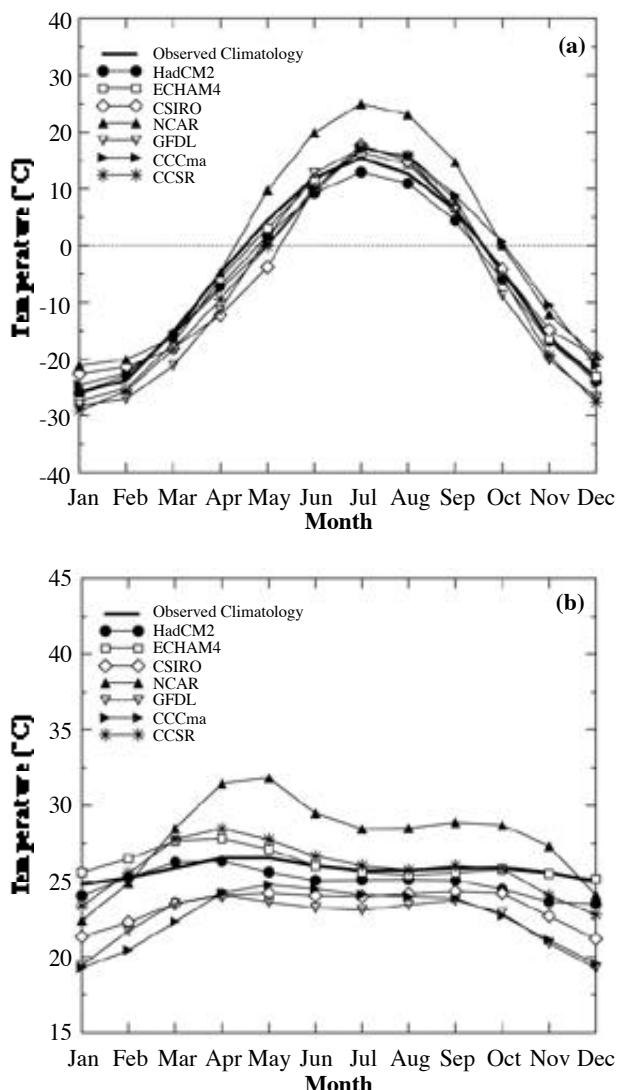

Figure 11-2: Validation of simulated and observed area-averaged annual cycles of surface air temperature over boreal (a) and southeast Asia (b) regions.

Asia as a result of increases in the atmospheric concentration of GHGs. Under the combined influence of GHGs and sulfate aerosols, surface warming will be restricted to $1.4 \pm 0.3^\circ\text{C}$ in the 2020s, $2.5 \pm 0.4^\circ\text{C}$ in the 2050s, and $3.8 \pm 0.5^\circ\text{C}$ in the 2080s. In general, projected warming over Asia is higher during NH winter than during summer for all time periods (see also Giorgi and Francisco, 2000). The area-averaged increase in surface air temperature is likely to be most pronounced over boreal Asia and least in southeast Asia in all seasons (Lal and Harasawa, 2001). It is evident from Table 11-2 that even though aerosol forcing reduces surface warming, the magnitude of projected warming is still considerable and could substantially impact the Asian region.

In December 1998, the writing team for the IPCC *Special Report on Emission Scenarios* (SRES) released a preliminary

set of four SRES “marker” scenarios: A1, A2, B1, and B2 (Nakicenovic *et al.*, 1998). Scenario B1 projects the most conservative future emissions of GHGs from Asia; scenario A2 is characteristic of scenarios with higher rates of GHG emissions in combination with higher sulfate and other aerosol emissions. The A1 scenario family has since been further divided into three groups that describe alternative directions of technological change in the energy system (IPCC, 2000). The three A1 groups are distinguished by their technological emphasis: fossil fuel-intensive (A1FI), nonfossil energy sources (A1T), or a balance across all sources (A1B). Projections of future aerosol loading as envisaged in SRES marker scenarios are significantly lower compared to the IS92a scenario.

Figure 11-5 illustrates the trends in area-averaged annual mean surface air temperature increase over land regions of Asia as

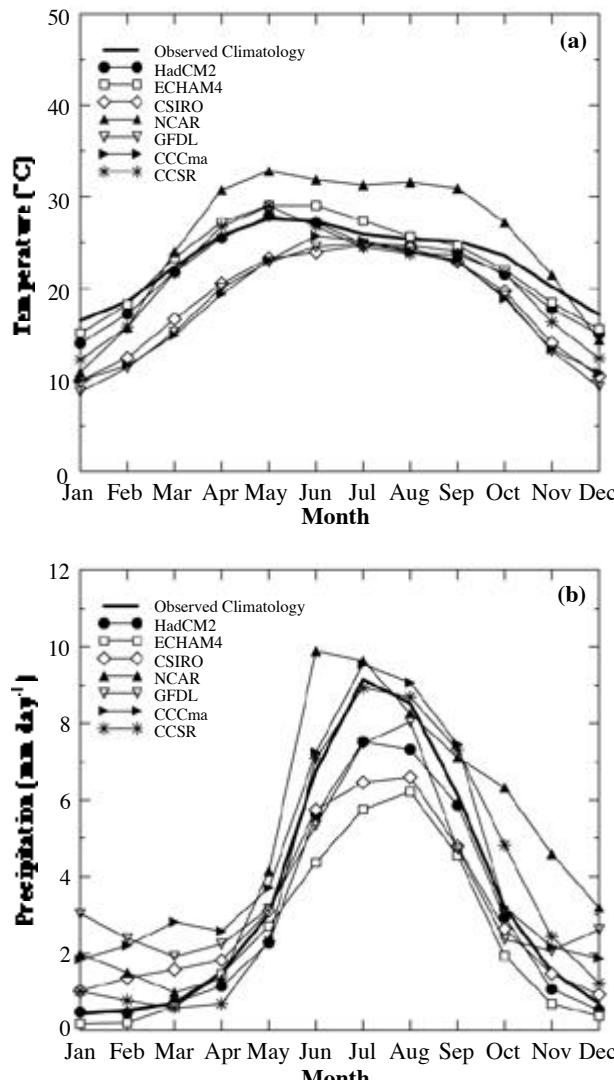

Figure 11-3: Validation of simulated and observed area-averaged annual cycles of surface air temperature (a) and precipitation (b) over south Asia.

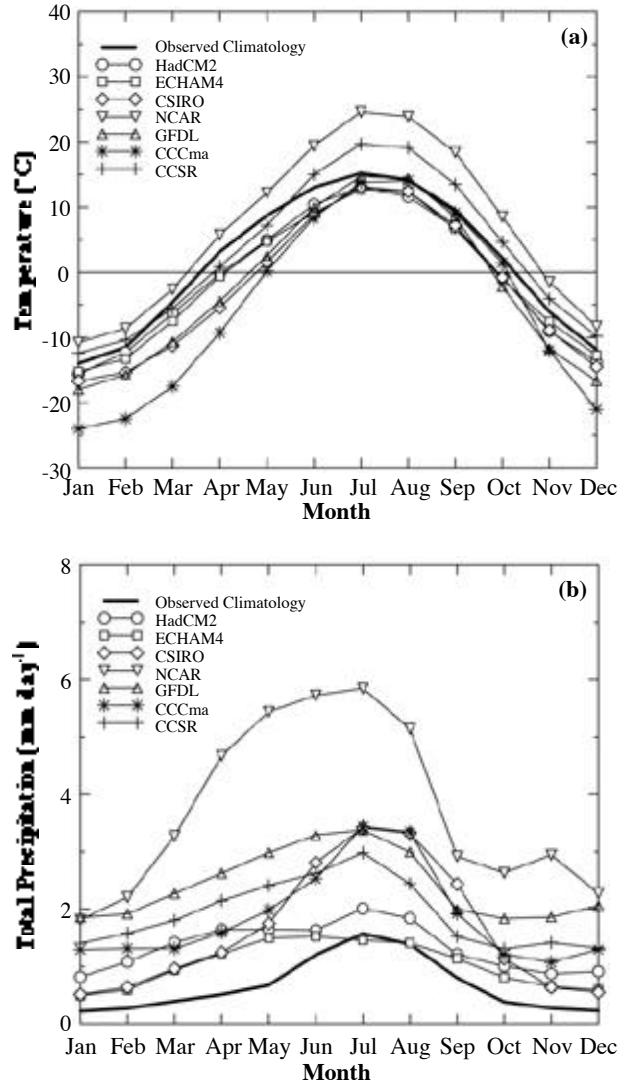

Figure 11-4: Validation of simulated and observed area-averaged annual cycles of surface air temperature (a) and precipitation (b) over Tibetan Plateau.

Table 11-2: Plausible changes in area-averaged surface air temperature (top) and precipitation (bottom) over Asia and its subregions as a result of future increases in greenhouse gases (under IS92a emission scenarios), as inferred from an ensemble of data generated in experiments with CCSR/NIES, CSIRO, ECHAM4, and HadCM2 AOGCMs. Numbers in parentheses are area-averaged changes when direct effects of sulfate aerosols are included.

simulated with CCSR/NIES AOGCMs for the IS92a scenario (GHG only and GHG + aerosols) and for the new SRES “marker” emission scenarios. Projections of future sulfate aerosol loading in SRES scenarios are significantly lower. Because the treatment of aerosol and GHG radiative effects in the old and new sets of scenario experiments is different, quantitative comparison of the results should be made with care. Nonetheless, the generally higher projected surface warming trend for SRES scenarios in the latter half of the 21st century is partially a result of intensive reduction of aerosol emissions. Projected surface warming trends for the IS92a and B1 emission pathways are close to each other. Maximum warming is simulated for the A1 emission scenario during the first half of the 21st century but is carried forward to the A2 emission scenario in the latter half of the 21st century. Projections of regional climate change that use these newer sets of emission scenarios for GHGs have not yet been thoroughly assessed for their applications in impact assessment studies.

11.1.3.2. Diurnal Temperature Range

One important aspect of the observed temperature change over the globe during the past century relates to its asymmetry during

the day and night (Karl *et al.*, 1991). Observed warming in surface air temperatures over several regions of the globe has been reported to be associated with an increase in minimum temperatures (accompanied by increasing cloudiness) and a decrease in DTR (Hansen *et al.*, 1998).

AOGCM simulations with increasing concentrations of GHGs in the atmosphere suggest relatively more pronounced increases in minimum temperature than in maximum temperature over Asia on an annual mean basis, as well as during the winter, for the 2050s and the 2080s—hence a decrease in DTR (Table 11-3). During the summer, however, an increase in DTR is simulated—suggesting thereby that the maximum temperature would have a more pronounced increase relative to the minimum temperature (Lal and Harasawa, 2001). The summertime increase in DTR over central Asia is significantly higher relative to that in other regions. Most of the subregions follow the same pattern of change in DTR, except south and southeast Asia. A marginal increase in DTR during the winter and on an annual mean basis is simulated over southeast Asia. Over the south Asia region, a decrease in DTR on an annual mean basis and during the winter and a more pronounced decrease in DTR during the summer are projected. The significantly higher decrease in DTR over

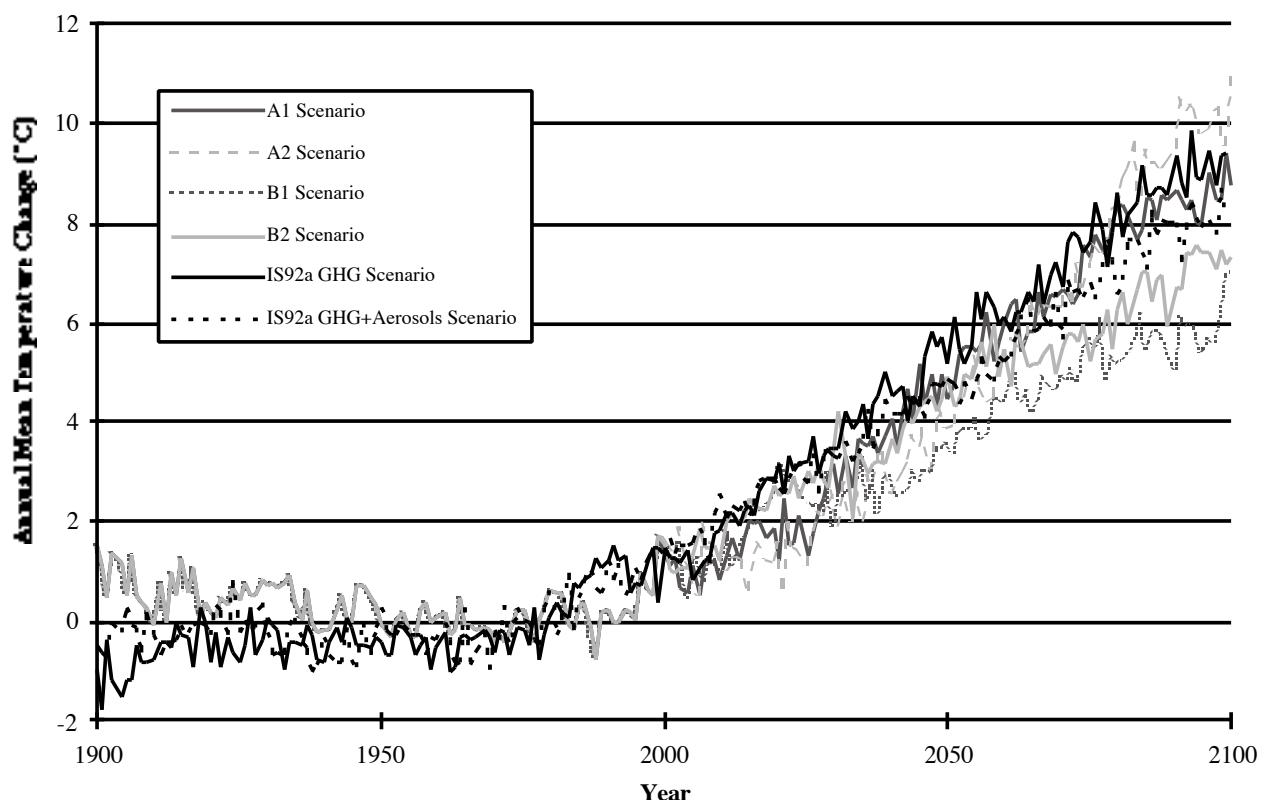

Figure 11-5: Future trends in area-averaged annual mean temperature increase over land regions of Asia as simulated by CCSRNIES AOGCM for IS92a and SRES emission scenarios. Because the climate sensitivity of model versions used for the new (SRES) and old (IS92a) sets of simulations are different, temperature trends shown are scaled so they can be compared directly; trends for IS92a scenarios are scaled by a factor of 1.56, which is the ratio of climate sensitivity averaged over Asia of new model version to that of old version. Also note that only the direct effect of sulfate aerosols is considered in the IS92a GHG+Aerosols simulation, whereas the direct and indirect effects of sulfate and carbon aerosols are considered in SRES simulations.

Table 11-3: Projected changes in diurnal temperature range over Asia and its subregions under IS92a emission scenarios, as inferred from an ensemble of data generated in experiments with CCSR/NIES, CSIRO, ECHAM4, and HadCM2 AOGCMs.

south Asia during the summer is a result of the presence of monsoon clouds over the region (Lal *et al.*, 1996). In general, the decline in DTR is slightly moderated in the presence of sulfate aerosols (Lal and Harasawa, 2001). Changes in DTR over Asia in this case suggest a decrease in both seasons. Similar changes also are seen over boreal Asia and temperate Asia.

11.1.3.3. Precipitation

In general, all AOGCMs simulate an enhanced hydrological cycle and an increase in annual mean rainfall over most of Asia (Giorgi and Francisco, 2000). An area-averaged annual mean increase in precipitation of $3\pm 1\%$ in the 2020s, $7\pm 2\%$ in the 2050s, and $11\pm 3\%$ in the 2080s over the land regions of Asia is projected as a result of future increases in the atmospheric concentration of GHGs. Under the combined influence of GHGs and sulfate aerosols, the projected increase in precipitation is limited to $2\pm 1\%$ in the decade 2020s, $3\pm 1\%$ in the 2050s, and $7\pm 3\%$ in the 2080s. Figure 11-6 depicts projected changes in precipitation relative to changes in surface air temperature, averaged for land regions of Asia for each of the four skilled AOGCMs on an annual mean basis as well as during winter and summer for the 2050s and 2080s. The increase in precipitation is maximum during NH winter for both the time periods (Lal and Harasawa, 2000b). Clearly, intermodel differences in projections of precipitation are relatively large particularly during the winter even when they are averaged for the entire Asian continent—suggesting low confidence in projections of future precipitation in current AOGCMs.

The increase in annual mean precipitation is projected to be highest in boreal Asia. During the winter, boreal Asia and the Tibetan Plateau have the most pronounced increase in precipitation (Table 11-2). Over central Asia, an increase in winter precipitation

and a decrease in summer precipitation are projected. Because the rainfall over this region is already low, severe water stress conditions—leading to expansion of deserts—are quite possible with a rise in surface air temperature here. The area-averaged annual mean and winter precipitation is projected to increase in temperate Asia. The models show high uncertainty in projections of future winter and summer precipitation over south Asia (with or without direct aerosol forcings). The effect of sulfate aerosols on Indian summer monsoon precipitation is to dampen the strength of the monsoon compared to that seen with GHGs only (Lal *et al.*, 1995a; Mitchell *et al.*, 1995; Cubasch *et al.*, 1996; Roeckner *et al.*, 1999). The overall effect of the combined forcing is at least partly dependent on the land/sea distribution of aerosol forcing and on whether the indirect effect is included along with the direct effect. To date, the effect of aerosol forcing (direct and indirect) on the variability of the monsoon has not been investigated.

Recent observations suggest that there is no appreciable long-term variation in the total number of tropical cyclones observed in the north Indian, southwest Indian, and southwest Pacific Oceans east of 160°E (Neumann, 1993; Lander and Guard, 1998). For the northwest subtropical Pacific basin, Chan and Shi (1996) found that the frequency of typhoons and the total number of tropical storms and typhoons has been more variable since about 1980. Several studies since the SAR have considered likely changes in tropical cyclones (Henderson-Sellers *et al.*, 1998; Knutson *et al.*, 1998; Krishnamurti *et al.*, 1998; Royer *et al.*, 1998). Some of these studies suggest an increase in tropical storm intensities with carbon dioxide (CO_2)-induced warming.

Some of the most pronounced year-to-year variability in climate features in many parts of Asia has been linked to ENSO. Since the SAR, analysis of several new AOGCM results indicates that as global temperatures increase, the Pacific climate will

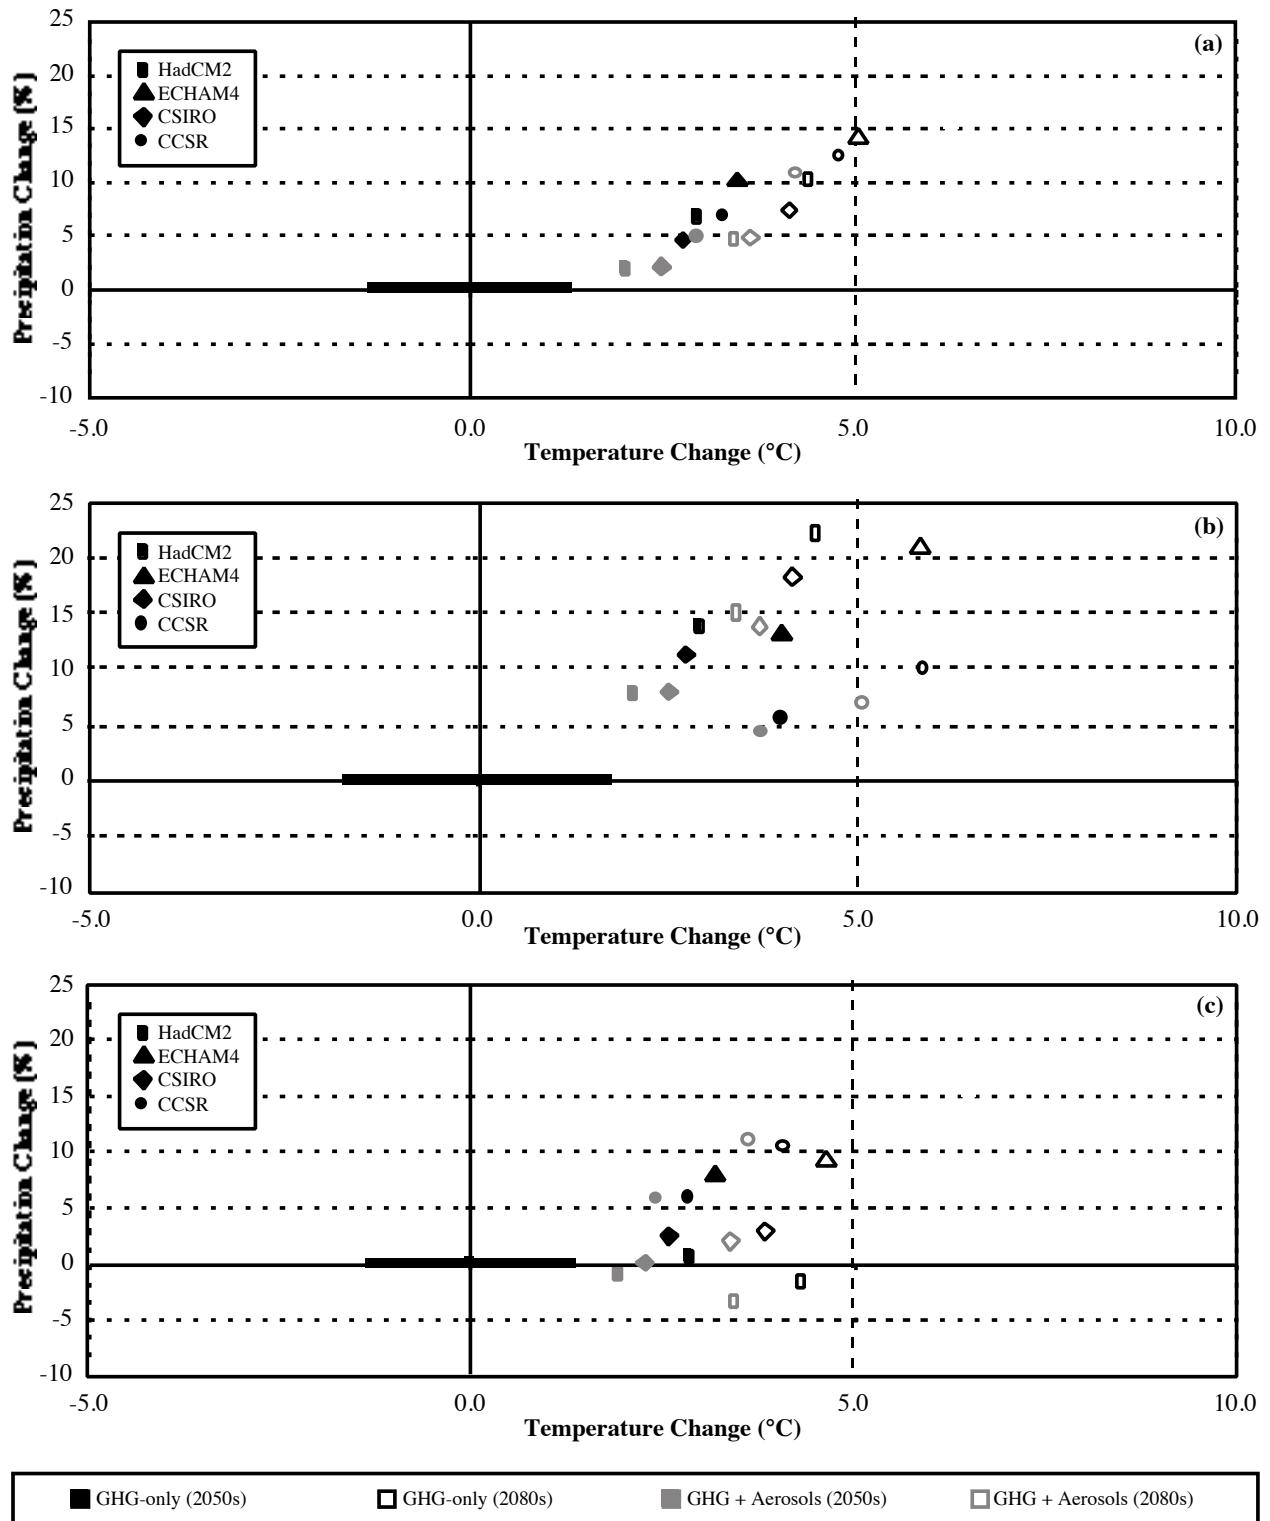

Figure 11-6: Projected changes in area-averaged annual (a) and seasonal [(b) DJF and (c) JJA] mean surface air temperature and precipitation over land regions of Asia for the 2050s and 2080s as obtained in select AOGCMs.

tend to resemble a more El Niño-like state (Mitchell *et al.*, 1995; Meehl and Washington, 1996; Knutson and Manabe, 1998; Boer *et al.*, 1999; Timmermann *et al.*, 1999). Collins (1999) finds an increased frequency of ENSO events and a shift in their seasonal cycle in a warmer atmosphere: The maximum occurs between August and October rather than around January as currently observed. Meehl and Washington (1996) indicate that future seasonal precipitation extremes associated with a given ENSO event are likely to be more intense in the tropical Indian Ocean region; anomalously wet areas could become wetter, and anomalously dry areas could become drier during future ENSO events.

Several recent studies (Kitoh *et al.*, 1997; Lal *et al.*, 2000) have confirmed earlier results (Kattenberg *et al.*, 1996) indicating an increase in interannual variability of daily precipitation in the Asian summer monsoon with increased GHGs. Lal *et al.* (2000) also report an increase in intraseasonal precipitation variability and suggest that intraseasonal and interannual increases are associated with increased intraseasonal convective activity during the summer. The intensity of extreme rainfall events is projected to be higher in a warmer atmosphere, suggesting a decrease in return period for extreme precipitation events and the possibility of more frequent flash floods in parts of India, Nepal, and Bangladesh (Lal *et al.*, 2000). However, Lal *et al.* (1995b) found no significant change in the number and intensity of monsoon depressions (which are largely responsible for the observed interannual variability of rainfall in the central plains of India) in the Bay of Bengal in a warmer climate. Because much of tropical Asia is intrinsically linked with the annual monsoon cycle, a better understanding of the future behavior of the monsoon and its variability is warranted for economic

planning, disaster mitigation, and development of adaptation strategies to cope with climate variability and climate change.

11.1.3.4. High-Resolution Climate Change Experiments

Although these AOGCMs treat the complex interactions of atmospheric physics and planetary-scale dynamics fairly well, coarse horizontal resolution in the models restricts realistic simulation of climatic details on spatial variability. For example, tropical precipitation has high temporal and spatial variability, which cannot be resolved realistically in currently available AOGCMs. Many investigations on the ability of GCMs to simulate the Asian monsoon have been reported in the literature (e.g., Meehl and Washington, 1993; Chakraborty and Lal, 1994; Bhaskaran *et al.*, 1995; Lal *et al.*, 1995a, 1997, 1998a,b). These studies suggest that although most GCMs are able to simulate the large-scale monsoon circulation well, generally they are less successful with the summer monsoon rainfall. Since the SAR, nested modeling approaches have been followed to generate high-resolution regional climate scenarios (Jones *et al.*, 1995; Lal *et al.*, 1998c; Hassell and Jones, 1999) with more realistic mesoscale details and the response of GHG forcings to the surface climatology over the Asian monsoon region.

Large-scale patterns of temperature change simulated by GCMs and nested regional climate models (RCMs) are found to be generally similar under $2\times\text{CO}_2$ forcing, but the regional model results present some additional details associated with coastline and local topographical features (Hirakuchi and Giorgi, 1995). In addition, projected warming over eastern China region in the summer is less pronounced in the RCM

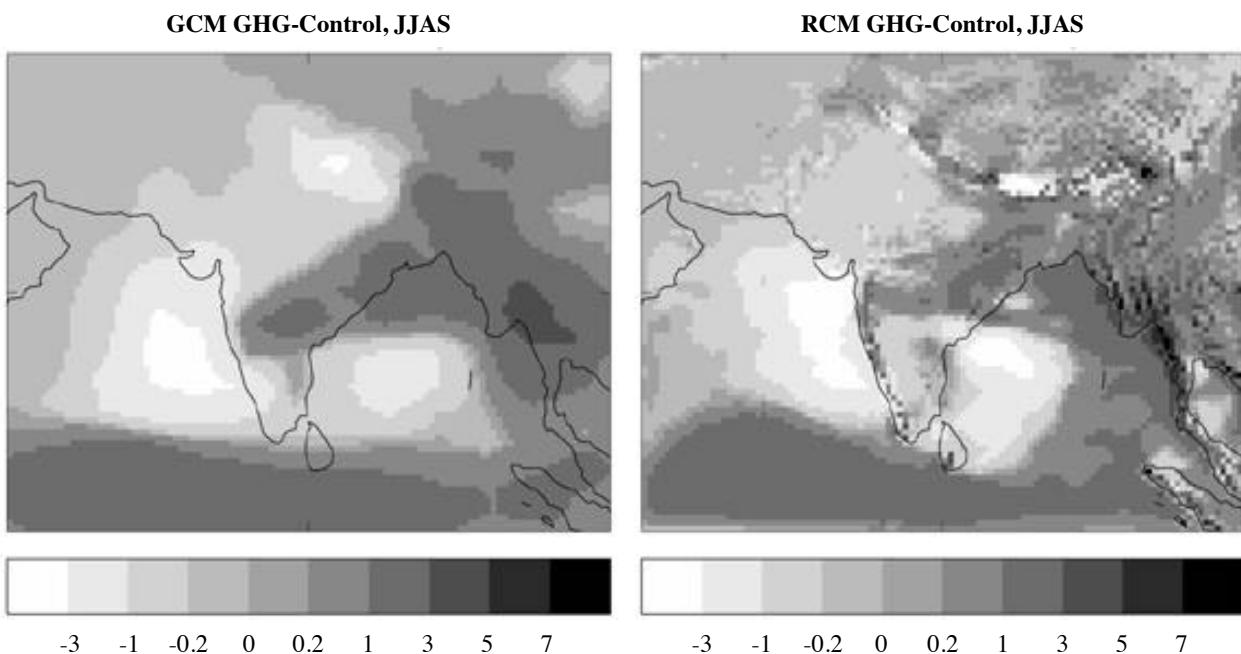

Figure 11-7: Spatial distribution of changes in monsoon rainfall over Indian subcontinent as simulated by Hadley Centre's global and regional climate models at the time of doubling of CO_2 in the atmosphere.

than in the GCM and is characterized by a different spatial pattern. This is related to an increase in monsoon precipitation simulated by the RCM there and associated surface cooling induced by evaporation and cloudiness. Nonetheless, the GCM and RCM simulations suggest a general increase in warming toward higher latitudes and greater warming in winter than in summer. The RCM produces a more pronounced increase in winter precipitation over southeastern China than does the GCM in response to orographic lifting of stronger low-level southerly onshore winds. The RCM also simulates increased precipitation in the monsoon rain belt over east China, Korea, and Japan during the summer.

The increase in surface air temperature simulated by the RCM over central and northern India is not as intense as in the GCM and does not extend as far south (Lal *et al.*, 1998c; Hassell and Jones, 1999). These anomalies are linked with changes in surface hydrological variables. Summer precipitation exhibits a more complex pattern of increases and decreases. Whereas an increase in rainfall is simulated over the eastern region of India, northwestern deserts see a small decrease in the absolute amount of rainfall in RCM simulation (Figure 11-7). Changes in soil moisture broadly follow those in precipitation except in eastern India, where they decrease as a result of enhanced drainage from the soil. The largest reductions (precipitation reduced to <1 mm day $^{-1}$; 60% decline in soil moisture) are simulated in the arid regions of northwest India and Pakistan. The projected increase in precipitation in flood-prone Bangladesh is approximately 20%. Nested RCM simulations have the potential to simulate the onset of the summer monsoon and its active/break cycle over India. The RCM captures the observed precipitation maximum over the southern tip of India during weak monsoon conditions, whereas the GCM does not.

Given the current state of climate modeling, projections of future regional climate have only limited confidence. The degree of confidence that could be attributed to RCM responses in terms of temporal and spatial changes resulting from GHG forcings would depend on more accurate simulation of the space and time evolution of large-scale monsoon circulation features in AOGCMs, as well as additional long-term RCM simulations with better skill. Current efforts on climate variability and climate change studies increasingly rely on diurnal, seasonal, latitudinal, and vertical patterns of temperature trends to provide evidence for anthropogenic signatures. Such approaches require increasingly detailed understanding of the spatial variability of all forcing mechanisms and their connections to global, hemispheric, and regional responses. Because the anthropogenic aerosol burden in the troposphere would have large spatial and temporal variations in the atmosphere, its future impact on regional scale would be in striking contrast to the impact from GHGs. It has also been suggested that aerosols produced by tropical biomass burning could lead to additional negative radiative forcing (Portmann *et al.*, 1997). Considerable uncertainty prevails about the indirect effect of aerosols on tropospheric clouds, which could strongly modulate the climate. The implications of localized radiative forcing on deep convection in tropical Asia and on Hadley circulation are still not understood (Lal *et al.*, 2000).

11.1.4. Sensitivity, Key Vulnerabilities, and Adaptability

11.1.4.1. Sensitivity and Key Vulnerabilities

An examination and analysis of the climate change-induced vulnerabilities in Asia has to be undertaken against the backdrop of the physical, economic, and social environment of the countries in the region. They provide not only the benchmark against which vulnerabilities are to be assessed but also the potential for adaptation to them. Surface water and groundwater resources in Asian countries play vital roles in forestry, agriculture, fisheries, livestock production, and industrial activity. The water and agriculture sectors are likely to be most sensitive to climate change-induced impacts in Asia.

As reported in IPCC (1998), climate change in boreal Asia could have serious effects on climate-dependent sectors such as agriculture, forestry, and water resources. Climate change and human activities, for example, may influence the levels of the Caspian and Aral Seas, with implications for the vulnerability of natural and social systems (Kelly *et al.*, 1983; Golubtsov *et al.*, 1996; Popov and Rice, 1997). The increase in surface temperature will have favorable effects on agriculture in the northernmost regions of Asia, and a general northward shift of crop zones is expected. However, as much as a 30% decrease in cereal production from the main agriculture regions of boreal Asia by 2050 has been projected (Budyko and Menzhulin, 1996; ICRF, 1998). A decrease in agriculture productivity of about 20% also is suggested in southwestern Siberia (ICRF, 1998). Forest ecosystems in boreal Asia could suffer from floods and increased volume of runoff, as well as melting of permafrost regions. Model-based assessments suggest that significant northward shifts (up to 400 km) in natural forest zones are likely in the next 50 years (Lelyakin *et al.*, 1997; Serebryanny and Khropov, 1997). There also is growing anxiety that significant increases in ultraviolet radiation, as observed in recent years, could have serious implications for ecosystems along the Arctic shore of Siberia (Makarov, 1999; Voskoboinikov, 1999; ACIA, 2000).

In arid and semi-arid Asia, the climate limits the portion of land that presently is available for agriculture and livestock production. Croplands in many of the countries in the region are irrigated because rainfall is low and highly variable. The agriculture sector here is potentially highly vulnerable to climate change because of degradation of the limited arable land. Almost two-thirds of domestic livestock are supported on rangelands, although in some countries a significant share of animal fodder also comes from crop residues (IPCC, 1998). The combination of elevated temperature and decreased precipitation in arid and semi-arid rangelands could cause a manifold increase in potential evapotranspiration, leading to severe water-stress conditions. Many desert organisms are near their limits of temperature tolerance. Because of the current marginality of soil-water and nutrient reserves, some ecosystems in semi-arid regions may be among the first to show the effects of climate change. Climate change has the potential to exacerbate the loss of biodiversity in this region.

The major impacts of global warming in temperate Asia will be large northward shifts of subtropical crop areas. Large increases in surface runoff—leading to soil erosion and degradation, frequent waterlogging in the south, and spring droughts in the north—ultimately will affect agriculture productivity (Arnell, 1999). As reported in IPCC (1998), the volume of runoff from glaciers in central Asia may increase three-fold by 2050. Permafrost in northeast China is expected to disappear if temperatures increase by 2°C or more. The northern part of China would be most vulnerable to hydrological impacts of climate change; future population growth and economic development here may exacerbate seriously the existing water shortage. Deltaic coasts in China would face severe problems from sea-level rise. Sea-level rise also will expand the flood-prone area and exacerbate beach erosion in Japan.

In monsoon Asia, the issue of sensitivity of physical and natural systems to the hydrological cycle is linked to major stresses caused by projected climate change on agricultural production and increased exposure of social and economic systems to impacts of extreme events, including forest die-back and increased fire risk; typhoons and tropical storms; floods and landslide; and human disease impacts. These stresses on physical systems translate into key social vulnerabilities, particularly in combination with unsustainable utilization of resources. For example, the drawing down of groundwater resources has increased the rate of relative sea-level change for many of the major cities of coastal Asia, such as Bangkok and Shanghai—thereby increasing the risk from climate change-induced sea-level rise (Jarupongsakul, 1999). Conversion of natural forests to palm oil plantations in many southeast Asian countries during recent decades (particularly Indonesia and Malaysia) increased the probability of uncontrolled forest fires and increased health and biodiversity impacts during the 1997 ENSO event (Yim, 1999; Barber and Schweithelm, 2000). The ecological security of mangroves and coral reefs may be put at risk by climate change. Sea-level rise could cause large-scale inundation along the coastline and recession of flat sandy beaches of south and southeast Asia. Monsoons in tropical Asia could become more variable if ENSO events become stronger and more frequent in a warmer atmosphere (Webster and Yang, 1992; Webster *et al.* 1998).

Vulnerability relates to social or natural systems and is delineated as such. The issues of social and physical vulnerability to climate change are directly related because the major sensitivities of ecological and natural systems across the regions of Asia translate into risks to socioeconomic systems. Social vulnerability is defined as the degree to which individuals or groups are susceptible to impacts; the determinants of social vulnerability are exposure to stress as a result of the impacts of climate change and the underlying social position (Adger, 1999a). On this basis, the key social vulnerabilities in the Asian context occur:

- Where resource-dependent communities have their resilience undermined by increased exposure to the physical stresses in water availability, agricultural impact, and other sensitivities mentioned above

- Where sustainability and equity (Munasinghe, 2000) are sacrificed for economic growth, exposing larger parts of the population to impacts.

11.1.4.2. Adaptability

Climate variability and change, both natural and anthropogenic, cause a wide range of direct and indirect impacts on natural and human systems. To understand which adaptation opportunities will be most cost-effective and have the greatest value, emphasis must be given to characteristics of system vulnerability, such as resilience, critical thresholds, and coping ranges, which are highly dependent on regions and nations. In this respect, lessons learned from past experiences regarding climate variability and change provide essential understanding of processes, actions, and successes.

The impacts of climate change and other drivers of environmental degradation (e.g., disparities in income level, technological gaps) are likely to be felt more severely in developing countries than in developed countries of Asia, irrespective of the magnitude of climate change, because of the poor resource and infrastructure bases. The developing countries need to scope the development of adaptation strategies incrementally to support development of existing policies that exploit “no regret” measures and “win-win” options (Smit *et al.*, 2000). Detailed and reliable regional scenarios of climate change need to be developed and used in rigorous vulnerability analysis (e.g., low-probability/high-consequence events versus high-probability/high-consequence events, risk perceptions). In developing countries, adaptation responses are closely linked to developmental activities. Consequently, there are likely to be large spillover effects between adaptation policies and developmental activities. Care in this regard must be taken in the evaluation of adaptation costs and benefits. In developing countries of Asia, options such as population growth control, poverty alleviation, and capacity building in food production, health care delivery, and water resource management hold great potential in creating more resilient social systems that are capable of withstanding the negative impacts of climate change.

11.2. Key Regional Concerns

Despite global technological and economic development, a large proportion of the nearly 1.5 billion people living in severe poverty at the dawn of the new millennium are located in Asia. Global per capita water supplies are declining and are now 30% lower than they were 25 years ago. By 2050, as much as 42% of the world’s population may have to live in countries with insufficient freshwater stocks to meet the combined needs of agriculture, industry, and domestic use. The world’s population will reach at least 8.9 billion by the middle of the 21st century (United Nations, 1998). India and China alone now account for 38% of the world’s population. Most of the additional population would be in developing countries. These countries are likely to suffer adverse agricultural responses; significant changes in

seasonal runoff; possibly severe vector-borne diseases; increased risks of severe tropical weather disturbances, including storms; vulnerability to sea-level rise; and other stresses. This section presents key regional concerns of various subregions of Asia related to climate change.

11.2.1. Ecosystems and Biodiversity

11.2.1.1. Mountain and Highland Systems

Relatively hospitable mountain regions in Asia are under pressure from human settlements and commercial cultivation, which have led to land degradation and adverse effects on water supply. Ongoing changes in different mountain systems within Asia include those associated with high crop production and those characterized by extensive animal husbandry and pastureland. Human encroachment in mountain regions has reduced vegetation cover, which has increased soil moisture evaporation, erosion, and siltation—with adverse effects on water quality and other resources. Changes in the snowfall pattern have been observed in mountain and highland systems, particularly in the Himalayas (Vergheze and Iyer, 1993). These changes will have wider implications—from marked impact on the monsoon regime to seasonal runoff and vegetation cover, including agriculture. Changes in the hydrological regime also will trigger episodes of extreme events.

One-tenth of the world's known species of higher altitude plants and animals occur in the Himalayas. In addition, some countries in Asia are centers of origin for many crop and fruit-tree species; as such, they are important sources of genes for their wild relatives. Biodiversity is being lost in these regions because of human activities, especially land degradation and the overuse of resources. In 1995, approximately 10% of known species in the Himalayas were listed as threatened, and the number of species on the verge of extinction has increased since then. As a consequence of global warming, the present distribution of species in high-elevation ecosystems is projected to shift to higher elevations, although the rates of vegetation change are expected to be slow and colonization success would be constrained by increased erosion and overland flows in the highly dissected and steep terrains of the Himalayan mountain range. Weedy species with a wide ecological tolerance will have an advantage over others (Kitayama and Mueller-Dombois, 1995). High-elevation tree species—such as *Abies*, *Acer*, and *Betula*—prevail in cold climates because of their adaptations to chilling winters. In Japan, the area of suitable habitat at higher elevations has shrunk over the past 30 years, and the variety of alpine plants that grow there has been rapidly reduced (Masuzawa, 1997, 2000). Increases in temperature would result in competition between such species and new arrivals. The sensitivity of alpine flora to climatic factors and, in particular, water stress in the summit region of Mt. Kinabalu—the highest mountain in southeast Asia—already have been demonstrated (Kitayama, 1996; Aiba and Kitayama, 1999). The accumulated stresses of climate change are likely to disrupt the ecology of mountain and highland systems.

11.2.1.2. Lakes/Streams, Rivers, and Glaciers

Lakes, streams, glaciers, and other freshwater ecosystems in Asia are highly diversified in terms of plant and animal species. These freshwater ecosystems have been stressed by environmental burdens, exploitation of natural resources, transformation of lands, and recreational activities. There is growing concern that climate change may accelerate the damage to freshwater ecosystems such as lakes, marshes, and rivers. More than 50,000 ha of coastal territories, including 35,000 ha of delta in the Selenga River and 12,000 ha of delta in the Upper Angara River, have been damaged during the past few years by precipitation and riverflow increases (Anokhin and Izrael, 2000). With an increased amount of precipitation likely in the future, more incidences of flooding and other adverse impacts are possible. With a rise in temperature, a decrease in the amount of snowfall in the Lake Biwa catchment in Japan is projected—which might exacerbate the process of eutrophication (Fushimi, 2000a). Deterioration of lake water quality also is suggested in Kasumigaura Lake in eastern Japan (Fujimoto *et al.*, 1995; Fukushima *et al.*, 2000). The response of lakes and streams to climate change will involve complex interactions between the effects of climate on areal inputs, hydrology, and catchments and in-lake processes.

Many of the major rivers in Asia have long been targets for development projects related to the hydroelectric, water supply, agriculture, industry, and navigation sectors. As a consequence, there have been shifts between freshwater and estuarine conditions as a result of high freshwater flows during the rainy season and low to nonexistent freshwater flows in the dry season. Increasing literol vegetation is causing health risks for local habitats in many countries of south Asia. Changes in aquatic habitat also have affected fisheries in lower valleys and deltas; the absence of nutrient-rich sediments has detrimental effects on fish productivity. Reduced flows in lower valley catchments also have resulted in eutrophication and poor water quality.

Many rivers originate from the glaciers in the Tianshan mountain range, which create wide alluvial fans at the foot of the northern Tianshan. The Hindu Kush Himalayan ranges are the source of some major rivers. The total amount of water flowing from the Himalayas to the plains of the Indian subcontinent is estimated at about 8.6×10^6 m³ per year. The Himalayas have nearly 1,500 glaciers; it is estimated that these glaciers cover an area of about 33,000 km² (Dyurgerov and Meier, 1997). These glaciers provide snow and the glacial meltwaters keep major rivers perennial throughout the year. In recent decades, the hydrological characteristics of watersheds in this region seem to have undergone substantial change as a result of extensive land-use change—leading to more frequent hydrological disasters, enhanced variability in rainfall and runoff, extensive reservoir sedimentation, and pollution of lakes (Ives and Messerli, 1989). Almost 67% of the glaciers in the Himalayan and Tianshan mountain ranges have retreated in the past decade (Ageta and Kadota, 1992; Yamada *et al.*, 1996; Fushimi, 2000b). The mean equilibrium-line altitude at which snow accumulation is equal to snow ablation for glaciers is

estimated to be about 50–80 m higher than the altitude during the first half of the 19th century (Pender, 1995). Available records suggest that Gangotri glacier is retreating by about 30 m yr⁻¹. A warming is likely to increase melting far more rapidly than accumulation. As reported in IPCC (1998), glacial melt is expected to increase under changed climate conditions, which would lead to increased summer flows in some river systems for a few decades, followed by a reduction in flow as the glaciers disappear.

11.2.1.3. Forests, Grasslands, and Rangelands

Most of the frontier forests in Asia are endangered today by rapid population growth, ever-increasing demand for agricultural land, poverty, poor institutional capacity, and lack of effective community participation in forestry activities (Mackenzie *et al.*, 1998). Climate change is expected to affect the boundaries of forest types and areas, primary productivity, species populations and migration, the occurrence of pests and diseases, and forest regeneration. The increase in GHGs also affects species composition and the structure of ecosystems because the environment limits the types of organisms that can thrive and the amount of plant tissues that can be sustained (Melillo *et al.*, 1996). Compositional and structural changes, in turn, affect ecosystem function (Schulze, 1994). The interaction between elevated CO₂ and climate change plays an important role in the overall response of net primary productivity to climate change at elevated CO₂ (Xiao *et al.*, 1998).

Climate change will have a profound effect on the future distribution, productivity, and health of forests throughout Asia (see also Section 5.6). Because warming is expected to be particularly large at high latitudes, climate change could have substantial impact on boreal forests (Dixon *et al.*, 1996; IPCC, 1996; Krinkina, 1997). Global warming will decrease permafrost areas, improve growing conditions, and decrease areas of disturbed stands and ecosystems in a general sense, although impacts would be significantly different at various locations within the boreal forests. Moreover, forest fire is expected to occur more frequently in boreal Asia as a result of increased mean temperature (Valendik, 1996; Lelyakin *et al.*, 1997). Pest activity also could increase with a rise in temperature, depending on the age composition of the boreal forests (Alfiorov *et al.*, 1998).

Asia's temperate forests are a globally important resource because of their high degree of endemism, biological diversity, ecological stability, and production potential. About 150 Mha of forests in central China have been cleared during the past several decades. Efforts are now underway to at least partially restore the area under forest cover in China through reforestation, soil recovery, and water conservation programs (Zhang *et al.*, 1997). Studies on projected impacts of climate change suggest that northeast China may be deprived of the conifer forests and its habitat, and broad-leaved forests in east China may shift northward by approximately 3° of latitude. These results are based on a 2°C increase in annual mean temperature and a 20%

increase in annual precipitation (Omasa *et al.*, 1996; Tsunekawa *et al.*, 1996).

Tropical moist forests have trees with higher densities of wood and larger proportions of branch wood relative to those in temperate forests. As many as 16 countries of tropical Asia are located within the humid tropical forest region. These forests and woodlands are important resources that must be safeguarded, given the heavy use of wood as fuel in some countries. Past policies in the humid tropics have focused mainly on natural forest protection and conservation (Skole *et al.*, 1998). However, there is a need to shift emphasis from conservation alone to a strategy that involves sustained development, investment performance, and public accountability (see Section 5.6). Encouragingly, the current annual rate of reforestation is highest in tropical Asia as a result of relatively high investments in reforestation schemes, including social forestry.

Most semi-arid lands in Asia are classified as rangelands, with a cover of grassland or scrublands. Although the share of land area used for agricultural purposes is about 82% of the total area, it is mainly low-productive pastures. With an increase in temperature of 2–3°C combined with reduced precipitation as projected for the future in the semi-arid and arid regions of Asia, grassland productivity is expected to decrease by as much as 40–90% (Smith *et al.*, 1996). Approximately 70% of pastures are facing degradation, with dramatic decreases in fodder yield over recent decades in some parts of Mongolia (Khuldorj *et al.*, 1998). Rangelands in Nepal also have been subject to degradation in recent years (NBAP, 2000). Climate change is likely to represent an additional stress to rapid social change in many of Asia's rangelands.

11.2.1.4. Drylands

Precipitation is scarce and has a high annual variance in dryland areas. Very high daily temperature variance is recorded with frequent sand storms, dust ghost, and intense sunshine. Arid plants usually belong to drought escaper, drought evader, drought resister, or drought endurer categories. Evaporative losses and water limitations are the most prominent factors dictating animal life in arid environments. Low rainfall dictates the formation of shallow or extremely shallow soils that often are characterized by high content of airborne particles and small fractions of rock-erosion elements. Most of the soils are poor in or completely devoid of organic matter, and the nutrient pools of the soils are low. Apparently, humans not only utilize the ecosystem services of this region but are also influencing the evolution of some of its important biotic elements. In Mongolia, for example, while soil fertility has decreased by about 20% in the past 40 years, about one-third of the pasture has been overgrazed and 5 Mha of arid land have constantly been threatened by moving sands (Khuldorj *et al.*, 1998). Soils exposed to degradation as a result of poor land management could become infertile as a result of climate change. Temperature increases would have negative impacts on natural vegetation in desert zones. Plants with surface root systems,

which utilize mostly precipitation moisture, will be vulnerable. Climate change also would have negative impacts on sheep breeding and lamb wool productivity.

Just as shifts in vegetation belts are expected in non-drylands, in the drylands of Asia a shift in dryland types is expected as a result of climate change. Drylands are ranked along an aridity index, in relation to the ratio of precipitation to potential evapotranspiration (i.e., to a gradient in soil moisture available for driving production). Because soil moisture is likely to decline in this region, the least-dry land type (dry subhumid drylands) are expected to become semi-arid, and semi-arid land is expected to become arid. It is notable that population pressure on dryland resources is reduced with increasing aridity, but resistance to degradation and resilience following degradation also is reduced with increasing aridity. Therefore, semi-arid drylands, which are intermediate in aridity as compared to arid drylands and dry subhumid ones, are most susceptible to becoming further desertified (Safriel, 1995). Because semi-arid drylands are very common among Asian drylands, large areas will become not only dry but also desertified as a result of climate change.,

11.2.1.5. Cryosphere and Permafrost

Permafrost is highly responsive to climatic fluctuations at several temporal and spatial scales (Nelson and Anisimov, 1993). Evidence of spatially extensive episodes of permafrost thawing and poleward contraction has been documented (Halsey *et al.*, 1995; Anisimov and Nelson, 1996b; Anisimov and Nelson, 1997; WASI, 1997). Depending on regional climate and local biological, topographic, and edaphic parameters, pronounced warming in the high latitudes of Asia could lead to thinning or disappearance of permafrost in locations where it now exists (Anisimov and Nelson, 1996a). Poleward movement of the southern boundary of the sporadic permafrost area is likely in Mongolia and northeast China. Large-scale shrinkage of the permafrost region in boreal Asia also is likely. In northern regions of boreal Asia, the mean annual temperature of permafrost, hence the depth of seasonal thawing (active layer thickness), will increase (Izrael *et al.*, 1999). The perennially frozen rocks will completely degrade within the present southern regions (ICRF, 1998). The development of thermokarst and thermal erosion because of perennial thawing and increase in the depth of seasonal thawing of ice-rich grounds and monomineral ice accumulations is a critical process in permafrost regions of boreal Asia (Izrael *et al.*, 1999). The change in rock temperature will result in a change in the strength characteristics, bearing capacity, and compressibility of frozen rocks, generation of thermokarst, thermal erosion, and some other geocryological processes (Garaglia and Ershov, 2000). In response to projected climate change, four main economic sectors in permafrost regions—surface and underground construction, the mining industry, heating energy demand, and agricultural development—will be affected (ICRF, 1995, 1998; Anisimov, 1999). Because large quantities of carbon are sequestered in the permafrost of boreal peatlands and tundra regions (Botch *et al.*, 1995; Ping,

1996), changes in distribution of frozen ground and systematic increase in the thickness of seasonally thawed layer are likely to result in the release of large amounts of CO₂ and possibly methane (CH₄) into the atmosphere.

The permafrost area on the Tibetan Plateau has an average altitude of about 5,000 m and is one of the several regions not significantly affected by direct human activities. Because of this area's thermal and moisture conditions are on the edge of the ecological limitations of vegetation, it is believed to be highly sensitive to global warming (Zhang *et al.*, 1996). The boundary between continuous and discontinuous (intermittent or seasonal) permafrost areas on the Tibetan Plateau are likely to shift toward the center of the plateau along the eastern and western margins (Anisimov and Nelson, 1996b).

11.2.1.6. Protected Areas and Risks to Living Species

Protected areas usually are designated and managed to keep wild species that live within the area from becoming extinct. Even after an area has been set aside as protected habitat, extinction or population declines may still occur as a result of changes in environmental conditions related to climate change, land use in surrounding areas, or widespread pollution. Climate change is likely to induce vegetation change that will force wild plant and animal species to shift their distribution in response to the new conditions. For example, a variety of changes in butterflies, dragonflies, beetles, and other migratory insects have been recorded in green corridors of Japan in recent years (Ubukata, 2000), and shifts have been recorded in the ranges of many North American, European, Arctic, and Antarctic bird and insect species (see Section 5.4). If the protected area is not large enough to contain an area that will be suitable under the new climate conditions, a species may become locally extinct. In contrast, protected areas that are large enough to cover an elevation or a latitudinal gradient should allow species to make adjustments along the gradient as conditions change. In some cases, such as in coastal areas, habitat may simply be lost as a result of factors such as sea-level rise, with no potential area for species to migrate.

Frontier forests in Asia are home to more than 50% of the world's terrestrial plant and animal species (Rice, 1998). Risks to this rich array of living species are increasing. For instance, of the 436 species of mammals and 1,500 species of birds in Indonesia, more than 100 species each of mammals and birds have been declared threatened (UNEP, 1999). Similar trends also are seen in China, India, Malaysia, Myanmar, and Thailand. In India, as many as 1,256 higher plant species, of more than 15,000 species, are threatened (Sukumar *et al.*, 1995).

Coastal areas are likely to be at risk from climate change-induced sea-level rise. A rise in the water level of estuaries will reduce the size and connectedness of small islands and coastal and estuarine reserves and increase their isolation. The Yangtze (Changjiang) and Mekong deltas on mainland China and the Mai Po marshes in Hong Kong are refueling stops for migratory

birds, especially ducks, geese, and shorebirds. The presence of these birds may be threatened by the disappearance of coastal marshes as a result of increases in sea level from global warming (Li *et al.*, 1991; Tang, 1995). Similarly, the Rann of Kutch in India supports one of the largest Greater Flamingo colonies in Asia (Ali, 1985; Bapat, 1992). With sea-level rise, these salt marshes and mudflats are likely to be submerged (Bandyopadhyay, 1993), which would result in decreased habitat for breeding flamingoes and lesser floricans (Sankaran *et al.*, 1992). In addition, about 2,000 Indian wild asses in the Rann of Kutch could lose their only habitat in India to rising sea level (Clark and Duncan, 1992).

The Sundarbans of Bangladesh, which support a diversity of wildlife, are at great risk from rising sea level. These coastal mangrove forests provide habitat for species such as Bengal tigers, Indian otters, spotted deer, wild boars, estuarine crocodiles, fiddler crabs, mud crabs, three marine lizard species, and five marine turtle species (Green, 1990). With a 1-m rise in sea level, the Sundarbans are likely to disappear, which may spell the demise of the tiger and other wildlife (Smith *et al.*, 1998).

Species that live in mountainous areas also are particularly at risk of losing habitat as a result of changes in climate. Extreme temperature conditions may cause these protected areas to undergo major changes, partly because of high rates of variation in habitat structure that naturally occur on mountain ranges as a result of changes in slope, steepness, and exposure. Protected areas also may be subjected to extreme surface runoffs because of rapid melting of winter snow. Because many Asian mountain ranges are east-west oriented, there will be little room for species to shift their ranges toward cooler mountainous habitat. An additional barrier to wildlife movements in mountainous habitat derives from the fact that many of the larger reserves in central Asia are located along international borders. Depending on topography, if these borders are heavily fenced, most of the larger terrestrial vertebrates will not be able to respond spatially to changes in their environment.

Besides loss of habitat, wild species are at risk from changes in environmental conditions that favor forest fires and drought. For example, forest fires under unseasonably high temperatures in Nepal may threaten local extinction for red pandas, leopards, monkeys, deer, bears, and other wild animals. If the frequency of these extreme events increases, the frequency of fire also may increase. Similarly, increases in the frequency of dry spells and local droughts may decrease populations. For example, drought-related decreases in the density and persistence of Green Leaf Warblers have been recorded on their wintering grounds in the Western Ghats of south India (Katti and Price, 1996). In desert ecosystems, protected areas often are located around oases, which are the basis for the existence of much of the local fauna. Protected oases often are far apart, so droughts that cause a decline in local forage often cause mass mortality because animals may not be able to move on to adjacent oases. The frequency of these droughts therefore is a key component in the viability of populations in such protected areas (Safriel, 1993).

Climate change is likely to act synergistically with many other stressors, such as land conversion and pollution, leading to major impacts on protected areas and species (see Chapter 5). Currently designated major protected areas in Asia need to be examined with respect to the ability of their species to shift in range in response to changing climate, as well as with respect to how much habitat could be lost. Many species—especially those in coastal areas and mountainous habitats—could experience large population declines; some may become extinct at least in part because of climate changes.

11.2.2. Agriculture and Food Security

11.2.2.1. Production Systems

Asia has the world's largest area under cereal cultivation and is the largest producer of staple foods (FAO, 1999a). Present crop yields in Asia are comparable to those in Europe and South America. Within Asia, India has the largest area under cereal cultivation. The total production of cereals in China is twice that of India, as a result of higher average productivity (FAO, 1999a). Most land that is suitable for cultivation is already in use; by 2010 per capita availability of land in developing countries of Asia will shrink from the present 0.8 ha to about 0.3 ha. Table 11-4 depicts the growth rate of rice cultivation area in select Asian countries. Current rates of land degradation suggest that a further 1.8 million km² of farmland could become unproductive in Asia by 2050, adding stress to a system that must ensure food security in the context of a rapidly growing population.

Rice is central to nutrition in Asia. In 1997, rice provided about 700 kilocalories per person per day or more for approximately 2.9 billion people, most of whom live in developing countries of Asia and Africa. During the 1990s, rice production and productivity in Asia grew at a much slower rate than did population. Yield deceleration of rice (the annual growth rate declined from 2.8% in the 1980s to 1.1% in the 1990s) in Asia has been attributed to water scarcity, indiscriminate addition and inefficient use of inputs such as inorganic fertilizers and pesticides, and policy issues and the reliance on a narrower genetic material base with impacts on variability (Hazell, 1985; Matson *et al.*, 1997; Naylor *et al.*, 1997). Several other factors also have contributed to productivity stagnation and the decline of rice (lower output/input ratio) in the intensive cropping system (two to three rice crops per year). Key factors currently contributing to the yield gap in different countries of Asia include biophysical, technical/management, socioeconomic, institutional/policy, technology transfer, and adoption/linkage problems.

Urbanization in Asia has accentuated increased demand for fresh vegetables; this demand is to be met by new production areas combined with more intensified horticulture crop management to raise the productivity per unit of land and water. In most cases, urban and peri-urban agriculture initiatives with uncontrolled use of agrochemicals are a high-risk activity.

Table 11-4: Changes in area under rice cultivation in select Asian countries, 1979–1999 (FAO, 1999a).

Country	Period	Total Rice Cultivation Area (10^3 ha)	Change in Rice Cultivation Area (10^3 ha)	Rate of Change in Rice Cultivation Area (ha yr^{-1})
Bangladesh	1979	10,160	310	14,762
	1999	10,470		
Cambodia	1979	774	1,187	56,524
	1999	1,961		
China	1979	34,560	-2,840	-135,238
	1999	31,720		
India	1979	39,414	3,586	170,762
	1999	43,000		
Indonesia	1979	8,804	2,820	134,286
	1999	11,624		
Malaysia	1979	738	-93	-4,429
	1999	645		
Myanmar	1979	4,442	1,016	48,381
	1999	5,458		
Nepal	1979	1,254	260	12,381
	1999	1,514		
Sri Lanka	1979	790	39	1,857
	1999	829		
Pakistan	1979	2,035	365	17,381
	1999	2,400		
Philippines	1979	3,637	341	16,238
	1999	3,978		
Thailand	1979	8,654	1,346	64,095
	1999	10,000		
Vietnam	1979	5,485	2,163	103,000
	1999	7,648		

Adequate steps need to be taken at regional and local levels to safeguard specialized and diversified urban production systems (vegetables, fruits, and root crops) through sustainable intensification of natural resource use and strengthening of decision support systems. Increased productivity and sustained production of food grains and legumes, industrial crops (oil, gum and resins, beverage, fiber, medicines, aromatic plants), and horticultural crops through crop diversification is critical for food and nutritional security in Asia.

Even minor deviations outside the “normal” weather range seriously impair the efficiency of externally applied inputs and

food production. Moisture stress from prolonged dry spells or thermal stress resulting from heat-wave conditions significantly affect the agricultural productivity when they occur in critical life stages of the crop (Rounsevell *et al.*, 1999). As reported in IPCC (1998), stress on water availability in Asia is likely to be exacerbated by climate change. Several studies aimed at understanding the nature and magnitude of gains or losses in yield of particular crops at selected sites in Asia under elevated CO₂ conditions and associated climatic change have been reported in the literature (e.g., Lou and Lin, 1999). These studies suggest that, in general, areas in mid- and high latitudes will experience increases in crop yield, whereas yields in areas in

the lower latitudes generally will decrease (see also Chapter 5). Climatic variability and change will seriously endanger sustained agricultural production in Asia in coming decades. The scheduling of the cropping season as well as the duration of the growing period of the crop also would be affected.

In general, increased CO₂ levels and a longer frost-free growing season are expected to enhance agricultural productivity in north Asia. The area under wheat cultivation is likely to expand in the north and west. The increase in surface temperature also may increase the growing season in temperate Asia, thereby prolonging the grain-filling period, which may result in higher yields (Rosenzweig and Hillel, 1998). In Japan, for example, simulation studies and field experiments indicate that enhanced CO₂ levels in a warmer atmosphere will substantially increase rice yields and yield stability in northern and north-central Japan (Horie *et al.*, 1995a). In south central and southwestern Japan, however, rice yields are expected to decline by at least 30% because of spikelet sterility and shorter rice growing duration (Matsui and Horie, 1992). Climate change should be advantageous to wheat yield in northeast China. Because of an increase in respiration in a warmer atmosphere demanding more water availability, rice yield in China is expected to decline (Wang, 1996a). In central and north China, higher temperatures during teasing and drawing stages and low soil moisture could result in reduced wheat yield. Increases in precipitation should be favorable for pests, diseases, and weeds in the south (Wang, 1996b; Dai, 1997). In tropical Asia, although wheat crops are likely to be sensitive to an increase in maximum temperature, rice crops would be vulnerable to an increase in minimum temperature. The adverse impacts of likely water shortage on wheat productivity in India could be minimized to a certain extent under elevated CO₂ levels; these impacts, however, would be largely maintained for rice crops, resulting in a net decline in rice yields (Aggarwal and Sinha, 1993; Rao and Sinha, 1994; Lal *et al.*, 1998d). Acute water shortage conditions combined with thermal stress should adversely affect wheat and, more severely, rice productivity in India even under the positive effects of elevated CO₂ in the future.

Key findings on the impacts of an increase in surface temperature and elevated CO₂ on rice production in Asia—based on a study carried out for Bangladesh, China, India, Indonesia, Japan, Malaysia, Myanmar, the Philippines, South Korea, and Thailand under the Simulation and System Analysis for Rice Production Project at the International Rice Research Institute—are summarized in Table 11-5. Two process-based crop simulation models—the ORYZA1 model (Kropff *et al.*, 1995) and the SIMRIW model (Horie *et al.*, 1995b)—suggest that the positive effects of enhanced photosynthesis resulting from doubling of CO₂ are more than offset by increases in temperature greater than 2°C (Matthews *et al.*, 1995a).

More than 10,000 different species of insect pest are found in the tropics, 90% of which are active in the humid tropics. The occurrence, development, and spread of crop diseases depend on integrated effects of pathogen, host, and environmental conditions. The survival rate of pathogens in winter or summer

Table 11-5: Model-simulated mean change (%) in potential yields of rice in Asia under fixed increments of air temperature and ambient CO₂ level (Matthews *et al.*, 1995b).

Model Used and Ambient CO ₂ Levels	Percent Change in Mean Potential Rice Yield in Asia resulting from Surface Air Temperature Increment of			
	0°C	+1°C	+2°C	+4°C
ORYZA1 Model				
340 ppm	0.00	-7.25	-14.18	-31.00
1.5xCO ₂	23.31	12.29	5.60	-15.66
2xCO ₂	36.39	26.42	16.76	-6.99
SIMRIW Model				
340 ppm	0.00	-4.58	-9.81	-26.15
1.5xCO ₂	12.99	7.81	1.89	-16.58
2xCO ₂	23.92	18.23	11.74	-8.54

could vary with an increase in surface temperature (Patterson *et al.*, 1999). Higher temperatures in winter will not only result in higher pathogen survival rates but also lead to extension of cropping area, which could provide more host plants for pathogens. Thus, the overall impact of climate change is likely to be an enlargement of the source, population, and size of pathogenic bacteria. Damage from diseases may be more serious because heat-stress conditions will weaken the disease-resistance of host plants and provide pathogenic bacteria with more favorable growth conditions. The growth, reproduction, and spread of disease bacteria also depend on air humidity; some diseases—such as wheat scab, rice blast, and sheath and culm blight of rice—will be more widespread in temperate and tropical regions of Asia if the climate becomes warmer and wetter.

11.2.2.2. Grain Supply and Demand in Asia

Asia's total cereal production more than tripled between 1961 and 1999, from 329.5 to nearly 1,025.8 Mt; the increase in harvest area was only marginal (from 271.8 to 324.5 Mha) during this period. Rice paddy production in Asia jumped from 198.7 to 533.5 Mt while the harvest area increased from 106.9 Mha in 1961 to 136.5 Mha in 1999. Similarly, wheat production in Asia increased from 45.8 to 261.7 Mt while the harvest area increased from 61.2 Mha in 1961 to 97.2 Mha in 1999. A three-fold increase in production of sugarcane and almost five-fold increase in oil crops took place in Asia during 1961–1999. Asian production of starchy roots also doubled during this period. Even as the Asian population increased a little more than two-fold—from 1.70 billion to 3.58 billion people—during this time, per capita consumption of calories in Asia has increased since the 1960s (FAO, 1999a). This improvement in the food situation has been the consequence of an increase in production, resulting from technological advances, that has outpaced population growth in Asia. However, because there is

a limit to the amount of arable land, while the Asian population continues to grow, the per capita area of harvest has consistently decreased.

The population growth rate has been a primary factor in the increase in demand for food grains in Asia. Since the mid-1980s, rapid changes in food supply and demand structures have been observed in most developing countries. Declines in self-sufficiency for grains have been particularly dramatic in countries with advanced economies, such as Japan, South Korea, Taiwan (China), and Malaysia, where the grain self-sufficiency rate has fallen below 30% in recent years. The rapid decline in grain self-sufficiency in these countries is unprecedented in any region of the world. Between 1970 and 1996, grain self-sufficiency fell from 45 to 27% in Japan, from 68 to 31% in Korea, from 61 to 19% in Taiwan (China), and from 60 to 25% in Malaysia (FAO, 1996). Declines in grain self-sufficiency also have been observed in the Philippines, Indonesia, and Sri Lanka. Populous countries such as China, India, Bangladesh, and Pakistan have long maintained grain self-sufficiency of more than 90%, but as these countries shift to industrialization it is possible that declines will be observed there as well. In contrast, Thailand and Vietnam, which encompass the great grain-producing regions of the Menam and Mekong River deltas, continue to maintain better than 100% self-sufficiency for grains.

The annual per capita consumption of meat in principal Asian countries also has shown an upward trend in recent years. Since the 1970s, South Korea and China have reported the most rapid increases in meat consumption. In South Korea, per capita meat consumption grew about seven-fold, from 5.2 to 40 kg between 1970 and 1997; in China, it increased nearly five-fold, from 8.8 to 42.5 kg. During the same period, per capita meat consumption more than doubled in Japan (42.2 kg in 1997) and Malaysia (51.9 kg in 1997). Meat consumption in Sri Lanka, Bangladesh, and India grew only marginally, remaining below or at 5 kg even in 1997—considerably lower than the level in east Asia. The increasing trend in meat consumption in temperate Asia means higher demand for livestock feed for the production of meat. Demand for this feed in Asia increased from 25.2 Mt in the 1970s to 61.2 Mt in 1980, 147.0 Mt in 1990, and 163.0 Mt in 1999. The demand for feed grain in Asia has grown at an annual rate of about 6.6% and has been a principal factor in the rapid increase in demand for world grain imports.

The world is moving toward a tighter grain supply and demand, and instability in the world grain market is rising. At the same time, Asia is becoming increasingly dependent on the world grain market. As shown in Figure 11-8, net grain import in Asia was 20.3 Mt in 1961; it increased to 80.9 Mt by 1998. The continuing increase in grain imports is a result of increasing

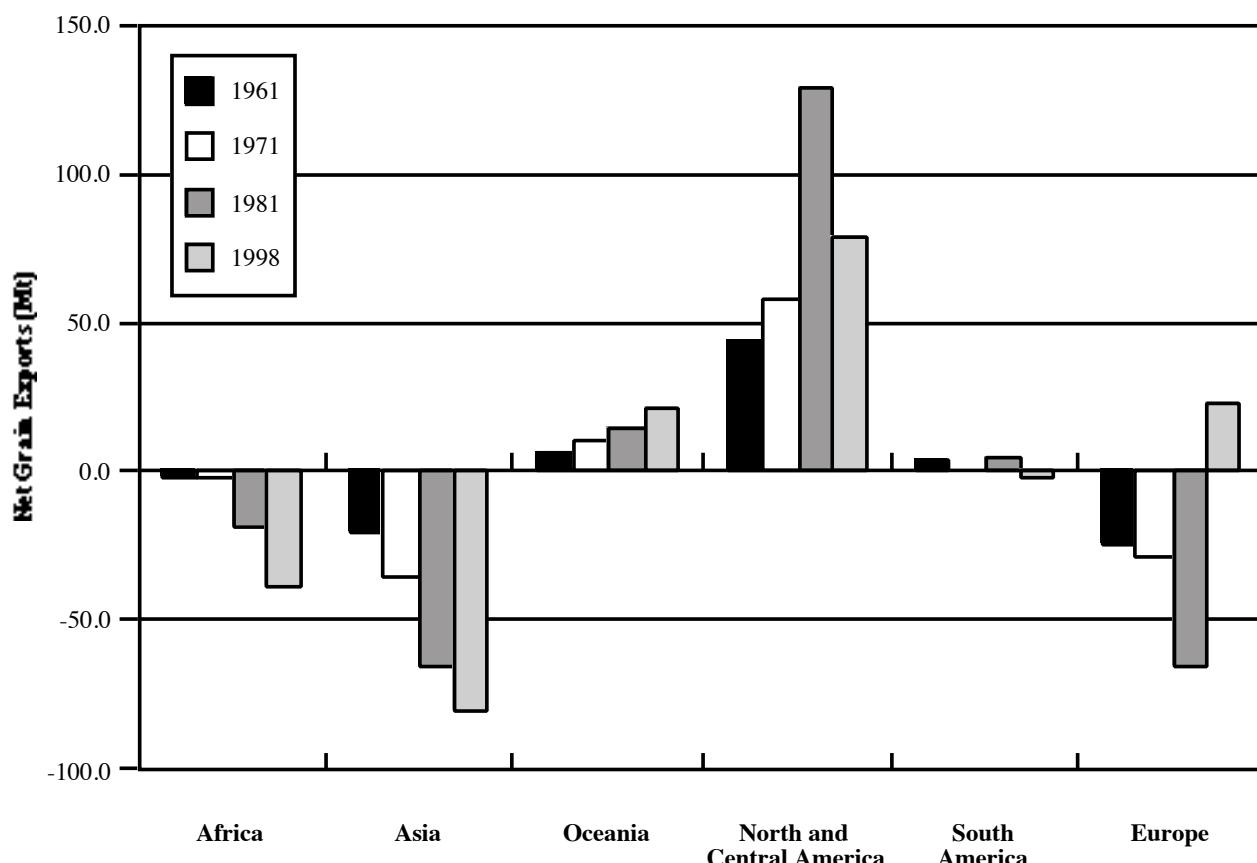

Figure 11-8: Trends in net grain exports in major world regions (USDA, 1999).

populations and increased demand for grain that accompanies economic growth, with which increases in grain production within the region cannot keep pace.

The impact of global warming on the international supply and demand of rice and wheat has been evaluated by Nakagawa *et al.* (1997) through the use of a partial equilibrium-type dynamic model for world supply and demand. Based on a world rice and wheat supply and demand model and a unit harvest scenario, the study projected that the serious impacts of global warming would be felt as early as the year 2020. The study suggests that the early impacts will not be so severe that humans are unable to control them. However, the gap between supply and demand

may grow in some regions of Asia, resulting in considerably increased reliance on imports. Furthermore, the problem of short-term fluctuations in the market because of an increased frequency of droughts, floods, and other extreme weather events will be exacerbated, making it necessary to promote measures to combat climate change on a global scale.

11.2.2.3. Food Security

A major new challenge in future food production to meet the demand of the growing Asian population is in coping with the changing environment, which may alter the current optimum

Box 11-2. Bangladesh: Food Insecurity in an Agrarian Nation

Malnutrition remains endemic in Bangladesh, an overwhelmingly agrarian country where most rural households do not own land and have few other opportunities to earn wage income. At barely 2,000 kilocalories per person per day, food availability falls short of meeting basic requirements. With extensive poverty, malnutrition, inadequate sanitation, and inadequate access to health care, the country is vulnerable to outbreaks of infectious, water-borne, or other types of diseases. Less than half the population of Bangladesh currently has access to adequate sanitation. Some areas of the country still face the risk of famine; others have frequent floods and often are devastated by cyclones and storm surges.

Overall, the rate of undernourishment is very high (37%), as is the prevalence of underweight, stunting, and wasting among children (Figure 11-9). Rates are high throughout the rural areas that are home to 80% of Bangladesh's population. More than 60% of rural households are functionally landless, and there are limited opportunities for income diversification (Mimura and Harasawa, 2000). The level of vulnerability is likely to increase as a result of severe land degradation, soil erosion, lack of appropriate technology, and the threat of sea-level rise from global warming. Climate change could result in a decreased supply of water and soil moisture during the dry season, increasing the demand for irrigation while supply drops. Improving irrigation efficiency and agricultural productivity will help make Bangladesh self-sufficient in crop production and reduce malnourishment. Higher yields may enable the country to store food supplies to carry it through low-harvest years (Azam, 1996). A switch to growing higher value crops and expansion of free market reforms in agriculture may enable Bangladesh to sell more crops for export. Diversification should help in providing robustness to withstand climate change and variability.

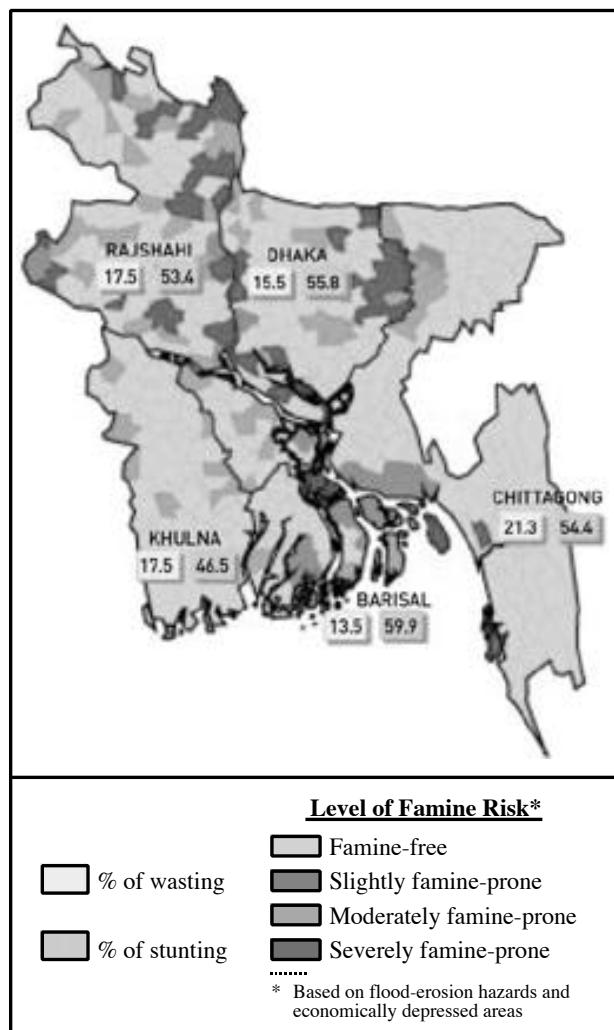

Figure 11-9: Food insecurity and malnutrition in Bangladesh (FAO, 1999b).

growing requirement of agricultural crops. The potential impacts of climate change on agriculture in Asia are crucial because of agriculture's ultimate role in providing food and fiber to Asia's human population. Countries in south and southeast Asia have shown strong reductions in undernourished population in the 1990s. Even so, it has been estimated that almost two-thirds (more than 500 million) of undernourished people live in developing countries of Asia and the Pacific. South Asia accounts for more than one-third of the world total (258 million). Another 64 million undernourished people live in southeast Asia; more than 160 million live in China (FAO, 1999b). The undernourished population almost doubled between 1995 and 1999—from 6 to 12%—as a result of the economic crisis in Indonesia. With the highest incidences of undernutrition and a very large population of children under the age of five, south

Asia accounts for almost half of the world's underweight and stunted children (see Box 11-2). Table 11-6 lists the prevalence of undernourishment in Asian developing countries.

Ongoing studies on crop productivity in relation to global warming cover not only biophysical aspects but also socioeconomic drivers and consequences (Fischer *et al.*, 1995; Islam, 1995). The economic impacts of climate change on world agriculture are expected to be relatively minor because decreasing food production in some areas will be balanced by gains in others (e.g., Kane *et al.*, 1991; Tobey *et al.*, 1992; Rosenzweig and Parry, 1993). Such findings however, should be viewed as aggregate results that mask crucial differences in inter-country and intra-country production impacts and the distribution of food resources. In Asia, where rice is one of the main staple

foods, production and distribution of rice-growing areas may be affected substantially by climate change. Disparity between rice-producing countries is already visible, and it is increasingly evident between developed and developing countries (Fischer *et al.*, 1996). The projected decline in potential yield and total production of rice in some Asian countries because of changes in climate and climate variability would have a significant effect on trade in agricultural commodities, hence on economic growth and stability (Matthews *et al.*, 1995b)

Increasing population growth and changing dietary patterns in Asia have resulted in more and more land moving from forests and grasslands into agricultural production. Regardless of the increased use of chemical fertilizers and pesticides, in addition to changes in irrigation practices and improved seed stock, yields for major cereal crops have stagnated in many Asian countries during recent years (Iglesias *et al.*, 1996; Sinha, 1997); further intensification of agriculture on area in cropland is certain, and conversion of more land to agricultural use is likely, especially in the developing countries of Asia. Both actions will have far-reaching implications with regard to increased soil erosion, loss of soil fertility, loss of genetic variability in crops, and depletion of water resources (Sinha *et al.*, 1998). Soil degradation is seemingly irreversible unless remedied through painstaking reconstruction of soil health.

A clear understanding of the relationship between climatic variability, crop management, and agricultural productivity is critical in assessing the impacts of climatic variability and change on crop production, the identification of adaptation strategies and appropriate management practices, and the formulation of mitigating measures to minimize the negative effects of climatic variability (including extreme events) on agricultural productivity. In the future, food security will be at the top of the agenda in Asian countries because of two emerging events: growing population, and many direct and indirect effects of climate change. Greatly enhanced efforts to understand the relationship between key climate elements and agriculture should provide a sound basis for meeting the challenges of optimizing the benefits of changing climatic resources.

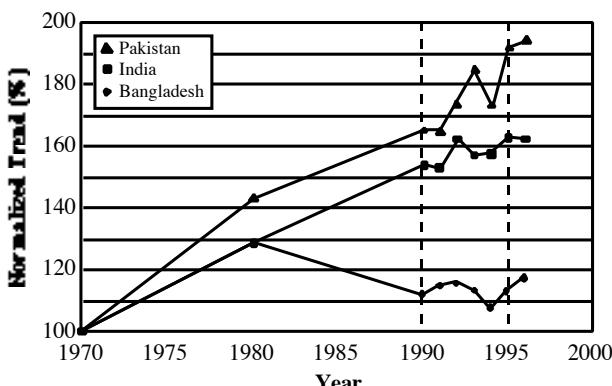

Figure 11-10: Normalized trends in grain production in Bangladesh, India, and Pakistan since 1970 (CIA, 1998).

In some Asian countries, the pace of food grain production has slowed in recent years as a result of depletion of soil nutrients and water resources, creation of salinity and waterlogging, resurgence of pests and diseases, and increased environmental pollution (Gadgil, 1995). Many natural as well as environmental factors—such as extremely dry or cold climates, erratic rainfall, storms and floods, topsoil erosion and severe land degradation, and poor investment and lack of appropriate technology—have played limiting roles in the agricultural potential of most developing countries of Asia (see also Section 5.3). For example, food grain production in Pakistan and India has continued to increase since the 1970s while it has stagnated in Bangladesh (Figure 11-10), largely because of increased losses to climate extremes and land degradation. In India, the estimated total requirement for food grains would be more than 250 Mt by 2010; the gross arable area is expected to increase from 191 to 215 Mha by 2010, which would require an increase of cropping intensity to approximately 150% (Sinha *et al.*, 1998). Because land is a fixed resource for agriculture, the need for more food in India could be met only through higher yield per units of land, water, energy, and time—such as through precision farming. To ensure food security in the developing countries of south and southeast Asia, it is necessary to expand agricultural production, develop the food distribution system, and promote nutrition education, as well as expand the economy and adjust the distribution of incomes.

11.2.3. Hydrology and Water Resources

11.2.3.1. Water Availability

One-third of the world's renewable water resources ($13,500 \text{ km}^3 \text{ yr}^{-1}$ out of $42,700 \text{ km}^3 \text{ yr}^{-1}$) are concentrated in Asia (Shiklomanov, 2001). Water availability varies widely across the different regions of Asia, however—from $77,000 \text{ m}^3 \text{ yr}^{-1}$ per capita to less than $1,000 \text{ m}^3 \text{ yr}^{-1}$ per capita. Table 11-7 provides available information on renewable local water resources, water availability, and water use dynamics by natural-economic region of Asia. The major share of Asian water resources (72%) is located in four countries: Russia ($3,107 \text{ km}^3 \text{ yr}^{-1}$), China ($2,700 \text{ km}^3 \text{ yr}^{-1}$), Indonesia ($2,530 \text{ km}^3 \text{ yr}^{-1}$), and India ($1,456 \text{ km}^3 \text{ yr}^{-1}$). Water resources of the two largest river systems of Asia—the Ganges (with Brahmaputra and Meghna) and the Yangtze (Changjiang)—attain $1,389 \text{ km}^3 \text{ yr}^{-1}$ ($794 \times 10^3 \text{ m}^3 \text{ yr}^{-1} \text{ km}^{-2}$) and $1,003 \text{ km}^3 \text{ yr}^{-1}$ ($554 \times 10^3 \text{ m}^3 \text{ yr}^{-1} \text{ km}^{-2}$). Figure 11-11 depicts the spatial distribution of currently estimated annual mean surface runoff over Asia. The runoff distribution within a year in Asia is most uniform in the rivers of southeast Asia. Over the rest of the continent, more than half of the annual runoff is discharged during the three summer months.

Water availability—in terms of temporal as well as spatial distribution—is expected to be highly vulnerable to anticipated climate change. Growing populations and concentration of population in urban areas will exert increasing pressures on water availability and water quality. As reported in IPCC (1998), runoff generally is expected to increase in the high latitudes

Asia

and near the equator and decrease in the mid-latitudes under anticipated climate change scenarios.

An assessment of implications of climate change for global hydrological regimes and water resources, using climate change scenarios developed from Hadley Centre model simulations (Arnell, 1999), allows examination of the potential impacts on Asia. A macro-scale hydrological model was used to simulate river flows across the globe at a spatial resolution of $0.5^\circ \times 0.5^\circ$, covering regions of 1,800–2,700 km 2 . The study suggests that average annual runoff in the basins of the Tigris, Euphrates, Indus, and Brahmaputra rivers would decline by 22, 25, 27, and 14%, respectively by the year 2050. Runoff in the Yangtze (Changjiang) and Huang He Rivers have the potential to increase as much as 37 and 26%, respectively. Increases in annual runoff also are projected in the Siberian rivers: the Yenisey (15%), the Lena (27%), the Ob (12%), and the Amur (14%). Areas with particularly large percentage change in high flows include temperate Asia. Significant changes in monthly runoff regimes also are projected over most of Asia.

Some areas of the Asian continent are expected to experience increases in water availability; other areas will have reduced water resources available. Surface runoff is projected to decrease drastically in arid and semi-arid Asia under climate change scenarios and would significantly affect the volume of water available for irrigation and other purposes. Sensitivity

analysis of water resources in Kazakhstan to projected climate change scenarios indicates that surface runoff would be substantially reduced as a result of an increase in surface air temperature of 2°C accompanied by a 5–10% decline in

precipitation during summer (Gruza *et al.*, 1997). In temperate Asia, future changes in surface runoff would be highly spatially inhomogeneous. An increase in surface runoff seems likely in Mongolia and northern China. The hydrological characteristics

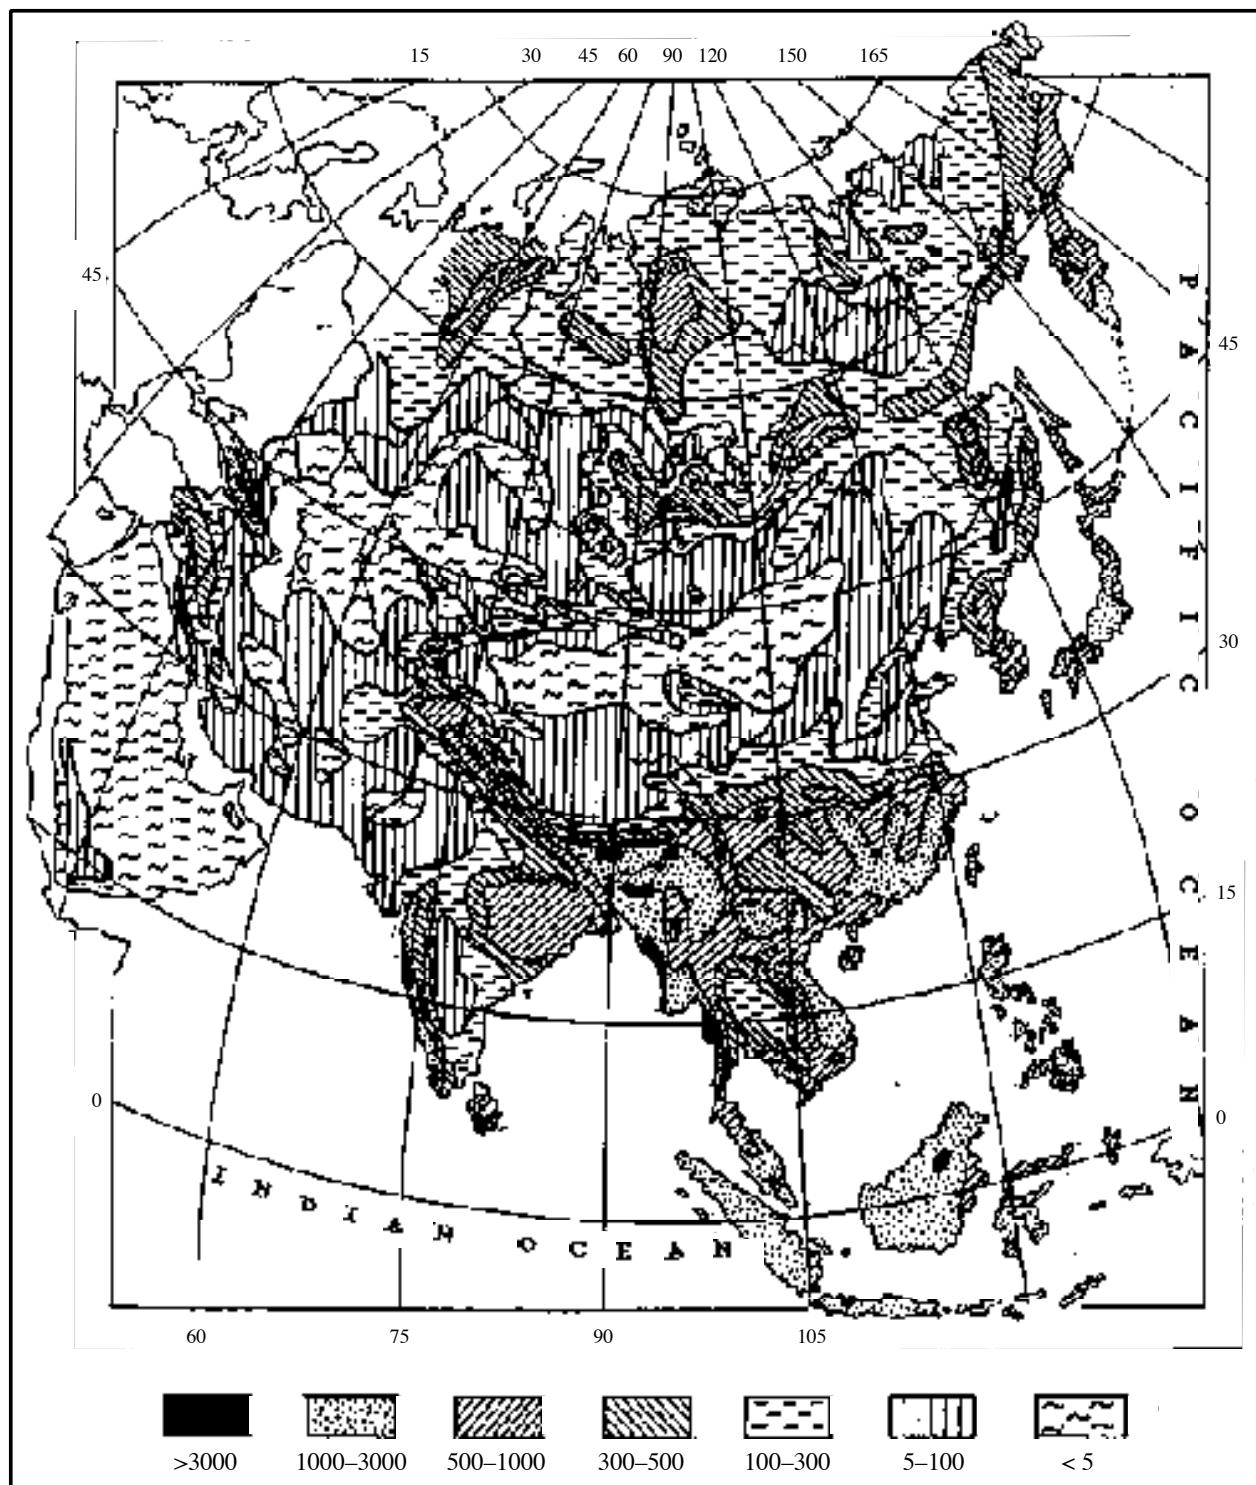

Figure 11-11: Spatial distribution of currently estimated surface runoff (mm) over Asian continent (Shiklomanov, 2001).

of Japanese rivers and lakes also are sensitive to climate change. Recent studies suggest that, on average, a 3°C increase in temperature coupled with a 10% increase in precipitation will increase river flows by approximately 15% in water-abundant areas. An increase in temperature also accelerates snow melting, which increases river flows from January through March but decreases flows from April through June (Hanaki *et al.*, 1998; Inoue and Yokoyama, 1998).

The perennial rivers originating in the high Himalayas receive water from snow and glaciers. Snow, ice, and glaciers in the region are approximately equivalent to about 1,400 km³ of ice. The contribution of snow to the runoff of major rivers in the eastern Himalayas is about 10% (Sharma, 1993) but more than 60% in the western Himalayas (Vohra, 1981). Because the melting season of snow coincides with the summer monsoon season, any intensification of the monsoon is likely to contribute to flood disasters in Himalayan catchments. Such impacts will be observed more in the western Himalayas compared to the eastern Himalayas because of the higher contribution of snowmelt runoff in the west (Sharma, 1997). An increase in surface runoff during autumn and a decrease in springtime surface runoff are projected in highland regions of south Asia. The increase in surface temperature also will contribute to a rise in the snowline—which, in effect, reduces the capacity of the natural reservoir. This situation will increase the risk of flood in Nepal, Bangladesh, Pakistan, and north India during the wet season (Singh, 1998). No significant changes are projected for annual mean surface runoff in southeast Asia;

an increase during winter and a decrease during summer season is likely, however.

Available data on the dynamics of freshwater use by natural-economic regions of Asia (Table 11-8) suggest that freshwater use—in terms of total water withdrawal and water consumption—have increased significantly in recent decades in all regions and is projected to increase further in the 21st century. Table 11-8 also suggests that water use in most regions of Asia (except Russia and southeast Asia) already has exceeded 20% of the available resources (Arnell, 1999) and will be increasing appreciably by 2025. It follows from this table that water is going to be a scarce commodity in Asia in the near future even without the threat of climate change.

11.2.3.2. Water Needs and Management Implications

At present, approximately 57% of total water withdrawal and 70% of water consumption in the world occurs within the countries of Asia. Table 11-8 presents the dynamics of freshwater use in Asia over the sectors of economic activities. As is evident from this table, agriculture (irrigation in particular) accounts for 81% of total water withdrawal and 91% of water consumption in Asia. The area of irrigated lands in Asia currently amounts to 175 Mha and may increase to 230 Mha by 2025. As Table 11-7 implies, the two most populated regions of south and southeast Asia account for about 68% of water withdrawal and about 69% of water consumption in Asia (see Chapter 4). More than

^aNominator = total water withdrawal; denominator = water consumption.

75% of the total water available in India currently is used for irrigation. As much as 20% is required to meet domestic and municipal needs—leaving just 5% for industrial needs. The only river in north India that has surplus water to meet future needs of the country is the Brahmaputra. This river, however, is an international river; other countries such as Bangladesh may not approve of building a dam across some of its tributaries. In peninsular India, only the Mahanadi and Godavari have surplus water, but conveying it to drought-prone areas of the south is problematic. Many states in India need to adopt measures for restricting the use of groundwater to prevent a water famine in the future. China's rapid economic growth, industrialization, and urbanization—accompanied by inadequate infrastructure investment and management capacity—have contributed to widespread problems of water scarcity throughout the country. Of the 640 major cities in China, more than 300 face water shortages; 100 face severe scarcities (UNDP, 1997).

Taking into account projected dynamics of economic development in the temperate, tropical, and arid and semi-arid regions of Asia, combined with the climate change-imposed effect on hydrological regimes, agriculture and the public water supply would require priority attention in these regions to secure sustainable development and avoid potential intersectoral and international water conflicts. Radical changes in water management strategies and substantial investments will be required in Asia to cope with water problems in the 21st century. Adaptation measures will include legal, institutional, and technical initiatives such as modifying existing and constructing new infrastructure (reservoirs, interbasin water transfer schemes), introducing water-saving technologies, upgrading efficiency of irrigation systems, enhancing wastewater recycling systems, introducing low water-use crops, and implementing groundwater protection programs.

At least 14 major international river watersheds exist in Asia. An integrated and decentralized system of restoration and conservation of the water cycle in these drainage basins is vital to mitigate the negative consequences of natural and externally imposed perturbations. Watershed management is challenging in countries where the people-to-land ratio is high and policy and management are inadequate, prompting use of even the most fragile and unsuitable areas in the watersheds for residential, cultivation, and other intensive uses. This is particularly true for countries such as Bangladesh, Nepal, the Philippines, Indonesia, and Vietnam, where many watersheds suffer badly from deforestation, indiscriminate land conversion, excessive soil erosion, declining land productivity, erratic and unreliable surface and groundwater resources, and loss of biodiversity. Many watersheds in Asia already are stressed by intensive use of the land and other resources and by inhospitable climate (especially in arid and semi-arid Asia), beyond their ability to adequately supply water, prevent floods, and deliver other goods and services. In the absence of appropriate adaptation strategies, these watersheds are highly vulnerable to climate change. Global climate change also may have serious water management implications on the territory of boreal Asia. Recent assessments (Izrael *et al.*, 1997a; CAFW, 1998) for all

major Siberian rivers (Ob, Yenisei, Lena) with 42% of the total freshwater inflow to the Arctic ocean show that the main water management problems by the year 2050 will be a consequence of significant annual runoff increases (up to 20%) and difficulties with seasonal inundation and flood control measures.

11.2.4. Oceanic and Coastal Ecosystems

11.2.4.1. Oceans and Coastal Zones

In line with global trends, more than half of the region's population—1.7 billion people—presently resides in the coastal zone of Asia (Middleton, 1999). Given the relentless and cumulative process of global environmental change driven by, among other factors, demographic changes, urbanization and industrial development, trade and transport demands, and lifestyle changes, the coastal zones of Asia are under increasing anthropogenic pressures (Turner *et al.*, 1996). The consequences of this process pose a significant threat to environmental and socioeconomic systems located in Asian coastal zones. All coastal areas are facing an increasing range of stresses and shocks, the scales of which now pose a threat to the resilience of human and environmental coastal systems and are likely to be exacerbated by climate change.

Climate impacts on coastal zones of Asia include accelerated sea-level rise and more frequent and severe storm events. Large populations in coastal areas of southeast and south Asia are vulnerable to pressure from unsustainable resource use and environmental degradation (e.g., Dow, 1999). These areas already are subject to numerous climate change-related stresses, including loss of coastal mangroves that act as major environmental determinants of coastal fisheries (Daily, 1997; Field *et al.*, 1998; Primavera, 1998). Major delta areas of Asia are likely to be subjected to stresses associated with sea-level rise, changes in water regimes, saltwater intrusion, siltation, and land loss (see Chapter 6). Low-lying coastal cities will be at the forefront of impacts; these cities include Shanghai, Tianjin, Guangzhou, Jakarta, Tokyo, Manila, Bangkok, Karachi, Mumbai, and Dhaka—all of which have witnessed significant environmental stresses in recent years. Jakarta, Bangkok, and Tianjin, for example, have experienced changes in relative sea level of as much as 5 cm yr⁻¹ during the 1980s and 1990s as a result of subsidence associated with groundwater withdrawal (ESD-CAS, 1994; Nicholls, 1995). In addition, increases in temperature can lead to increased eutrophication in wetlands and freshwater supplies.

Tropical Asia experiences the impact of present-day climate variability associated with ENSO, therefore is more prone to changes in ENSO-related impacts with global climate change. The ENSO phenomenon is a major cause of year-to-year variability in the number of cyclones in the Asia Pacific region (Li, 1987; Nishimori and Yoshino, 1990; Lander, 1994). The numbers are higher during La Niña events, particularly late in the season over southeast Asia (Kelly and Adger, 2000). The 1982–1983 El Niño caused a decline in rainfall and associated

impacts over large areas, including parts of Indonesia (Salafsky, 1994, 1998; Glantz, 1996). El Niño events are known to have significant impacts on coastal areas and water resources in southeast Asia through decreased precipitation in El Niño years and increased frequency of typhoons in subsequent La Niña years (Kelly and Adger, 2000).

Sea levels of interior seas in arid and semi-arid Asia have dramatically changed, driven either by climatic or anthropogenic factors. The level of the Caspian Sea lowered by about 4 m from 1930 to 1977; since 1978 it has begun rising (Mikhailov, 1998). The coastline also propagated landward by 20–40 km; 2 Mha of farming land and more than 100 oil wells have been inundated. Many cities in the coastal zone, such as Makhachkala and Kaspisk, are seriously damaged (Svitoch, 1997). The Volga delta propagated 17 km during the period of lowering sea level but has retreated 12–15 km during the period of the rise in sea level (Kasimov, 1997; Tian and Liu, 1999). Caspian Sea level fluctuations are attributed mainly to the Volga water discharge controlled by climate anomalies in its catchment area (Malinin, 1994). The Aral Sea area also reduced, from 60,000 to 28,500 km², in the period 1960–1989; the exposed seabed (particularly deltas) now have frequent dust and salt storms, and there are shortages of freshwater (Ellis, 1990; Tian and Liu, 1999).

11.2.4.2. Deltas, Estuarine, and Other Coastal Ecosystems

River-borne sediments have formed at least 10 deltas in the coastal zones of Asia with an area of more than 10,000 km² each (Coleman and Wright, 1975). Delta and estuarine ecosystems are sensitive to complex responses to agents associated with climate change (Sanchez-Arcilla and Jimenez, 1997). Low-lying deltas are especially vulnerable to sea-level rise and increasing shoreline wave action (Walker, 1998). A decrease in river water discharge, as projected under some climate change scenarios, could lead to hindrance of delta progradation and increase the risk of irreversible change for the ecosystem in estuarine-deltaic areas (Qian, *et al.*, 1993; Shi, 1995). Tidal rivers and estuaries will become more prone to saltwater intrusion as a result of projected sea-level rise (Huang, *et al.*, 1982; Li, 1984, 1985; Shi, 1995). Sea-level changes associated with global warming would be exacerbated by tectonic submergence, ground subsidence as a result of groundwater withdrawal, rise of water level created by delta progradation, and eustatic sea-level rise.

Low-lying muddy coastlines associated with large deltas form a significant resource and support large human populations. In China, for example, such low-lying deltas cover about 4,000 km—22% of the total coastline. These muddy coastal ecosystems are basically distributed along large deltas and partly in semi-closed bays (Ren, 1985). Erosion of muddy coastlines in Asia—as documented in China, for example—is triggered largely by sediment starvation resulting from human activities and delta evolution rather than sea-level rise (Ji *et al.*, 1993; Chen and Chen, 1998). Beach erosion is widespread in the

coastal zone of Asia and has been reported in China, Japan, Indonesia, Sri Lanka, Thailand, Bangladesh, and Malaysia (Xia *et al.*, 1993; Sato and Mimura 1997; Teh 1997; Nishioka and Harasawa, 1998; Huq *et al.*, 1999; Middleton, 1999).

Coastal wetlands frequently are associated with deltas, estuaries, lagoons, and sheltered bays. Tidal flats of the muddy coast in Asia constitutes the main part of the coastal wetland (Bird, 1992). Large-scale wetland reclamation in the major deltas has taken place during the past few decades (Lang *et al.*, 1998; Liu *et al.*, 1998). Lagoons, which are important wetlands, are located across the coastal regions of India, Sri Lanka, Malaysia, Indonesia, China, and Russia. The transitional area between uplift and subsidence belts has favored the formation of lagoons along China's coastline (Li and Wang, 1991). These lagoons tend to be decreasing in area as a result of silting of sediments and plant growing (Zhu, 1991). Sea-level rise and reduction of river-borne sediments will decelerate delta progradation and wetland renewal. The rich biodiversity of wetlands in Asia is seriously threatened by loss of wetlands from sea-level rise (Nicholls *et al.*, 1999).

Mangroves are made up of salt-adapted evergreen trees; they are restricted to the intertidal zone along the vast coastlines of tropical countries in Asia and extend landward along tidal rivers. The Sundarbans in Bangladesh and adjacent areas in India, covering about 6,000 km², are the largest mangrove forests in the world (Allison, 1998). Depletion of mangrove forests by anthropogenic pressures has become a serious problem (Farnsworth and Ellison, 1997). Approximately half of mangrove forests in Thailand were reduced by 56% during 1961–1996. In the Philippines, more than 75% of the mangrove forests have been lost in less than 70 years. Destruction of Indonesia's estimated 44,000 km² of mangroves has taken place mainly since 1975 (Middleton, 1999; UNEP, 1999). Mangrove forests are highly vulnerable to climate change-induced sea-level rise because it will change the salinity distribution and hence productivity. Large-scale changes in species composition and zonation in mangrove forests also are expected as a result of changes in sedimentation and organic accumulation, the nature of the coastal profile, and species interaction (Aksornkaoe and Paphavasit, 1993).

11.2.4.3. Coral Reefs

Coral reefs play a crucial role in fishery production and in protecting the coastline from wave action and erosion (Ruddle *et al.*, 1988; Middleton, 1999). Southeast Asia has almost one-third of the world's mapped coral reefs (Pennisi, 1997); these reefs extend to the northern extreme range in Japan (Nishioka and Harasawa, 1998). Coral reef productivity is a function of their structure, biological recycling, and high retention of nutrients. Reefs in Indonesia and the Philippines are noted for extraordinarily high levels of biodiversity: Each contains at least 2,500 species of fish. Severe coral bleaching can occur as a result of seawater warming and clear skies (resulting in higher incident solar radiation).

Major coral bleaching events have occurred in 1983 (Japan, Indonesia), 1987 (Maldives), 1991 (Thailand, Japan), 1995 (Thailand, Philippines), and 1998 (Maldives, Sri Lanka, India, Indonesia, Thailand, Japan, Malaysia, Philippines, Singapore, Vietnam, Cambodia). As a result of the major 1998 coral bleaching in the south Asia region, many reefs dominated by branching species have been severely damaged, with high mortality of these species. In coastal seas around the Maldives, Sri Lanka, the Andaman Islands of India, and Japan, reef community structure has switched from dominance by fast-growing branching species to monopolization by the more physically rigorous and slow-growing massive corals (Wilkinson, 1998). Deforestation in many island countries of Asia and quarrying of live corals for manufacture of calcium carbonate have led to significant coral decline or severe damage to the entire ecosystem.

Studies show that a moderate rise in sea level around the coast of Thailand would stimulate the growth of coral reef flats and extend corals shoreward. The enhanced growth potential is likely to be restricted by human infrastructure and development along the coast (Chansang, 1993). Asia's coral reefs are undergoing rapid destruction in terms of habitat richness (Cesar *et al.*, 1997; Nie *et al.*, 1997; Pennisi, 1998) as a result of several factors, including extreme temperatures and solar irradiance, subaerial exposure, sedimentation, freshwater dilution, contaminants, and diseases (Glynn, 1996). Virtually all of the Philippines' reefs and approximately 83% of Indonesia's reefs are at risk from destructive fishing techniques, reef mining, sedimentation, and marine pollution (Middleton, 1999; UNEP, 1999). The increase in atmospheric CO₂ concentration (resulting in higher CaCO₃ concentrations in seawater) and consequent rise in sea surface temperature (SST) is likely to have serious damaging effects on reef accretion and biodiversity.

11.2.4.4. Fisheries and Aquaculture

Asia dominates world aquaculture, producing four-fifths of all farmed fish, shrimp, and shellfish (FAO, 1997). Farming of fish, shrimp, shellfish, and seaweeds has become a vital source of food supply in Asia in recent decades. Fishery products are staples for the Asian population and are embedded in its culture. Fish, an important source of food protein, is critical to food security in many countries of Asia, particularly among poor communities in coastal areas. The annual fish catch and aquaculture production in Asia reached a peak at about 20.7 and 19.1 Mt, respectively, in the year 1998. Japan has the largest distant-waters fishery production. Inland fishery production is dominated by China and India, which have shown increases in recent years as a result of stock enhancement practices.

Fish farming requires land and water—two resources that already are in short supply in many countries in Asia. Nearly half of the land now used for shrimp ponds in Thailand was formerly used for rice paddies; water diversion for shrimp ponds has lowered groundwater levels noticeably in coastal areas of Thailand. In China, concern over the loss of arable land has led to restrictions on any further conversion of farmland to

aquaculture ponds. Intensive production systems and large-scale facilities used to raise high-value shrimp, salmon, and other premium species has taken a heavy toll on coastal habitats, with mangrove swamps in southeast Asia being cleared at an alarming rate. Thailand lost more than 15% of its mangrove forests to shrimp ponds from 1987 to 1993 (World Bank, 1996). Destruction of mangroves has left these coastal areas exposed to erosion and flooding, altered natural drainage patterns, and increased salt intrusion.

The fishery resources of Japan, China, and many other countries of Asia are being depleted by overfishing, excessive use of pesticides, industrial pollution, red tide, and even construction of dikes and other coastal structures (Zou and Wu, 1993; Sato and Mimura, 1997). Loss of inshore fish nursery habitats to coastal development, as well as pollution from land-based activities, causes significant change to ecosystems supporting fisheries (see also Chapter 6). Marine productivity is greatly affected by temperature changes that control plankton shift, such as seasonal shifting of sardine in the Sea of Japan and induced during the cyclical occurrence of the ENSO in low latitudes (Chen and Shen, 1999; Piaykarnchana, 1999; Terazaki, 1999). The impact of global warming on fisheries will depend on the complicated food chain, which could be disturbed by sea-level rise, changes in ocean currents, and alteration of mixing layer thickness.

Anomalies in the water temperatures of major oceanic currents (e.g., declines in sardine catch in the Sea of Japan associated with changing patterns of the Kuroshio current in ENSO years) have resulted in low commercial fish catch in recent years (Yoshino, 1998b). The steady wintertime decrease in mean wind speed observed over the Sea of Japan between 1960 and 1990 has accelerated surface temperature increase and stagnated bottom water formation in recent years (Varlamov *et al.*, 1997). The rise in SST will shift the southern limit of salmon species further to the north (Seino *et al.*, 1998). It is also suggested that the Sea of Japan bottom water will become anoxic within a few hundred years; a decreased oxygen supply will lead to major losses in biological productivity in deep waters (Gamo, 1999). Fish production of certain species may decrease because of the decline of river volume (Zhou, 1991). Increases in marine culture products and declines in marine fishery output are current trends in most south Asian countries that are engaged in commercial fishery activity. It is likely that increased surface runoff and higher nutrient load might lead to potentially beneficial increases in plankton within the coastal zone of boreal Asia. However, increased frequency of El Niño events, which are likely in a warmer atmosphere, could lead to measurable declines in plankton biomass and fish larvae abundance in coastal waters of south and southeast Asia (see also Chapter 6). Such declines in lower levels of the food chain will have negative impacts on fisheries in Asia.

11.2.4.5. Tropical Cyclone and Storm Surges

Asia is close to the warm pool of the west equatorial Pacific Ocean, and tropical cyclones and associated storm surges

strongly affect coastal zones of tropical and temperate Asia. Tropical cyclones and storm surges are one of most critical factors affecting loss of human lives in India and Bangladesh (Sato and Mimura, 1997). Approximately 76% of the total loss of human lives from cyclonic storms has occurred in India and Bangladesh (Ali, 1999). Several Asian countries are faced with cyclones and associated storm surges every year, which causes serious economic losses (Ali, 1999; Huang, 1999; Kelly and Adger, 2000).

There is concern that global warming may affect tropical cyclone characteristics, including intensity, because SST plays an important role in determining whether tropical disturbances form and intensify. Several researchers have used modeling techniques to examine the possible effects of global warming on tropical storms (Lighthill *et al.*, 1994; Sugi *et al.*, 1996; Henderson-Sellers and Zhang, 1997; Holland, 1997; Tonkin *et al.*, 1997; Henderson-Sellers *et al.*, 1998; Knutson *et al.*, 1998; Krishnamurti *et al.*, 1998; Royer *et al.*, 1998). Lighthill *et al.* (1994) conclude that there is no reason to expect any overall change in global tropical cyclone frequencies, although substantial regional changes may occur. Recent studies indicate that the maximum potential intensities of cyclones will possibly undergo a modest increase of as much as 10–20% in a warmer atmosphere (see Chapter 3 and TAR WGI Chapter 9). More recent analyses (Nakagawa *et al.*, 1998; Walsh and Pittock, 1998; Jones *et al.*, 1999) support the possibility of an increase in cyclone intensity. Coastal erosion in Asia should increase with sea-level rise, and storm surges could still exacerbate hazards, even if the number and intensities of tropical cyclones do not change (IPCC, 1998; Walsh and Pittock, 1998).

11.2.4.6. Potential Impacts and Coastal Zone Management

As outlined in IPCC (1998), climate-related stresses in coastal areas include loss and salinization of agricultural land resulting from changes in sea level, likely changes in the intensity of tropical cyclones, and the possibility of reduced productivity in coastal and oceanic fisheries. Table 11-9 lists estimates of potential land loss resulting from sea-level rise and the number

of people exposed, assuming no adaptation (Mimura *et al.*, 1998; Nicholls and Mimura, 1998). These estimates of potential land loss and populations exposed demonstrate the scale of the issue for the major low-lying regions of coastal Asia. The results are most dramatic in Bangladesh and Vietnam, where 15 million and 17 million people, respectively, could be exposed given a relative change in sea level of 1 m (Brammer, 1993; Haque and Zaman, 1993)—though it should be recognized that a 1-m sea-level rise is at the extreme range of presently available scenarios. Nonetheless, these examples demonstrate the sensitivity of coastal areas to climate change impacts and unsustainable utilization of resources in these areas. The impacts could be exacerbated by continued population growth in low-lying agricultural and urban areas (Nicholls *et al.*, 1999). At the same time, adaptation strategies will alter the nature of the risk and change the socially differentiated nature of the vulnerability of populations living in hazardous regions. Response strategies that are based solely on tackling the physical parameters of risks from sea-level rise and tropical cyclones have been shown in some circumstances to enhance the vulnerability of certain parts of the population—usually those with least ability to influence decisionmaking (Blaikie *et al.*, 1994; Hewitt, 1997; Mustafa, 1998; Adger, 1999b).

Human activities, including protection facilities themselves, aggravate the vulnerability of the coastal regions to climate change and sea-level rise. There are complex interrelationships and feedbacks between human driving forces and impacts, on one hand, and climate- and sea level-induced changes and effects on the other (IPCC, 1996). At the interface between ocean and terrestrial resources, coastal ecosystems undergo stress from competing multi-use demands, while having to retain their functional diversity and resilience in the face of global environmental change (Bower and Turner, 1998). To enhance coastal resilience and facilitate adaptation, integrated management of coastal zones must take into account the multiple resource demand and variety of stakeholders, as well as natural variability, recognizing the importance of the institutional, cultural, and historical context (Klein and Nicholls, 1999).

Table 11-9: Potential land loss and population exposed in Asian countries for selected magnitudes of sea-level rise and under no adaptation measures (modified from Nicholls and Mimura, 1998; Mimura *et al.*, 1998).

Country	Sea-Level Rise (cm)	Potential Land Loss (km ²)	Potential Land Loss (%)	Population Exposed (millions)	Population Exposed (%)
Bangladesh	45	15,668	10.9	5.5	5.0
	100	29,846	20.7	14.8	13.5
India	100	5,763	0.4	7.1	0.8
Indonesia	60	34,000	1.9	2.0	1.1
Japan	50	1,412	0.4	2.9	2.3
Malaysia	100	7,000	2.1	>0.05	>0.3
Pakistan	20	1,700	0.2	n.a.	n.a.
Vietnam	100	40,000	12.1	17.1	23.1

n.a. = not available.

Integrated coastal zone management (ICZM) is an iterative and evolutionary process for achieving sustainable development by developing and implementing a continuous management capability that can respond to changing conditions, including the effects of climate change (Bijlsma *et al.*, 1996). Essentially, ICZM is a cooperative effort on the part of coastal zone stakeholders that results in a “win-win” outcome. ICZM already has been developed and implemented in some Asian countries for the allocation of environmental, sociocultural, and institutional resources to achieve conservation and sustainable multiple use of the coastal zone (Sato and Mimura, 1997). Since the 1970s, the Philippines has formulated programs and projects on coastal management, covering fishery and mangrove reforestation (Perez *et al.*, 1999). Mangrove rehabilitation has been recommended to mitigate climate impacts in coastal zones of Vietnam (Tri *et al.*, 1998). Since the 1960s, a groundwater withdrawal/pumping-back system has been carried out to mitigate ground subsidence in Shanghai and Tianjing. Fishing in certain seasons has been banned and the annual quality of fish catch restricted in the coastal zone of China (ESD-CAS, 1994). Sri Lanka conserves coastal tourism resources by using ICZM principles (White *et al.*, 1997). Coastal natural conservation parks have been established in Bangladesh, Thailand, China, and other countries (Sato and Mimura, 1997; Allison, 1998). However, land ownership and management responsibility issues in Bangladesh have inhibited coastal zone management. Similarly, privatization and decentralization of storm protection systems in Vietnam have created a vacuum for strategic management and increased the potential impacts of climate variability (Adger, 1999b, 2000).

Given that many potential climate change impacts on coastal zones feature irreversible effects, surprise outcomes, and unpredictable changes, the appropriate policy response should be to maximize flexibility and enhance the resilience and adaptation potential of these areas (Pritchard *et al.*, 1998). By contrast, coastal management in Asia to date more often than not has been dominated by policies that have sought to buffer socioeconomic activities and assets from natural hazards and risks via hard engineering protection (Chua, 1998).

11.2.5. Human Health

11.2.5.1. Thermal Stress and Air Pollution-Related Diseases

A remarkable increase in the number of heatstroke patients and mortality was observed when maximum daily temperatures in Nanjing, China, exceeded 36°C for 17 days during July 1988 (Ando *et al.*, 1996). In Japan as well, intense heat in summer is now becoming more common in large cities. The numbers of heatstroke patients are reported to have increased exponentially with temperatures of more than 31°C in Tokyo, Japan, and 35°C in Nanjing, China. Beyond a maximum daily temperature of 36°C, a remarkable increase in the number of heatstroke patients and deaths caused by heatstroke has been observed (Honda *et al.*, 1995; Ando, 1998). Typical hyperthermia occurs during hot days and during physical exercise in the summer (Nylen *et al.*, 1997).

Climate change will have a wide range of health impacts all across Asia (see Chapter 9). Although a reduction in health stresses and wintertime deaths is anticipated as a result of less frequent occurrence of extreme cold temperatures in boreal and temperate Asia, an increase in the frequency and duration of severe heat waves and humid conditions during the summer will increase the risk of mortality and morbidity, principally in older age groups and urban poor populations of temperate and tropical Asia (Epstein *et al.*, 1995). Heat stress-related chronic health damages also are likely for physiological functions, metabolic processes, and immune systems (Bouchama *et al.*, 1991; Ando, 1998).

Adverse health impacts also result from the build-up of high concentrations of air pollutants such as nitrogen dioxide (NO_2), ozone, and air-borne particulates in large urban areas. Combined exposures to higher temperatures and air pollutants appear to be critical risk factors for cerebral infarction and cerebral ischemia during the summer months (Piver *et al.*, 1999). As summarized in Figure 11-12, the heat index (a combination of daily mean temperature and relative humidity) and the concentration of NO_2 are shown to be significant risk factors for heatstroke in males age 65 years and older residing in Tokyo, Japan (Piver *et al.*, 1999). The number of heatstroke emergency cases per million residents is found to be greater in males than in females in the same age groups. Global warming also will increase the incidences of some diseases, such as respiratory and cardiovascular diseases, in arid and semi-arid, temperate, and tropical Asia.

11.2.5.2. Vector-Borne Diseases

Health impacts secondary to the impacts of climate change on ecological and social systems should include changes in the occurrence of vector-borne infectious diseases in temperate

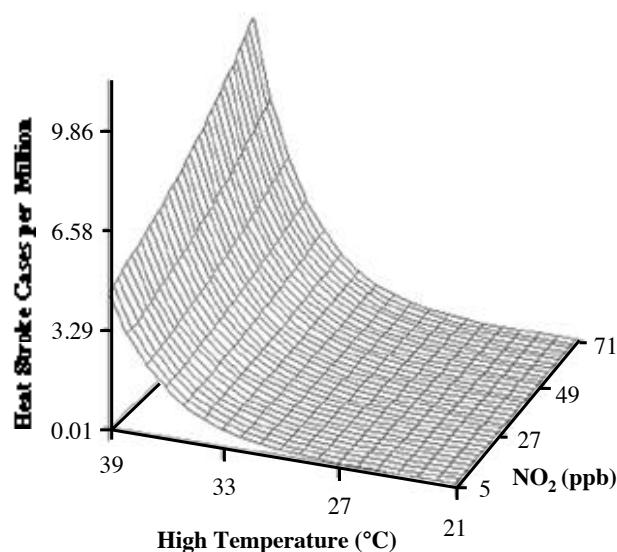

Figure 11-12: Heat stroke morbidity (cases per million; Tokyo, July-August, 1980–1995, males >65 years) (Piver *et al.*, 1999).

and tropical Asia (see Chapter 9). The distribution of diseases such as malaria is influenced by the spread of vectors and the climate dependence of infectious pathogens (Hales *et al.*, 1996; McMichael *et al.*, 1996; Epstein *et al.*, 1998). In recent years, the resistance of anopheline mosquito to pesticides and of malaria parasites to chloroquine has affected eradication activities (Trigg and Kondrachina, 1998). Malaria still is one of the most important diseases in countries in tropical Asia such as India (Bouma *et al.*, 1994; Akhtar and McMichael, 1996; Mukhopadhyay *et al.*, 1997), Bangladesh, Sri Lanka (Bouma and Van der Kaay, 1996; Gunawardena *et al.*, 1998), Myanmar, Thailand, Malaysia (Rahman *et al.*, 1997), Cambodia, Laos, Vietnam (Hien *et al.*, 1997), Indonesia (Fryauff *et al.*, 1997), Papua New Guinea (Genton *et al.*, 1998), and Yunnan, China (Jiao *et al.*, 1997; Xu and Liu, 1997) as a result of the presence of the mosquito vectors and the lack of effective control.

With a rise in surface temperature and changes in rainfall patterns, the distribution of vectors such as mosquito species may change (Patz and Martens, 1996; Reiter, 1998). Changes in environmental temperature and precipitation could expand vector-borne diseases into temperate and arid Asia. The spread of vector-borne diseases into more northern latitudes may pose a serious threat to human health. Climate change is likely to have principal impacts on epidemics of malaria, dengue, and other vector-borne diseases in Asia (Martens *et al.*, 1999). The epidemic areas of vector-borne diseases in Asia would depend on many demographic and societal factors, as well as environmental hygiene for vector control, available health infrastructure, and medical facilities (see also Chapter 9).

11.2.5.3. Diseases Resulting from Higher UV-B Exposures

Depletion of stratospheric ozone that normally filters out ultraviolet radiation in sunlight in the region from 280 to 320 nm (the UV-B region) has been linked to widespread use of volatile halogenated organic compounds, particularly chlorinated and brominated methanes and chlorofluorocarbons. Some of these compounds also are effective GHGs and therefore contribute to global warming as well. The quantitative relationship between UV-B dose and its physiological effect varies with the wavelength of UV-B exposure (Ilyas *et al.*, 1999). These effects include melanoma and non-melanoma skin cancers, cataracts and other ocular diseases, and dysfunction of the systemic and cutaneous immune systems (Kripke, 1994). The known effects of UV-B on the eye include inflammatory reactions from acute exposure, snow blindness (photo-kerato-conjunctivitis), and long-term damage to the cornea and lens (cataracts) from chronic exposure. It has been demonstrated that damage to melanocytes in human skin initiates the progression of changes leading to melanoma skin cancer (Kripke, 1994). Suppression of the immune response by UV-B radiation involves damage to Langerhans cells and subsequent activation of T-lymphocytes, thus increasing the severity of certain infectious diseases.

The impacts of greater exposure to shorter wavelength UV radiation on human health are cumulative and, for some

effects, may have long latencies. Noticeable increases in UV-B radiation over high and mid-latitudes as a result of depletion of stratospheric ozone have occurred in recent decades (McKenzie *et al.*, 1999; WMO, 1999; ACIA, 2000). Climate change could make conditions for the spread of diseases associated with higher UV-B doses more favorable.

11.2.5.4. Other Diseases

The distribution of water-borne infectious diseases is influenced mainly by the hygienic circumstance of water (Epstein, 1992; Echeverria *et al.*, 1995; Colwell, 1996; Esrey, 1996). Water-borne diseases—including cholera and the suite of diarrheal diseases caused by organisms such as giardia, salmonella, and cryptosporidium—are common with contamination of drinking water quality in many countries of south Asia (Echeverria *et al.*, 1995; Colwell, 1996; Esrey, 1996). Higher SSTs and rich nutrient load in major river deltas would support extended phytoplankton blooms in selected coastal areas of temperate and tropical Asia. These phytoplankton blooms are habitats for the survival and spread of infectious bacterial diseases. The cholera outbreak in Bangladesh during 1994 has been attributed to the presence of extended phytoplankton blooms (Colwell, 1996). The aforementioned water-borne diseases could become more common in many countries of south Asia in a warmer climate.

For preventive actions, impact assessments are necessary on various aspects such as the nutritional situation, drinking water supply, water salinity, and ecosystem damage (Kaye and Novell, 1994; Graczyk and Fried, 1998). Water-borne infectious diseases, natural disaster, environmental migration, nutritional deficiency, and environmental pollution should be major risk factors for human health (Thongkrajai *et al.*, 1990; Pazzaglia *et al.*, 1995; Colwell, 1996). The risk factor of diseases also will depend on infrastructure, economic conditions, the hygienic situation, and medical facilities. Risk could be reduced by awareness in the communities that are more vulnerable to instability in the future environment.

In Asia, economic and population growth will expand rapidly during the 21st century in many countries. The rapid increase in population will be accompanied by migration from rural communities to overcrowded large cities (Stephens, 1995). Disasters linked to climate extremes such as floods and droughts also would impact local and regional populations and enforce migration. The huge energy consumption by the expanding population in urban cities would result in degradation of air and water quality, whereas rapid expansion of the economy will bring about improvements in living standards, such as improved environmental sanitation, hygienic practice, and medical treatment facilities. Therefore, better understanding of the interaction among climate change and environmental and health status in communities at regional and local scales is crucial to forge physiological acclimatization and social adaptations in the future.

11.2.6. Human Dimensions

11.2.6.1. Climate Extremes and Migration

The impacts of climate change on Asia will place additional stress on socioeconomic and physical systems. These pressures may induce change in demographic processes. Demographic trends, including the stability and size of populations, will be influenced directly through the impacts of climate change on human health as described in Section 11.2.5 and indirectly through the impacts of climate change on food security and the viability of natural resource-based economic activity. A further demographic response will come about through the risk of extreme events on human settlements. If the incidence and magnitudes of events such as droughts and coastal floods increase, there could be large-scale demographic responses—for example, through migration. Migration in itself is not necessarily a signal of vulnerability to present-day extreme events. Motivations for migration are diverse; much rural-to-urban migration in Asia takes place as a result of increased economic opportunities in megacities (cities with at least 8 million inhabitants). Future increases in the frequency and intensity of severe weather systems as a consequence of climate change can trigger mass migration, however.

The annual rate of growth in migration on a global scale has been greatest in developing countries of south and southeast Asia. For instance, population growth and land scarcity has encouraged the migration of more than 10 million Bangladeshi natives to neighboring Indian states during the past 2 decades. This migration has been exacerbated by a series of floods and droughts affecting the livelihoods of landless and poor farmers in this region. Land loss in coastal areas resulting from inundation from sea-level rise as a result of climate change is likely to lead to increased displacement of resident populations. Many south Asian countries increasingly expect the number of internally displaced persons to rise in future.

Immigrant labor often benefits both the donor and the host cities/countries (Connell and Conway, 2000). However, perceptions of regional/national identity, language/cultural differences, and fears of unemployment may contribute to increased hostilities between immigrants and nationals in years to come. Climate change will act in parallel with a complex array of social, cultural, and economic motivations for and impacts of migration (Pebbley, 1998; Conway *et al.*, 2000; Kates, 2000). Irrespective of resource constraints in developing countries of Asia, they have to better equip themselves through appropriate public education and awareness programs with disaster preparedness measures, including infrastructures for effective resettlement of displaced people as a consequence of weather calamities.

11.2.6.2. Infrastructure Linkages

The urban population in Asia is growing at four to five times the rate of the rural population. At this rate, more than 60% of the people in Asia will be living in towns and cities by 2015.

An estimated 80% of the increase will occur in developing countries. The number of megacities in Asia would grow to at least 23 of the world's 36 by the year 2015 (United Nations, 1998). Urbanization is rapid in fast-growing economies of south and southeast Asia, where the average annual urban growth rate is more than 4%. The current pace and scale of change often strains the capacity of local and national governments to provide even the most basic services to urban residents. An estimated 25–40% of urban inhabitants in developing countries today live in impoverished slums and squatter settlements, with little or no access to water, sanitation, or refuse collection (World Bank, 1997).

Basic infrastructure demand in urban corridors is likely to increase dramatically in the future. Already governments in several developing countries of Asia are introducing suites of acts and laws to ensure provision of adequate public services and minimize adverse effects on surrounding communities and ecosystems. For instance, Indonesia introduced the Spatial Use Management Act in 1992 for the identification of environmentally sensitive areas—where development activities would be restricted—and for improved planning for the location and support of activities such as industrial development (Djoekardi, 1995). Developing countries in Asia would soon need to develop new priorities and policies that try to address demands created by the increasing number of people in cities while capitalizing on the benefits of urbanization, such as economic growth and efficient delivery of services. Climate change has the potential to exacerbate basic infrastructure demands of urban inhabitants in many countries of Asia.

11.2.6.3. Industry, Energy, and Transportation

In many cities in the developing countries of Asia, movement of the labor force from dispersed agricultural centers to concentrated industrial sectors has increased urbanization and expansion of the suburban area where industries are located. This situation has caused serious traffic, housing, and sanitary problems. Moreover, a substantial share of industrial growth in developing countries revolves around the transformation of raw materials into industrial products such as steel, paper, and chemicals. Production of industrial chemicals has been shifting from developed countries to developing countries of Asia in recent years. Not only are these processes resource-intensive, in addition, industries such as electricity generation, chemicals and petroleum refining, mining, paper production, and leather tanning tend to produce a disproportionately large amount of hazardous and toxic wastes and already have caused serious air and water pollution. Moreover, because of poor regulatory capacity, developing countries have become targets for dumping of toxic wastes such as polychlorinated biphenyls (PCBs) by multinational companies.

In developing countries of Asia, an increase in paper consumption of more than 80% is expected to occur by 2010. However, a shortfall in the supply of all wood products and especially pulp and paper is likely in the 21st century as a result of declines in

natural vegetation productivity. This trend will put immense pressure on unmanaged forests of Asia. Some countries in Asia have resorted to agroforestry and farm woodlots to meet their increasing demand for pulp and paper on a near-term basis. Over the long term, however, anticipated growth in demand for wood products of all types probably will necessitate changes in forest management practices such as greater reliance on industrial plantations. Heat stress to livestock herded in open areas would reduce animal weight gain, dairy and wool production, and feed conversion efficiency in arid and semi-arid Asia (IPCC, 1996). An increase in the frequency of drought and heavy rainfall could result in a decline in tea yield in Sri Lanka (IPCC, 1998). Climate change could have adverse impacts on agroindustries such as food, beverages, tobacco, natural fiber textiles, leather, wood, and rubber.

The manufacturing industry could be affected indirectly through the availability of water, energy supply, and transportation systems throughout Asia. Mining operations, which are required to produce raw materials such as coal (practiced intensively in China and India because of heavy demand), exposes sulfur- and iron-bearing rocks to weathering and erosion that would be aggravated by global warming. Mineral industries discharge large amounts of waste ore known as tailings. Manufacturing industries release effluent to the air and water during production processes. For instance, cement production and foundry operations release particulates; metal industries release SO₂, CO₂, HF, and organic solvents; and chemical plants release particulates, SO₂, and various hydrocarbons. Food processing, pulp and paper industries, brewing, and tanning industries release effluents in the form of contaminated water and sediments. This degradation of the environment may be exacerbated by climate change.

Climate change will adversely affect hydroelectric energy generation in Asia, exacerbating already depleted water resources in several major rivers in Asia. Increased humidity and hence more cloudiness in a warmer atmosphere could inhibit direct solar radiation. Photovoltaic technology, which is used extensively in Indonesia and a few other south Asian countries for remote area electrification programs, could be jeopardized. Changes in wind patterns could affect existing windmill installations. Availability of biomass, particularly fuel wood, depends on forest area and the quantity of rainfall. In areas with excess rainfall, CO₂ enrichment and higher temperatures could increase fuelwood production and supply. Geothermal resources also may be affected by changes in precipitation patterns. For instance, an increase in rainfall could increase recharge of groundwater for most geothermal fields (IPCC, 1996).

In general, no major impacts of climate change on the production and distribution facilities of fossil fuels are likely, other than policies aimed at reducing GHG emissions from burning of fossil fuels. However, offshore exploration, production, and distribution facilities of oil and natural gas would be influenced by sea-level rise and extreme weather events such as cyclonic storms and associated surges that are likely to be exacerbated by climate change. Most power plants and oil refineries in Asia

also are located along the coastlines to facilitate transportation and easy access to cooling water supply. Construction of seawalls will be needed to protect these facilities against sea-level rise (Mimura *et al.*, 1998).

As reported in IPCC (1996), energy demand for heating, cooling, and agriculture activities can be influenced by climate change. Global warming would increase energy demand for cooling in the tropical Asia region and reduce energy demand for heating in boreal Asia. A similar pattern could be observed in temperate Asia, either in summer or winter. For agricultural activities, more energy would be needed for irrigation pumping during warmer weather as the soil becomes drier.

Tourism and outdoor recreational activities are likely to be disrupted in pattern by climate change. Global warming is expected to shorten the skiing season in many areas and affect the feasibility of some ski facilities (IPCC, 1998). Summer recreational activities in coastal recreational areas may be affected with the inundation of beaches. In Malaysia, for example, unprotected resorts located near the coastline would be lost through erosion; others that are not affected by erosion or inundation will cease to operate because of the loss of beaches (Teh, 1997). The increased frequency of forest fires because of drier conditions in Indonesia during the 1997 El Niño resulted in haze that affected the tourism industries of Indonesia, Singapore, and Malaysia (Schweithelm *et al.*, 1999). Some wildlife reservation areas that are famous as tourist spots may lose their attraction because of the disappearance of flora and fauna in the changed ecosystems. For example, it has been suggested that the flowering dates of cherry blossoms in Japan and Korea could move 3–4 days earlier if air temperatures during March increase by 1°C (Seino *et al.*, 1998). Extreme weather events in highland regions also would threaten rafting, mountain climbing, and other high-altitude tourism.

Transportation systems, including infrastructure and fuel, can be influenced directly and indirectly by climate change. A longer rainy season, melting of ice deposits, and sea-level rise could directly damage infrastructures such as roads, railways, runways, terminals, airports, and harbors, thereby disrupting transportation systems. Climate change would increase the inherent necessity for expansion of infrastructure and alter fuel consumption patterns. In Siberia, for instance, frozen rivers that currently are used as roads would require a shift to water transport or construction of permanent roads with shorter winters. As reported in IPCC (1996), similar impacts could be experienced from permafrost melting.

11.2.6.4. Financial Aspects

The financial services sector typically includes banking, insurance, stock exchanges, and brokerages, as well as financial services firms such as investment banks, advisory services, and asset management, among others. Banking crises, currency speculation, and devaluation have become common in recent years in Asia and now are key policy concerns. Climate change

could have serious consequences for this sector because many adaptation and mitigation measures such as crop insurance against floods or droughts are mediated or implemented through this sector. The implications and role of risk management techniques such as derivatives, options, and swaps are some of the new developments in financial services to dampen the impact of disasters on national finances.

There is a growing body of literature on the economic impacts of global warming that takes adaptation into account in estimating the imposed costs of climate change, but these studies fall short of specifically estimating the costs and benefits of adaptation. The basis for estimating adaptation costs is the economic opportunity cost of a product or activity. Estimating this cost requires price and other data from market transactions such as sectoral coverage and assumptions about markets, behaviors, and policy instruments in addition to economic growth path as a function of socioeconomic conditions, resource endowment, and government policies. Multiple baseline choices are critical in the estimation and evaluation of the financial costs, based on accurate reporting of financial flows (see also Chapter 8).

Although global gross domestic product (GDP) has increased by a factor of three since 1960, the number of weather-related disasters has increased four-fold, real economic losses seven-fold, and insured losses 12-fold in the same period (see also Chapter 8). These losses have had some notable regional impacts—particularly in developing countries of Asia, where the impacts of climate change are expected to be greatest in terms of loss of life and effects on investment. Individual large events have shown visible short-term impacts on insurance profitability and pricing and public finance. There is only limited penetration of or access to insurance in developing countries. This situation makes them more vulnerable and will impair their ability to adapt. The property/casualty insurance segment and small specialized or undiversified companies have greater sensitivity. Coping mechanisms and adaptation strategies will depend largely on public or international support. Given finite financial resources and international aid, increased climate-related losses would compete with development efforts.

Adaptation to climate change presents complex challenges to the finance sector. Increasing risk could lead to a greater volume of traditional business, as well as development of new risk and financing products (e.g., catastrophe bonds). However, increased variability of loss events would result in greater actuarial uncertainty. The design of an optimal adaptation program in any country would have to be based on comparison of damages avoided with the costs of adaptation. Other factors, particularly in developing countries with incomplete markets, also enter the decisionmaking process—such as the impacts of policies on different social groups in society, particularly those that are vulnerable; employment generation and opportunities; improved air and water quality; and the impacts of policies on broader concerns such as sustainability.

11.3. Vulnerability and Adaptation Potential

11.3.1. Resilience of Resources, Populations, and Infrastructure

The adaptive capacity of a resource system or a human society depends on the resilience of these systems. Resilience in the face of climate change, as with resilience to present-day hazards such as floods and droughts, therefore depends on the scale, intensity, and rate of change of the climate system, as well as the inherent ability of ecosystems or communities to adjust to new circumstances (Riebsame *et al.*, 1995). Resilience is the ability of a system to return to a predisturbed state without incurring any lasting fundamental change. Resilient resource systems recover to some normal range of operation after a perturbation. The processes of short-term adjustment to changes in land productivity and food scarcity in traditional societies of Asian countries are resilient to perturbations. This resilience has been demonstrated in a range of resource systems throughout Asia, including highland agriculture, large-scale irrigated agriculture, and fishery-dependent communities (e.g., Bray, 1986; Bayliss-Smith, 1991; Tang 1992; Grove *et al.*, 1998; Ruddle, 1998; Adger, 1999a). Long-term adaptation to climate change requires anticipatory actions, which would require considerable investment of capital, labor, and time hence diversion from scarce available resources, existing services, and infrastructure. Constraints on such resources clearly are more acute in the developing countries of Asia. The three crucial sectors of land resources, water resources, and food productivity are of highest priority for planned adaptation, particularly for the poorer resource-dependent countries.

Adaptation to climate change in Asian countries depends on the real cost of adaptive measures, the existence and engagement of appropriate institutions, access to technology, and biophysical constraints such as land and water resource availability, soil characteristics, genetic diversity for crop breeding (e.g., development of heat-resistant rice cultivars), and topography. Demand for land and water already is increasing to support growing populations, increased agricultural activities, and expanding modern urban infrastructure. Most developing countries in Asia face significant impacts from present-day climatic hazards. Faced with impending floods, the economic insecurity of communities and rural households, lack of timely warnings, ignorance of the severity of danger from flood, and lack of efficient transport systems, some developing countries of Asia often choose not to evacuate homes to avoid climate-related disasters. Such circumstances also act as constraints for the alleviation of poverty and hence reinforce social vulnerability. For many developing countries in Asia, climate change is only one of a host of environmental problems; these countries have to individually and collectively evaluate the tradeoffs between climate change actions and nearer term needs (such as food security, air and water pollution, and energy demand). Adaptation measures designed to anticipate the potential effects of climate change can help to offset many of the negative effects (Burton, 1997). Adaptation measures that ameliorate the impacts of present-day climate variability

include sea defenses, institutional adaptations, plant breeding, and adoption of new technologies in agriculture. Many countries in Asia already commit significant resources to ameliorating climate-related hazards (e.g., Golubtsov *et al.*, 1996; Nishioka and Harasawa, 1998; Ali, 1999; Huq *et al.*, 1999).

Development and broad application of integrated modeling efforts (those that consider interactions of biophysical and socioeconomic factors) and modeling approaches that are particularly applicable at the regional scale warrant increased attention. For example, mountain systems in Asia are vulnerable with respect to ecological and social systems, for reasons of high heterogeneity. Management of Asia's mountain landscape therefore demands diversified strategies that link ecological and social components for location-specific solutions (Ehrenfeld, 1991; Ramakrishnan, 1992). Inclusion of complex feedbacks between systems may change significantly the current "mean" estimate of impacts.

Sustainable development within Asia's agroecosystems is crucial to provide adequate food security for traditional farming communities in the lowlands and the uplands in developing countries and to ensure *in situ* conservation of crop biodiversity for sustaining high-input modern agriculture itself. However, conserving biodiversity with concerns for higher production from these complex agroecosystems is a challenging task, for which novel development alternatives are required (Ramakrishnan, 1992; Ramakrishnan *et al.*, 1996; Swift *et al.*, 1996). Traditional societies have always manipulated biodiversity to ensure ecosystem resilience and to cope with uncertainties in the environment, rather than to increase production on a short-term basis. There is increasing evidence now to suggest that we could learn from their traditional ecological knowledge base (Gadgil *et al.*, 1993) for coping with uncertainties associated with global change.

The resilience of agricultural practices in the face of climate change depends on the nature and magnitude of region-specific climate change, regional sensitivity, or the threshold and social resilience and adaptive capacity of agricultural communities. Adjustment of planting dates to minimize the effect of temperature increase-induced spikelet sterility can be used to reduce yield instability, for example, by avoiding having the flowering period to coincide with the hottest period. Adaptation measures to reduce the negative effects of increased climatic variability may include changing the cropping calendar to take advantage of the wet period and to avoid extreme weather events (e.g., typhoons and storms) during the growing season. Crop varieties that are resistant to lodging (e.g., short rice cultivars) may withstand strong winds during the sensitive stage of crop growth. A combination of farm-level adaptations and economic adjustments such as increased investment in agriculture infrastructure and reallocation of existing land and water resources would be desired in the agriculture sector. Increasing demand for water by competing sectors may limit the viability of irrigation as a sustainable adaptation to climate change. Expansion of irrigation as a response to climate change will be difficult and costly in many of the countries in Asia even under favorable circumstances. Mounting societal pressures to

reduce environmental degradation will likely foster an increase in protective regulatory policies, further complicating adaptations to climate change (Easterling, 1996).

A commonly prescribed adaptation to climate change in the water sector is to enhance characteristics that offer flexibility hence enhancing resilience. Flexibility issues are particularly important with regard to the development of water resources for industry or agriculture. Major projects such as dams actually may limit flexibility if they lose effectiveness as regional hydrological water balances undergo major changes. With likely changes in climate variability, dams and sea defenses built to withstand a 100-year extreme event may not be adequate thus leading to a risk of major catastrophe. If hydrological patterns change markedly and irrigated agriculture is required to relocate in response, prior investments may be lost as existing infrastructures become obsolete, and additional investments will be needed. This necessitates critical scrutiny of a range of available choices that incorporate economic and environmental concerns. The potential for adaptation should not lead to complacency (Rosenzweig and Hillel, 1995). Some adaptive measures may have detrimental impacts of their own.

The issue of natural resource management in Asia has a highly complex set of interconnections between natural and social systems. Natural resource management in largely rural tropical environments must reconcile ecological and social processes that operate at a range of scales, from species up to the landscape level. Studies have shown that ecologically important keystone species often are socially selected by many rural societies (Jodha, 1996). The possibility for species selection for rehabilitating a degraded ecosystem should be based on a value system that the local people understand and appreciate; therefore, their participation in the process of developmental activity is important. Community perceptions of soil and water management can be a powerful agent for sustainable management of natural resources (e.g., in the case of highly fragile and vulnerable Himalayan mountain systems) (Ramakrishnan *et al.*, 1994). In other words, natural resource management in tropical Asia must be sensitive to social and even cultural perceptions (Ramakrishnan, 1998), as well as traditional resource management practices.

Major fishery-related environmental issues include the effects of trawling on sea-bottom habitats and the detrimental effects of catches of nontarget species on populations and ecosystems. Fishery resources also are threatened by activities other than commercial fishing. Loss of inshore fish nursery habitats from coastal development and pollution from land-based activities cause significant change to ecosystems that support fisheries. Effective conservation and sustainable management of marine and inland fisheries are needed at the regional level so that living aquatic resources can continue to meet regional and national nutritional needs. Asian economic growth has failed to alleviate poverty for a large share of Asian people to date. Achieving economic and industrial growth in Asia that is sustainable—both ecologically and economically viable over the long term—would require more than just cleaner, more

efficient industrial processes; it demands a reorientation toward becoming less material-intensive and attempting to contribute toward protecting our environment and ecosystem.

11.3.2. Regional and Sectoral Strategies

Regions of the Asian continent differ widely in their biophysical characteristics hence in their physical vulnerability to climate change. Different regions also experience highly differentiated social vulnerability. Adaptation strategies therefore will be differentiated across regions and sectors, depending on their vulnerability profiles. In the following subsections, vulnerabilities and related adaptation strategies are discussed for four broad regions of Asia and for selected sectors.

11.3.2.1. Boreal Asia

At present, only areas of sporadic permafrost are used for agriculture. Global warming should play a positive role for agriculture in boreal Asia. The growing season is likely to expand by 1–1.5 months by 2100. The increase in mean monthly air temperatures during the summer will increase active soil temperatures. In addition, winter air temperatures will substantially increase (Sirotenko *et al.*, 1997). Shifts in the limit of the permafrost zone to the north, formation of vast areas of perennial ground thawing, and better soil climate will contribute to a northward shift of agriculture boundary. The key step for an agriculture adaptation strategy could be the choice of suitable crops and cultivars. Shifts in sowing date of spring crops will allow more effective use of the soil moisture content formed by snow melting. The dates of spring crop sowing could be moved forward in a crop rotation calendar in southern regions, and farmers could plant a second crop that could even be vegetable with a short growth period (Laverov, 1998). Optimum use of fertilizers and ecologically clean agrotechnologies would be beneficial for agriculture.

Climate change has the potential to exacerbate water resource stresses in some areas but ameliorate them in most parts of boreal Asia. The increase in surface temperatures will have considerable effect on the timing of snowmelt hence the timing of the flow regime (Arnell, 1999). Diversions of water systems would adversely impact fisheries and fishery habitat in the region (Rozengurt, 1991). A decrease in water flow during the dry summer season is likely in some parts of boreal Asia. Extraction of groundwaters from deep aquifers has been proposed as an option, keeping in view the likely surface water quality deterioration during dry periods (Laverov, 1998). It would be necessary to increase the capacity of recycled water supply systems and autonomous water-use systems. However, even with water-saving measures it may be necessary to cut water intake for industry needs during dry periods to meet increasing demand in the future. Bottom-deepening along navigation channels may be required to facilitate the transport of goods and material through rivers.

11.3.2.2. Arid and Semi-Arid Asia

The major impact of climate change in arid and semi-arid Asia is likely to be an acute shortage of water resources associated with significant increases in surface air temperature. Conservation of water used for irrigated agriculture therefore should be given priority attention. With increased evapotranspiration, any adaptation strategy in agriculture should be oriented toward a shift from conventional crops to types of agriculture that are not vulnerable to evapotranspiration (Safriel, 1995). These strategies entail either intensive agriculture in greenhouses—within which rates of evapotranspiration are much reduced—or developing alternatives such as aquaculture that will partly replace agriculture (e.g., fish for human/animal feed, crustaceans for human feed, and unicellular algae for fish/prawn feed, as well as for food additives and medicinal and cosmetic uses). All of these organisms are of high yield; they enjoy solar radiation and often heat, and they do not evaporate or transpire water. Expansion of commercial and artesian fisheries also could help reduce dependence on food productivity. Protection of soils from degradation should be given serious consideration.

Climate change would exacerbate threats to biodiversity resulting from land-use/cover change and population pressure in Asia. Ecosystem services can be impaired by loss of key species in arid and semi-arid Asia (Xiao *et al.*, 1998). Because intraspecies variation in response to environmental stress usually exists in populations subjected to year-to-year climate change, some genotypes in such populations are expected to be more resistant to climate change than others. Such genotypes are more common in peripheral populations than in core populations of species. Although the core population may become extinct because of global warming, resistant types in peripheral populations will survive and can be used to rehabilitate and restore affected ecosystems (Safriel *et al.*, 1994; Kark *et al.*, 1999). The geographic locations of the peripheral species population usually coincide with climatic transition zones, such as at the edges of drylands or along the transition between different types of drylands. Many countries in the region have more than one dryland type and hence should have peripheral populations—especially in desert and nondesert transitions, which often occur within semi-arid drylands. Identifying regions with concentrations of peripheral populations of species of interest and protecting their habitats from being lost to development therefore can play a role in enhancing planned adaptation for natural and semi-natural ecosystems.

11.3.2.3. Temperate Asia

Projected surface warming and shifts in rainfall in temperate Asia are significant and will induce increases in photorespiration, maintenance respiration, and saturation deficits—causing stomatal closure and decline in productivity (White *et al.*, 1999). An adaptive response in the agriculture sector should be an effort to breed heat-resistant crop varieties by utilizing genetic resources that may be better adapted to warmer and drier conditions. Improvements in farming systems, fertilizer management, and

soil conservation form major adaptation strategies (Lou and Lin, 1999). Research is needed to define current limits to heat resistance and the feasibility of manipulating such attributes through modern genetic techniques. Crop architecture and physiology may be genetically altered to adapt to warmer environmental conditions. The genetic resources of seeds maintained in germplasm banks may be screened to find sources of resistance to changing diseases and insects, as well as tolerances to heat and water stress and better compatibility with new agriculture technologies. Genetic manipulation also may help to exploit the potentially beneficial effects of CO₂ enhancement on crop growth and water-use efficiency.

The process of rapid urbanization and industrialization in several Asian megacities has placed enormous stress on urban infrastructure, human well-being, cultural integrity, and socioeconomic arrangements. These urban cities are giant resource sinks and create a large “ecological footprint” on the surrounding countryside. The negative environmental impacts of expanding cities are already large; as they continue to grow and become more prosperous, these impacts are likely to increase. Rising levels of air and water pollution in many of the large cities are considerable. Production and consumption systems that sustain life in cities are largely responsible for many of these changes. As climate changes, the demand for basic infrastructure facilities such as housing, electricity, food supply and distribution, and drinking water supply will increase, and municipalities would have a difficult time managing waste recycling and waste disposal. Development policies that mitigate or avert some of these long-term problems would have to be country-specific and depend heavily on the availability of infrastructure resources, the size of the floating population, and sustainable behavioral changes in society.

Climate change will impinge on a diverse, complex, and dynamic form of climatic hazards such as floods, droughts, sea-level rise, and storm surges in the countries of temperate Asia. Preparation for changes in climate variability should include provision for the possibility of increased flooding, as well as incidences of drought. The present path of development in this region is placing more fixed infrastructures and economic activity within the coastal zone. This trend seems to offer limited scope for adjustments against flooding in the coastal zone resulting from sea-level rise. The likelihood of damage to infrastructure and loss of human life because of unexpected extreme events will rise. A wide range of precautionary measures at the regional and national levels—including awareness, perception, and the acceptability of risk factors among regional communities—are warranted to avert or reduce the impacts of such disasters on economic and social structures. Many current technical and socioeconomic barriers will need to be overcome to prevent risks to human health resulting from increases in disease incidences associated with climate change.

11.3.2.4. Tropical Asia

Agricultural adaptation to climatic variability is an evolving process. Planned interventions through research, extension, or

pricing or marketing policies can have inadvertent detrimental impacts for poor farmers. Agricultural productivity in tropical Asia is sensitive not only to temperature increases but also to changes in the nature and characteristics of monsoons. An increase in leaf surface temperatures would have significant effects on crop metabolism and yields, and it may make crops more sensitive to moisture stress (Riha *et al.*, 1996). Cropping systems may have to change to include growing suitable cultivars (to counteract compression of crop development), increasing crop intensities (i.e., the number of successive crops produced per unit area per year), or planting different types of crops (Sinha *et al.*, 1998). Farmers will have to adapt to changing hydrological regimes by changing crops. For example, farmers in Pakistan may grow more sugarcane if additional water becomes available, and they may grow less rice if water supplies dwindle. The yield ceiling must be raised and the yield gap narrowed while maintaining sustainable production and a friendly environment. Development of new varieties with higher yield potential and stability is complementary to bridging the yield gap. Efficient production of a socially optimal level of agricultural output in this region ultimately may depend on biotechnological applications, but only if these applications prove to be environmentally sustainable.

Groundwater is the main source of freshwater in many parts of tropical Asia, particularly in semi-arid regions. Water resources already are limited in terms of supply and demand in this region. The aquifers in most countries have been depleted by high withdrawal and low recharge rates, and significant drawdown problems exist. Even with increases in precipitation, surface runoff may diminish in some river basins under projected climate change scenarios because of greater evaporation in a warmer atmosphere (higher hydrological elasticity). Increased runoff in some river basins can cause deleterious effects such as greater flooding, waterlogging, and salinity. More than 25% of the irrigated land in the Indus basin already is affected by waterlogging and salinization (Hillel, 1991). Freshwater availability in the coastal regions is likely to undergo substantial changes as a result of a series of chain effects. Improvements in runoff management and irrigation technology (e.g., river runoff control by reservoirs, water transfers, and land conservation practices) will be crucial. Increasing efforts should be directed toward rainwater harvesting and other water-conserving practices to slow the decline in water levels in aquifers. Recycling of wastewater should be encouraged in drought-prone countries in tropical Asia. However, major water development decisions to augment water supplies may have greater relative hydrological, environmental, and social impacts than climate change *per se* in the shorter term. Climate change will affect the benefits to be accrued by future water development projects and therefore should be taken into consideration in the context of water resource policies and planning.

With rapid development of the economy in several countries in tropical Asia during recent decades, the patterns of land use and land cover have been modified significantly; a sequence of transitions and conversions is discernable. As a result of different natural and socioeconomic conditions, the speed and scale of

land-use change is very diverse in different parts of Asia. This process has contributed to significant losses in total forest cover; changes in standing biomass and the soil carbon budget; extinction of mammals, birds, and vascular plants; soil degradation; and threats to food security. Excessive human and livestock population pressure in association with inappropriate agricultural extension activities also lend an explanation for widespread land degradation in tropical Asia. Salinization and acidification of soil in low-lying coastal areas would adversely affect cropland in addition to land losses from permanent inundation of deltas from anticipated sea-level rise.

Many of the major rivers originating in mountains and highlands are charged with sediments, depending on the types of land uses in the watersheds (e.g., from forestry and agroforestry to open agriculture). Marginalization of production areas in highlands will continue to increase soil losses, land slips, and slides in the region. It has been suggested that upland micro-watersheds can be hydroecologically sustainable only if good forest cover and dense forests are maintained (Rai, 1999). Under changing climate conditions, the pressure toward small- and large-scale transfers of land for agricultural and urban uses may grow.

Sea-level rise poses the greatest threat and challenge for sustainable adaptation within south and southeast Asia. The sea level already is rising in many locations, primarily as a result of geological processes and anthropogenic manipulations. Projected sea-level rise along the Asian coastlines represents an increase of three to four times over present rates (Chansang, 1993; Midun and Lee, 1995; Mimura and Harasawa, 2000). The potential impacts of accelerated sea-level rise include inundation of low-lying deltas and estuaries, retreat of shorelines, and changes in the water table (Wong, 1992; Sivardhana, 1993). Episodic flooding from high storm surges would penetrate much further inland. Salinization and acidification of soil in low-lying coastal areas will adversely affect agricultural production, in addition to land losses from permanent inundation of deltas from anticipated sea-level rise. The impacts will vary from region to region because of local factors such as land subsidence, susceptibility to coastal erosion or sedimentation, varying tidal ranges, and cyclonicity (Bird, 1993). The Ganges-Brahmaputra in Bangladesh, the Irrawaddy in Myanmar, the Chao Phraya in Thailand, and the Mekong and Song Hong in Vietnam are among the key low-lying river deltas in tropical Asia that are most vulnerable to sea-level rise. Local-level social and institutional adaptations in sensitive regions and development and promotion of risk management can potentially prevent accelerated impacts to these deltas through protection of the ecology of the region from further human interventions so they can sustain themselves at least in a short time horizon.

11.3.3. Institutional and Financial Barriers

As reported in IPCC (1996), the global cost of weather-related disasters to insurers had risen rapidly since 1960 as a result of increased frequency and severity of extreme climate events.

The property insurance industry is most likely to be directly affected by climate change because it is already vulnerable to variability in extreme weather events (Dlugolecki *et al.*, 1996). The trend of rapidly growing damage from weather-related disasters has continued. There have been several major climatic hazards in Asia in the late 1990s. There is, however, only very limited penetration of property insurance or agriculture crop insurance in many of the areas that are most affected by recent floods and cyclonic storms. The impacts of flooding are concentrated on the poorest sections of society and people living in marginal areas. There is a need, particularly in Asia, for increased recognition by the financial sector that climate change could affect its future. Climate change can be considered a threat as well as an opportunity for the insurance industry because an increase in risks and perceived risks implies more business opportunities for the sector.

Decisionmaking processes on the choice and capacity of adaptation to the impacts of climate change vary from country to country, depending on its social structure, culture, and economic capacity, as well as the level of environmental disruptions in the Asian region. Institutional inertia, a scarcity of technological adaptation options, and additional economic burdens in developing countries of Asia will be limiting factors for investment in environmental protection and would force people in these countries to face greater risks.

11.4. Synthesis

This chapter discusses the current status of our understanding of likely future changes in climate variables, such as surface temperature, precipitation, soil moisture, extreme events, their potential impacts on natural environment and human society, and possible adaptative options in the Asian region. These factors are delineated on a subregional, national, and sectoral basis. This section attempts to formulate a synthesis of climate change and its implications and consequences for Asia and identify commonality throughout the region, as well as subregional and national differences in terms of climate change and its consequences.

This synthesis also aims to identify the critical climatic threshold, feedbacks, interactions and nonlinearities involved in interactive systems of climate, natural environment, and human society. These analyses will provide a basis for further indepth understanding of the implications of climate change, setting policy-oriented goals to arrest human interventions to the climate system, and planning adaptive responses.

11.4.1. Key Observations and Uncertainties

Asia is characterized by an extreme diversity of natural environment, in longitudinal, latitudinal, and vertical directions. Each subregion and country is supported by natural resources such as water, forests, grasslands/rangelands, and fisheries, which have been utilized by diverse Asian societies in a sustainable

manner over the centuries. Promotion of public awareness and participation in region-specific adaptation and mitigation strategies is essential, however, particularly in the developing countries of Asia, to effectively and collectively overcome problems associated with climate change. In general, climate change will impose significant stresses on available natural resources throughout Asia. At the same time, combinations of specific geographical settings and changes in climate will bring about different impacts on different subregions.

Asia has long been affected by natural hazards such as intense rainfall, flooding, droughts, extreme temperatures, snow avalanches, and other impacts of tropical cyclones, monsoons, and ENSO. The security and sustainability of the region is highly dependent on future trends of such extreme events and preparedness for them. However, there remains great uncertainty in projections of likely changes in tropical cyclones, monsoons, and El Niño. It should be noted that the key vulnerabilities related to such natural hazards are still largely qualitative, and there are possibilities of unforeseen surprises in the future.

Many systems are sensitive to natural climate variability in Asia as well as climate change and hence may not be resilient to climate change. These systems include mangroves, lakes, glaciers, deltas, rivers, and ecosystems within the permafrost region. Threshold levels of response are likely to be exceeded by projected climate change. Changes in these systems will occur at different climate thresholds in various regions of Asia. For example, a 0.5°C rise in mean temperature and 10-cm rise in sea level could lead to inundation of 15% (approximately

750 km²) of the Bangladesh Sundarbans, the largest mangrove ecosystem in Asia. A 45-cm rise in sea level, corresponding to a 2°C rise in mean temperature, is required to introduce changes in the low saline zone of the Sundarbans (Smith *et al.*, 1998). Table 11-10 lists selected examples of regions that are sensitive to climate change, based on region- and country-specific studies.

Although many resource systems and populations exhibit high degrees of resilience and adaptive capacity, there is a significant risk that critical thresholds may be breached as a result of climate change, undermining this resilience. The environmental risks in a region could vary significantly for different sectors, depending on the degree of warming. To develop a risk profile for precautionary management of climate change, it is necessary to assess the critical climate threshold for a region for each of the relevant priority sectors, such as water and agriculture. For instance, a small degree of surface warming could be beneficial for agriculture in Russia but may be detrimental in India or Bangladesh. Increased glacier melt in the Himalayas may cause serious floods in Nepal, India, and Bangladesh. The potential environmental risks to water and marine resources in marginal seas of Asia such as the Sea of Japan, Bohai Bay, and the Yellow Sea also will depend on the degree of climate change—which could differ significantly in these regions. For many countries in Asia, there is sparse scientific research on the evaluation of sector-specific critical climatic thresholds. The response of driving forces such as economic growth, population increase, and technological progress in each country or region also should be included in the determination of thresholds for precautionary risk management as an adaptation strategy to climate change.

Table 11-10: Sensitivity of selected Asian regions to climate change (based on ICRF, 1998; Mirza, 1998; Smith *et al.*, 1998; Mizina *et al.*, 1999).

Change in Climatic Elements and Sea-Level Rise	Vulnerable Region	Primary Change	Impacts	
			Primary Secondary	
0.5–2°C (10- to 45-cm sea-level rise)	Bangladesh Sundarbans	– Inundation of about 15% (~750 km ²) – Increase in salinity	– Loss of plant species – Loss of wildlife	– Economic loss – Exacerbated insecurity and loss of employment
4°C (+10% rainfall)	Siberian permafrosts	– Reduction in continuous permafrost – Shift in southern limit of Siberian permafrost by ~100–200 km northward	– Change in rock strength – Change in bearing capacity – Change in compressibility of frozen rocks – Thermal erosion	– Effects on construction industries – Effects on mining industry – Effects on agricultural development
>3°C (+20% rainfall)	Water resources in Kazakhstan	– Change in runoff	– Increase in winter floods – Decrease in summer flows	– Risk to life and property – Summer water stress
~2°C (-5 to 10% rainfall; 45-cm sea-level rise)	Bangladesh lowlands	– About 23–29% increase in extent of inundation	– Change in flood depth category – Change in monsoon rice cropping pattern	– Risk to life and property – Increased health problems – Reduction in rice yield

Rapid demographic transition accompanying significant economic growth is likely in many Asian countries in the 21st century. These trends exacerbate pressures on resource use, the climate system, and the natural environment. Population growth and varying economic and technological conditions in Asia are likely to affect some societies and resources more than changes in climate *per se*. Moreover, socioeconomic and technological developments will interact with many vulnerable sectors. However, predicting population growth rates and future economic conditions is as uncertain an exercise as predicting the future climate. Institutional and legal structures may change and will co-evolve with climatic risks. GHG emission scenarios are especially important, but future emission trends will depend on population growth and prevailing economic and technological conditions. There have been limited studies that simultaneously take into account climate change and other human-induced stresses. For vulnerability and adaptation to be addressed comprehensively, they must be considered in a context of multiple stresses caused by climate change and other anthropogenic activities.

Table 11-11 summarizes the vulnerability of key sectors, from food and fiber through settlements, for subregions of Asia. This summary is derived from a synthesis of available scientific research reviewed in this chapter; it represents a consensus view of the authors. Levels of confidence assigned to vulnerability also are shown in Table 11-11, again based on iterative assessment of the available scientific evidence. Currently available research synthesized in this table reveals a wide range of vulnerability, as well as a wide range of uncertainties in the assessment of these vulnerabilities. Geographical resolution as well as integration and scaling of basic physical and biological responses are the key factors contributing to these uncertainties. The limited database also makes it difficult to aggregate various responses with only a few sample or spot assessments. Nevertheless, some key trends emerge from the synthesis. A consistent message is the vulnerability of south and southeast Asia across many sectors, as well as a high degree of confidence about this assertion.

Across virtually all subregions, water resources and natural ecosystems are appraised as highly vulnerable to climate change, although the level of confidence varies for some regions because of lack of data or greater complexity in the resource systems. There may be some minor benefits to boreal Asia, making it more resilient to potential impacts, but natural ecosystems clearly are under threat in this subregion.

11.4.2. Future Needs

The early signs of climate change already observed in some parts of Asia and elsewhere may become more prominent over the period of 1 or 2 decades. If this time is not used appropriately, it may be too late to avoid upheavals and significant human impacts for some nations. Climate change could lead either to cooperation or to conflict over the world's major resources. Integrated planning may be the greatest global challenge, now motivated by the potential for environmental and social transformation caused by climate change.

In the 21st century, Asian countries will have to produce more food and other agricultural commodities under conditions of diminishing per capita arable land and irrigation water resources and expanding biotic as well as abiotic stresses, including climatic constraints. The dual demands for food and ecological security would have to be based on appropriate use of biotechnology, information technology, and ecotechnology. Practical achievements in bringing about the desired paradigm shift in sustainable agriculture will depend on public policy support and political action. Critical areas for intervention would be:

- Improving the availability of seed/planting material of high-yielding varieties
- Developing and promoting the use of hybrids, especially for rainfed agro-ecosystems
- Expanding areas under different crops and commodities, through diversification of agriculture

Table 11-II: Vulnerability of key sectors to impacts of climate change for select subregions in Asia. Vulnerability scale is as follows: highly vulnerable (-2), moderately vulnerable (-1), slightly or not vulnerable (0), slightly resilient (+1), and most resilient (+2). Confidence levels abbreviated to VH (very high), H (high), M (medium), L (low), and VL (very low).

Regions	Food and Fiber	Biodiversity	Water Resources	Coastal Ecosystems	Human Health	Settlements
Boreal Asia	+1 / H	-2 / M	+1 / M	+1 / L	-1 / L	0 / M
Arid and Semi-Arid Asia						
– Central Asia	-2 / H	-1 / L	-2 / H	-1 / L	-1 / M	-1 / M
– Tibetan Plateau	0 / L	-2 / M	-1 / L	Not applicable	No information	No information
Temperate Asia	-2 / H	-1 / M	-2 / H	-2 / H	-2 / M	-2 / H
Tropical Asia						
– South Asia	-2 / H	-2 / M	-2 / H	-2 / H	-1 / M	-2 / M
– Southeast Asia	-2 / H	-2 / M	-2 / H	-2 / H	-1 / M	-2 / M

- Improving the productivity of crops, existing plantations, and livestock
- Developing infrastructure for post-harvest management, marketing, and agribusiness
- Small farm mechanisms
- Transfer of technological inputs through assessments and refinements at regular time intervals in consonance with our understanding of climate variability and climate change.

Ensuring food security may remain an unaccomplished dream for many Asian countries unless appropriate strategies are put in place to ensure environmental and ecological protection and conservation of natural resources.

The food security issue is highly dependent on equitable guaranteed access to foods. Equitable access is highly differentiated across populations in the agrarian nations of Asia. This situation is further aggravated by natural disasters such as floods and droughts, which are known to have caused great famines in south Asian countries. Poverty in many south Asian countries seems to be the cause of not only hunger but even lack of shelter, access to clean drinking water, illiteracy, ill health, and other forms of human deprivation. Opportunities for assured and remunerative marketing at microenterprise levels should promote equitable use of available food resources.

In view of present uncertainties over the pace and magnitude of climate change, the most promising policy options are those for which benefits accrue even if no climate change takes place. Such policy actions include the following:

- Breeding of new crop varieties and species (heat- and salt-tolerant crops, low-water-use crops)
- Maintenance of seed banks, liberalization of trade of agricultural commodities, flexibility of commodity support programs, agricultural drought management
- Promotion of efficiency of irrigation and water use and dissemination of conservation management practices
- Trans-national cooperation to promote sustainable water resources management and flood risk management
- Rehabilitation of degraded forests and watersheds (such strategies can enhance biodiversity conservation and provide source of livelihood for many poor forest and upland watershed dwellers)
- Strengthening of biophysical and socioeconomic resources and resource use-related databases for natural and social systems and focused research to further our understanding of the climate-ecosystem-social system interaction. Data and information generated through these activities will be useful not only for designing appropriate mitigation and adaptation measures but also for management planning and decisionmaking.

The climate change issue has presented decisionmakers in Asian countries with a set of formidable complications: a considerable number of uncertainties (which are inherent in the complexity of the problem), the potential for irreversible

damages to ecosystems, a very long planning horizon, long time lags between GHG emissions and effects, wide regional variation in causes and effects, the global scope of the problem, and the need to consider multiple GHGs and aerosols. The value of better information about climate change processes and impacts and responses to arrest these risks is likely to be great. A prudent strategy to deal with climate change would be to collectively reduce emission levels of GHGs through a portfolio of actions aimed at mitigation and adaptation measures. The agriculture and forestry sectors in several countries of Asia have a large GHG mitigation potential that should make a significant contribution to this strategy.

The principle of sustainable development must guide all future development strategies in developing and developed countries of Asia. Serious efforts toward promoting innovative research on efficient technology options and creative environmental literacy are needed while Asian countries adapt to new environmental policies and programs. The challenge lies in identifying opportunities that would facilitate sustainable development by making use of existing technologies and developing policies that make climate-sensitive sectors resilient to climate variability. This strategy will require developing countries in Asia to have more access to appropriate technologies, information, and adequate financing. In addition, adaptation will require anticipation and planning; failure to prepare systems for projected change in climate means, variability, and extremes could lead to capital-intensive development of infrastructures or technologies that are ill-suited to future conditions, as well as missed opportunities to lower the cost of adaptation.

EXECUTIVE SUMMARY

The Australia and New Zealand Region: This region spans the tropics to mid-latitudes and has varied climates and ecosystems, including deserts, rainforests, coral reefs, and alpine areas. The climate is strongly influenced by the surrounding oceans. The El Niño-Southern Oscillation (ENSO) phenomenon leads to floods and prolonged droughts, especially in eastern Australia and parts of New Zealand. The region therefore is sensitive to the possible changes toward a more El Niño-like mean state suggested by Working Group I. Extreme events are a major source of current climate impacts, and changes in extreme events are expected to dominate impacts of climate change. Return periods for heavy rains, floods, and storm surges of a given magnitude at particular locations would be modified by possible increases in intensity of tropical cyclones, mid-latitude storms, and heavy rain events (medium confidence) and changes in the location-specific frequency of tropical cyclones (low to medium confidence). Scenarios of climate change based on recent coupled atmosphere-ocean climate models suggest that large areas of mainland Australia will experience significant decreases in rainfall during the 21st century (low to medium confidence).

Before stabilization of greenhouse gas (GHG) concentrations, the north-south temperature gradient in mid-southern latitudes is expected to increase (medium to high confidence), strengthening the westerlies and the associated west-to-east gradient of rainfall across Tasmania and New Zealand. Following stabilization of GHG concentrations, these trends would be reversed (medium confidence).

Water Supply and Hydrology: In some areas, water resources already are stressed and are highly vulnerable, with intense competition for water supply. This is especially so with respect to salinization (parts of Australia) and competition for water between agriculture, power generation, urban areas, and environmental flows (high confidence). Increased evaporation and possible decreases of rainfall in many areas would adversely affect water supply, agriculture, and the survival and reproduction of key species in parts of Australia and New Zealand (medium confidence).

Ecosystems and Conservation: Warming of 1°C would threaten the survival of species currently growing near the upper limit of their temperature range, notably in some Australian alpine regions that already are near these limits, as well as in the southwest of western Australia. Other species that have restricted climatic niches and are unable to migrate because of fragmentation of the landscape, soil differences, or topography could become endangered or extinct. Other ecosystems that are

particularly threatened by climate change include coral reefs (Australia) and freshwater wetlands in the coastal zone and inland.

Food and Fiber: Agricultural activities are particularly vulnerable to regional reductions in rainfall in southwest and inland Australia (medium confidence) and eastern New Zealand. Drought frequency and consequent stresses on agriculture are likely to increase in parts of Australia and New Zealand as a result of higher temperatures and possibly more frequent El Niños (medium confidence). Enhanced plant growth and water-use efficiency (WUE) resulting from carbon dioxide (CO_2) increases may provide initial benefits that offset any negative impacts from climate change (medium confidence), although the balance is expected to become negative with warmings in excess of 2–4°C and associated rainfall decreases (medium confidence). Reliance on exports of agricultural and forest products makes the region sensitive to changes in commodity prices induced by changes in climate elsewhere.

Australian and New Zealand fisheries are influenced by the extent and location of nutrient upwellings governed by prevailing winds and boundary currents. In addition, ENSO influences recruitment of some fish species and the incidence of toxic algal blooms. There is as yet insufficient knowledge about impacts of climate changes on regional ocean currents and about physical-biological linkages to enable confident predictions of changes in fisheries productivity.

Settlements, Industry, and Human Health: Marked trends to greater population and investment in exposed coastal regions are increasing vulnerability to tropical cyclones and storm surges. Thus, projected increases in tropical cyclone intensity and possible changes in their location-specific frequency, along with sea-level rise, would have major impacts—notably, increased storm-surge heights for a given return period (medium to high confidence). Increased frequency of high-intensity rainfall would increase flood damages to settlements and infrastructure (medium confidence). There is high confidence that projected climate changes will enhance the spread of some disease vectors, thereby increasing the potential for disease outbreaks, despite existing biosecurity and health services.

Vulnerability and Adaptation: Climate change will add to existing stresses on achievement of sustainable land use and conservation of terrestrial and aquatic biodiversity. These stresses include invasion by exotic animal and plant species, degradation and fragmentation of natural ecosystems through agricultural and urban development, dryland salinization

(Australia), removal of forest cover (Australia and New Zealand), and competition for scarce water resources. Within both countries there are economically and socially disadvantaged groups of people, especially indigenous peoples, that are particularly vulnerable to additional stresses on health and living conditions induced by climate change. Major exacerbating problems include rapid population and infrastructure growth in vulnerable coastal areas, inappropriate use of water resources, and complex institutional arrangements. Adaptation to climate change, as a means of maximizing gains and minimizing losses, is important for Australia and New Zealand but is relatively little explored. Options include improving water-use efficiency and effective trading mechanisms for water; more appropriate land-use policies; provision of climate information and seasonal forecasts to land users, to help them manage for climate variability and change; improved crop cultivars; revised engineering standards and zoning for infrastructure development; and improved biosecurity and health services. Such measures often will have other benefits, but they also may have costs and limits.

Integrated Assessments: Comprehensive cross-sectoral estimates of net climate change impact costs for various GHG emission scenarios, as well as for different societal scenarios, are not yet available. Confidence remains very low in the previously reported (Basher *et al.*, 1998) estimate for Australia and New Zealand of -1.2 to -3.8% of gross domestic product for an equivalent doubling of CO₂ concentrations. This out-of-date estimate did not account for many currently identified effects and adaptations.

Summary: Australia has significant vulnerability to changes in temperature and precipitation projected for the next 50–100 years (very high confidence) because it already has extensive arid and semi-arid areas and lies largely in the tropics and subtropics. New Zealand, a smaller and more mountainous country with a generally more temperate maritime climate, may be more resilient to climate changes than Australia, although considerable regional vulnerability remains (medium confidence).

12.1. The Australasian Region

12.1.1. Overview

Australasia is defined here as Australia, New Zealand, and their outlying tropical and mid-latitude islands. Australia is a large, relatively flat continent reaching from the tropics to mid-latitudes, with relatively nutrient-poor soils, a very arid interior, and rainfall that varies substantially on seasonal, annual, and decadal time scales, whereas New Zealand is much smaller, mountainous, and mostly well-watered. The ecosystems of both countries contain a large proportion of endemic species, reflecting their long evolutionary history and isolation from other land masses. They have been subject to significant human influences, before and after European settlement 200 years ago.

The region's climate is strongly influenced by the surrounding oceans. Key climatic features include tropical cyclones and monsoons in northern Australia; migratory mid-latitude storm systems in the south, including New Zealand; and the ENSO phenomenon, which causes floods and prolonged droughts, especially in eastern Australia.

The total land area is 8 million km², and the population is approximately 22 million. Much of the region is very sparsely populated; most people (85%) live in a relatively small number of coastal cities and towns. Both countries have significant populations of indigenous peoples who generally have lower economic and health status. The two countries have developed economies and are members of the Organisation for Economic Cooperation and Development (OECD); unlike other OECD countries, however, their export trade is dominated by commodity-based industries of agriculture and mining.

12.1.2. Previous Work

The Australasian chapter (Basher *et al.*, 1998) of the IPCC *Special Report on Regional Impacts of Climate Change* (RICC) (IPCC, 1998) provides an extensive assessment of likely climate change impacts and adaptation options for Australia and New Zealand, based on work published until early 1998. That report concludes that Australia's relatively low latitude makes it particularly vulnerable through impacts on its scarce water resources and crops that presently are growing near or above their optimum temperatures, whereas New Zealand—a cooler, wetter, mid-latitude country—may gain some benefit from the ready availability of suitable crops and a likely increase in agricultural production with regional warming. Nevertheless, a wide range of situations in which vulnerability was thought to be moderate to high were identified for both countries—particularly for ecosystems, hydrology, coastal zones, settlements and industry, and health. Indirect local impacts from possible climatically driven changes in international conditions—notably commodity prices and international trade—also was identified as a major issue in the 1998 report, as well as by the New Zealand Climate Change Programme (1990). Key points from Basher *et al.* (1998) follow.

Climate and Climate Trends: Climate trends were reported to be consistent with those in other parts of the world, with mean temperature increases of as much as 0.1°C per decade over the past century, a faster increase in nighttime than daytime temperatures, and sea level rising an average of about 20 mm per decade over the past 50 years. Increases in average rainfall and the frequency of heavy rainfalls were reported for large areas of Australia.

Climate Scenarios: Australian scenarios reported for 2030 exhibited temperature increases of 0.3–1.4°C, uncertain overall rainfall decrease of as much as 10%, and more high-intensity rainfall events. Projected changes for 2070 were about twice the 2030 changes. New Zealand projections included similar temperature increases, as well as stronger westerly air flow, with resulting precipitation increases in the west and decreases in the east.

Water Supply and Hydrology: Possible overall reduction in runoff, with changes in soil moisture and runoff varying considerably from place to place but reaching as much as ±20%, was suggested for parts of Australia by 2030. Sharpened competition was expected among water users, with the large Murray-Darling Basin river system facing strong constraints. Enhanced groundwater recharge and dam-filling events were expected from more frequent high-rainfall events, which also were expected to increase flooding, landslides, and erosion. A reduced snow season was expected to decrease the viability of the ski industry, although it would provide seasonally smoother hydroelectricity generation in New Zealand.

Ecosystems and Conservation: Significant potential impacts identified on Australasian land-based ecosystems included alteration in soil characteristics, water and nutrient cycling, plant productivity, species interactions, and ecosystem composition and function, exacerbated by any increases in fire occurrence and insect outbreaks. Aquatic systems would be affected by changes in runoff, river flow, and associated transport of nutrients, wastes, and sediments. These changes and sea-level rise would affect estuaries and mangroves. Australia's coral reefs were considered to be vulnerable to temperature-induced bleaching and possibly to sea-level rise and weather change.

Food and Fiber: Direct impacts on agriculture from CO₂ increases and climate changes were expected to vary widely in space and time, with perhaps beneficial effects early in the 21st century, followed by more detrimental effects in parts of Australia as warming increases. Any changes in global production and hence international food commodity prices would have major economic impacts. The net impact on production forestry from changes in tree productivity, forest operational conditions, weeds, disease, and wildfire incidence was not clear. The impact on fisheries could not be confidently predicted.

Settlements and Industry: Possible changes were noted in the frequency and magnitude of climatic “natural disaster” events affecting economically important infrastructure. Likely impacts of climate change were identified on water and air quality,

water supply and drainage, waste disposal, energy production, transport operations, insurance, and tourism.

Human Health: Increases were expected in heat-stress mortality (particularly in Australia), the incidence of tropical vector-borne diseases such as dengue, and urban pollution-related respiratory problems.

Adaptation Potential and Vulnerability: Some of the region's ecosystems were identified as very vulnerable, with fragmentation and alteration of landscape by urban and agricultural development limiting natural adaptability. Land-use management was the primary adaptation option identified. Although coral reefs were identified as vulnerable, it was suggested that they might be able to keep pace with sea-level rise.

Techniques that already provide considerable adaptability of agriculture to existing climate variability may apply to climate change over the next few decades. However, at longer time horizons the climate was expected to become less favorable to agricultural production in Australia, leading to increased vulnerability. Scientifically based integrated fisheries and coastal zone management were regarded as principal adaptation options for fisheries.

Adaptation options identified for settlements and infrastructure included integrated catchment management, changes to water pricing systems, water efficiency initiatives, building or modifying engineering structures, relocation of buildings, and urban planning and management. Low-lying coastal settlements were regarded as highly vulnerable to high sea level and storm events. Adaptation options included integrated coastal zone management (ICZM); redesign, rebuilding, or relocation of capital assets; and protection of beaches and dunes. New Zealand is exposed to impacts on its Pacific island territories, including the eventual possibility of having to accept environmental refugees.

A moderate degree of vulnerability was identified for human health, with adaptation responses including strengthening existing public health infrastructure and meeting the needs of vulnerable groups such as isolated communities and the poor.

12.1.3. Socioeconomic Trends

The region's population is growing at a rate of about 1.2% yr⁻¹, approximately equally from natural increase and immigration. The population is progressively aging, in line with other OECD countries. Health status is improving, but indigenous peoples lag significantly. The main population centers are growing faster than rural areas. Australian lower latitude coastal zones are developing two to three times faster than the Australian average (see Section 12.6.4), for urban/suburban uses and for recreation and tourism. In New Zealand, there is a steady internal migration northward to Auckland.

Agricultural commodity prices have tended to fall, but yields per hectare have risen, and farm sizes and total volume of production

have increased (ABARE, 1997; Wilson and Johnson, 1997). Average return on agricultural assets is low. Service industries are an increasing fraction of all industry, and there is a trend toward more intensive agriculture and forestry and to diversification of rural land use, including specialty crops and tourism. There is increasing competition for water in areas of low rainfall where irrigation is essential to intensive cropping; urban demands are rising quickly, and water is needed to maintain natural ecosystems (Hassall and Associates, *et al.*, 1998). Tourism is a major growth industry that is increasing the pressure on areas of attractions such as coastal zones and reefs.

Environmental concerns include air and water pollution from urban industries, land transport, and intensive farming and related processing and soil erosion, rising water tables, and salinization. Environmental management increasingly is based on the principle of sustainable management, as enshrined in New Zealand's Resource Management Act, and an integrated approach to environmental impacts in both countries. A major trend to a "user pays" principle and, especially in Australia, to market-driven water rights, with caps on irrigation supplies, is causing significant changes in rural industry. However, there still are many instances, particularly in coastal management, where these principles are not applied.

12.1.4. Climate Trends

Trends identified in the region continue to be generally consistent with those elsewhere in the world. Research on regional trends has been summarized in Salinger *et al.* (1996) and in specific studies by Plummer (1996), Torok and Nicholls (1996), Holbrook and Bindoff (1997, 2000), Lavery *et al.* (1997), Plummer *et al.* (1997), Zheng *et al.* (1997), McKeon *et al.* (1998), Collins and Della-Marta (1999), Hennessy *et al.* (1999), and Plummer *et al.* (1999).

Mean temperatures have risen by 0.05–0.1°C per decade over the past century, with a commensurate increase in the frequency of very warm days and a decrease in the frequency of frosts and very cold days (Plummer *et al.*, 1999; Collins *et al.*, 2000). Nighttime temperatures have risen faster than daytime temperatures; hence, the diurnal temperature range has decreased noticeably in most places. The past decade has seen the highest recorded mean annual temperatures.

Trends in rainfall are less clear. Australian annual mean rainfall has increased by a marginally significant amount over the past century (Collins and Della-Marta, 1999; Hennessy *et al.*, 1999). However, increases in the frequency of heavy rainfalls and average rainfall are significant in many parts of Australia. Average rainfall has increased most in the northwest and southeast quadrants (Collins and Della-Marta, 1999). The largest and most statistically significant change has been a decline in rainfall in the winter-rainfall-dominated region of the far southwest of western Australia, where in the period 1910–1995, winter (June-July-August, JJA) rainfall declined by 25%, mainly during the 1960s and 1970s. Previous studies (Wright, 1974;

Allan and Haylock, 1993; Yu and Neil, 1993), as well as a more recent one (Smith *et al.*, 2000), have noted this decrease and attribute it to atmospheric circulation changes, predominantly resulting from natural variability.

There are marked interdecadal variations over northern and eastern Australia in summer half-year rainfall, which are dominated by ENSO-induced variations (Power *et al.*, 1999a). There also are clear interannual and decadal variations in central and eastern Australian rainfall associated with Indian and

Pacific Ocean sea surface temperatures (SSTs) (Power *et al.*, 1999b). Some of the regional linear trends observed during the past century merely may reflect a particular pattern of decadal variation. Thus, the high degree of decadal variability may enhance or obscure a signal that is related to climatic change for several decades. A growing body of evidence is being obtained about past climate variability from coral cores (e.g., Lough and Barnes, 1997; Isdale *et al.*, 1998; Quinn *et al.*, 1998).

The strength of the relationship between eastern Australian climate and ENSO has been observed to vary over the past century. This seems to be linked to longer term climate oscillations such as the North Pacific Decadal Oscillation (NPDO) (e.g., Power *et al.*, 1999a). Salinger and Mullan (1999) examined the 20-year periods before and after 1977 and showed increases after 1977 (some statistically significant) in mean rainfall for New Zealand's west coast, associated with strengthening westerly winds. These fluctuations in rainfall are partially explained by the increase in El Niño conditions over recent decades. There is some evidence of long-term variations in the Australasian region in storm frequency and tropical cyclones (Nicholls *et al.*, 1996a; Radford *et al.*, 1996; Hopkins and Holland, 1997; Leighton *et al.*, 1997). Nicholls *et al.* (1998) show that although there has been a decrease in tropical cyclone numbers from 1969 to 1996 in the Australian region (105°E to 160°E), there has been an increase in the frequency of intense tropical cyclones with central pressures of less than 970 hPa.

The average rise in sea level in the Australia/New Zealand region over the past 50 years is about 20 mm per decade (Rintoul *et al.*, 1996; Salinger *et al.*, 1996), which is within the range of the current estimate of global sea-level rise (IPCC, 1996, WGI Section 7.2.1). However, the greater frequency and duration of El Niño episodes since the mid-1970s has reduced local New Zealand sea-level trends: The average sea-level change since 1975 at Auckland is close to zero (Bell *et al.*, 1999). There has been a weak warming trend in ocean temperatures to 100-m depth in the southwest Pacific (39°S to 49°S , 141°E to 179°E) of about 0.13°C during the 34-year period 1955–1988 (Holbrook and Bindoff, 1997), and there have been shorter period SST fluctuations associated with ENSO.

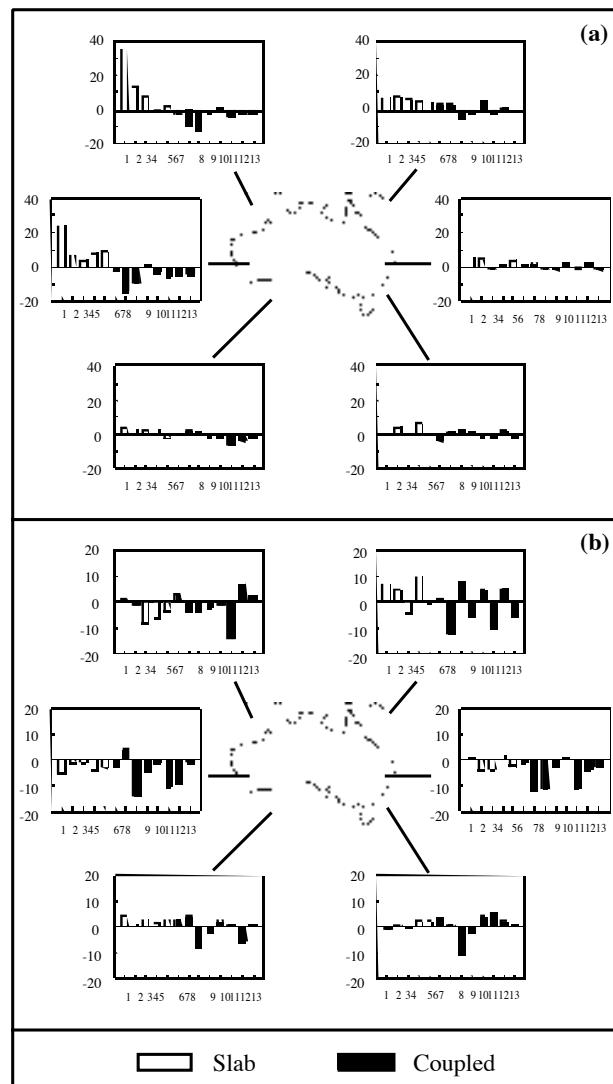

Figure 12-1: Enhanced greenhouse changes in rainfall (as % change per $^{\circ}\text{C}$ of global warming) for five slab-ocean GCM simulations (open bars) and eight coupled ocean-atmosphere GCM simulations (full bars), for six subregions of Australia in (a) summer (DJF) and (b) winter (JJA). Source: Whetton *et al.*, 2001 (where individual models are identified). Spatial patterns and scatter plots are given for most of the same coupled models in Hulme and Sheard (1999) and Carter *et al.* (2000).

12.1.5. Climate Scenarios Used in Regional Studies

12.1.5.1. Spatial Patterns of Temperature and Rainfall

Most recent impact studies for Australia and New Zealand have been based on scenarios released by the Commonwealth Scientific and Industrial Research Organisation (CSIRO, 1996a) or the National Institute of Water and Atmosphere (NIWA—Renwick *et al.*, 1998b). The CSIRO (1996a) scenarios included two sets of rainfall scenarios that are based on results from equilibrium slab-ocean general circulation model (GCM) and transient coupled ocean-atmosphere GCM (AOGCM) simulations. Some impact and adaptation studies since RICC have used results from a 140-year simulation over the whole region that uses the CSIRO regional climate model (RCM) at

125-km resolution nested in the CSIRO Mark 2 coupled GCM run in transient mode from 1961 to 2100, as well as similar simulations at 60-km resolution over eastern Australia. Figure 12-1 (from Whetton *et al.*, 2001) summarizes results of slab-ocean and coupled AOGCM simulations of rainfall changes for various subregions of Australia in summer (December-January-February, DJF) and winter (JJA), respectively.

Figures 12-1a and 12-1b clearly show a variety of estimates for different model simulations; nevertheless, there is a tendency toward more decreases in winter rainfall in the southwest and the central eastern coast of Australia in the coupled model results than in the slab-ocean model results and a similar tendency for more agreement between coupled model results on less rainfall in the northwest and central west in summer.

In line with WGI conclusions, more recent scenarios, such as those of Hulme and Sheard (1999) and Carter *et al.* (2000) rely exclusively on coupled models; they also are based on the newer emissions scenarios from the IPCC's *Special Report on Emissions Scenarios* (SRES) rather than the IS92 scenarios described in IPCC (1996). This leads to some changes in the regional scenarios. According to Whetton (1999), the CSIRO (1996a) scenarios give warmings of 0.3–1.4°C in 2030 and 0.6–3.8°C in 2070 relative to 1990, compared to estimates by Hulme and Sheard (1999) of 0.8–3.9°C by the 2050s and 1.0–5.9°C in the 2080s, relative to the 1961–1990 averages. As discussed by Whetton (1999), both sets of scenarios use results from several coupled models, but the use of the SRES emissions scenarios leads to greater warmings in Hulme and Sheard (1999) than those that are based on the IS92 emission scenarios in CSIRO (1996). Nevertheless, the Hulme and Sheard (1999) results are preliminary in that they use scaled results from non-SRES simulations, rather than actual GCM simulations with SRES emissions.

Rainfall scenarios that are based on the coupled model results in CSIRO (1996a) show decreases of 0–8% in 2030 and 0–20% in 2070, except in southern Victoria and Tasmania in winter and eastern Australia in summer, where rainfall changes by –4 to +4% in 2030 and –10 to +10% in 2070. The Hulme and Sheard (1999) scenarios suggest that annual precipitation averaged over either northern or southern Australia is likely to change by –25 to +5%. Larger decreases are indicated for the 2080s and for some specific locations (e.g., a 50% decrease in parts of the southwest of western Australia in winter). This last finding suggests that even though the rainfall decrease in this region in the late 20th century was almost certainly dominated by natural variability (Smith *et al.*, 2000), a decreasing trend resulting from the enhanced greenhouse effect may dominate in this region by the mid- to late 21st century.

It is important to note that changing from joint use of equilibrium slab-ocean GCM and transient coupled AOGCM results to exclusive reliance on coupled model results in the Australian scenarios leads to a marked narrowing of the uncertainty range in rainfall changes predicted for southern Australia, with a tendency to more negative changes on the mainland (see

Figure 12-1; Hulme and Sheard, 1999; Carter *et al.*, 2000). This means that the results of impact studies that used the wider range of rainfall scenarios, as in the CSIRO (1996a) scenarios (e.g., Schreider *et al.*, 1996), should be reinterpreted to focus on the drier end of the previous range. This is consistent with more recent studies by Kothavala (1999) and Arnell (1999).

To summarize the rainfall results, drier conditions are anticipated for most of Australia over the 21st century. However, consistent with conclusions in WGI, an increase in heavy rainfall also is projected, even in regions with small decreases in mean rainfall. This is a result of a shift in the frequency distribution of daily rainfall toward fewer light and moderate events and more heavy events. This could lead to more droughts and more floods.

Recent Australian impact studies have tended to use regional scenarios of temperature and rainfall changes per degree of global warming, based on the CSIRO RCM transient simulations, scaled to the range of uncertainty of the global warming derived from the IPCC Second Assessment Report (SAR) range of scenarios. For example, Hennessy *et al.* (1998) gives scenarios for six regions of New South Wales (NSW), based on a 60-km resolution simulation. Ranges are given for estimated changes in maximum and minimum temperatures, summer days over 35°C, winter days below 0°C, seasonal mean rainfall changes, and numbers of extremely wet or dry seasons per decade. Statistical downscaling (discussed in detail in Chapter 3) has not been used extensively in Australia apart from work by Charles *et al.* (1999) on the southwest of western Australia. It should be noted that in some cases, RCM results may change the sign of rainfall changes derived from coarser resolution GCMs, because of local topographic and other effects (Whetton *et al.*, 2001).

New Zealand scenarios reported in RICC (Basher *et al.*, 1998) are based on statistical downscaling from equilibrium GCM runs with CO₂ held constant at twice its present concentration. Renwick *et al.* (1998b, 2000) also have downscaled equilibrium GCM simulations over New Zealand, using a nested RCM.

A key factor in rainfall scenarios for New Zealand is the strength of the mid-latitude westerlies because of the strong orographic influence of the backbone mountain ranges lying across this flow (Wratt *et al.*, 1996). Earlier equilibrium slab-ocean GCM runs (applicable only long after stabilization of climate change) and the regional simulations obtained by downscaling them through statistical and nested modeling techniques predict a weakening of the westerlies across New Zealand, particularly in winter. As a result, downscaled equilibrium model runs predict that winter precipitation will remain constant or decrease slightly in the west but increase in Otago and Southland (Whetton *et al.*, 1996a; Renwick *et al.*, 2000). In contrast, transient coupled AOGCM runs suggest that over the next 100 years or more, the mean strength of the westerlies actually will increase in the New Zealand region, particularly in winter (Whetton *et al.*, 1996a; Russell and Rind, 1999; Mpelasoka *et al.*, 2001). As a result, downscaled transient model results predict that rainfalls will increase in the west of New Zealand but decrease

in the east (Mullan *et al.*, 2001) as shown in Figure 12-2. Slightly larger temperature increases are predicted in the north of the country than in the south. Projected temporal changes in the westerlies before and after stabilization of climate also are likely to influence rainfall in southern Australia, especially in Tasmania.

GCM simulations extending beyond the stabilization of GHG concentrations indicate that global warming continues for centuries after stabilization of concentrations (Wigley, 1995; Whetton *et al.*, 1998; TAR WGI Chapters 9 and 11) but at a much reduced rate as the oceans gradually catch up with the stabilized radiative forcing. Importantly for the Australasian region, simulated patterns of warming and rainfall changes in the southern hemisphere change dramatically after stabilization of GHG concentrations. This is because of a reversal of the lag in warming of the Southern Ocean relative to the rest of the globe. This lag increases up to stabilization but decreases after stabilization (Whetton *et al.*, 1998), with consequent reversal of changes in the north-south temperature gradient, the mid-latitude westerlies, and associated rainfall patterns.

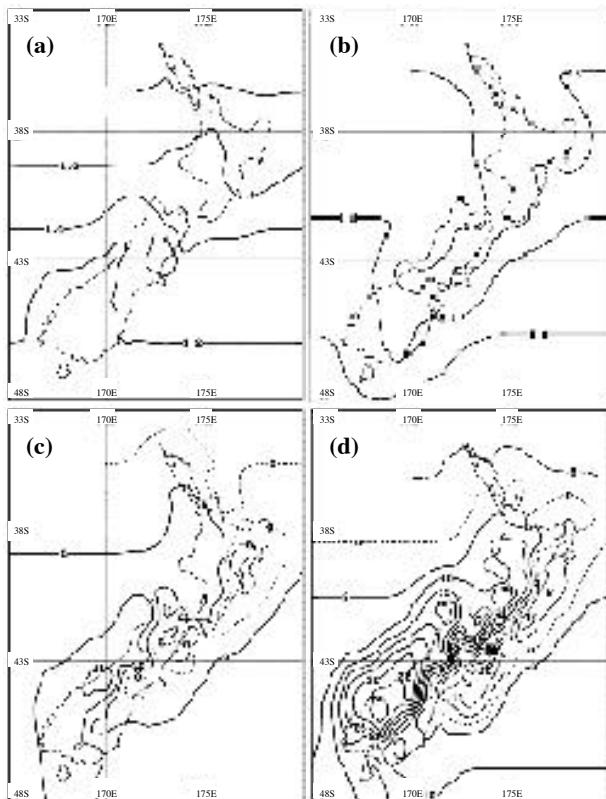

Figure 12-2: Scenarios for changes from the 1980s to the 2080s for New Zealand: (a) mean summer (DJF) temperature ($^{\circ}\text{C}$), (b) mean winter (JJA) temperature ($^{\circ}\text{C}$), (c) summer precipitation (%), and (d) winter precipitation (%). These plots were derived by averaging downscaled projections from four GCMs (CCC, CCSR, CSIRO9, and HadCM2) driven by CO_2 concentrations increasing at a compound rate of $1\% \text{ yr}^{-1}$, plus specified sulfate aerosol concentrations (Mullan *et al.*, 2001).

12.1.5.2. Uncertainties and Probabilistic Scenarios

Some of the Australasian scenarios include uncertainty bands, based on the ranges of global warmings resulting from the IPCC IS92 emissions scenarios, the IPCC range of global sensitivity, or ranges of estimates of Australasian temperature or rainfall changes from different GCMs. Unquantified additional sources of uncertainty include changes in emission scenarios, such as to the new SRES scenarios; regional effects of biospheric feedback; and regional effects of global aerosol distributions. Quantification of potential changes in extreme events, tropical cyclones, and ENSO also are major uncertainties (see below), and uncertainty about the strength of the westerly circulation and hence rainfall regimes is a source of uncertainty for New Zealand. The modeled lag in warming in the Southern Ocean in the 20th century appears to be greater than that observed (Whetton *et al.*, 1996a), but this has not yet been thoroughly analyzed. Other conceivable lower probability, high-impact changes (see Chapter 3) such as changes in ocean circulation, ENSO behavior, or tropical cyclones could have important regional impacts.

Probabilistic scenarios for risk and adaptation analyses (see Section 12.8.4), based on the quantifiable range of uncertainties, have been explored by CSIRO (Pittock, 1999; Jones, 2000; Pittock and Jones, 2000).

12.1.5.3. Changes in Extreme Events and Sea Level

Pittock *et al.* (1999) have summarized the past importance of extreme events for Australia and prospects for the future. Major climatic hazards arise in Australia and New Zealand from tropical cyclones, floods, droughts, windstorm, snowstorm, wildfires, landslides, hail, lightning, heat waves, frost, and storm surges. Events that are directly related to temperature are more predictable (more heat waves, fewer frosts) than those associated with wind and rain; Chapter 3 discusses relevant projections and confidence levels (see Table 3-10). The incidence of wildfire in Australia is expected to increase with global warming (Beer and Williams, 1995; Pittock *et al.*, 1999; Williams *et al.*, 2001), as is that of landslides and storm surges (the latter because of both higher mean sea level and increased storm intensities). Changes in hail and lightning frequencies are uncertain, although there are some arguments for expected increases (Price and Rind, 1994; McMaster, 1999; Pittock *et al.*, 1999).

More intense tropical cyclones in the Australian region (see Table 3-10; Walsh and Ryan, 2000) would have serious implications for storm-surge heights, wind damages, and flooding. If they were to travel further poleward (Walsh and Katzfey, 2000), they would be more likely to impact on coastal regions in the southwest of western Australia, southern Queensland, and the northern NSW coastal region, as well as northern parts of New Zealand. The locations of tropical cyclone genesis in the region are correlated with ENSO (Evans and Allan, 1992; Basher and Zheng, 1995), so any change in

the mean state of the tropical Pacific may affect the risk of tropical cyclone occurrence in particular locations.

Mid-latitude storms also may increase in intensity (see Table 3-10), and their frequency and location could change—for example, as a result of changes in the westerlies and ENSO. This would impact return periods for mid-latitude storm surges, high winds, and other phenomena.

Interannual variability in ENSO leads to major floods and droughts in Australia and New Zealand. Such variations are expected to continue under enhanced greenhouse conditions, though possibly with greater hydrological extremes as a result of more intense rainfall in La Niña years and more intense drought resulting from higher rates of evaporation during El Niño years (Walsh *et al.*, 1999). A more El Niño-like mean state of the tropical Pacific Ocean (see Table 3-10; Cai and Whetton, 2000) would imply greater drought frequency (Kothaval, 1999; Walsh *et al.*, 2000), as does the drying trend found over the Murray-Darling Basin in recent AOGCM simulations (Arnell, 1999).

Mean sea level is expected to increase, with local and regional variations as a result of land-sea movements and changes to ocean currents and climatic forcing (see Chapter 3). In addition, local and regional meteorological forcing leads to temporary fluctuations in sea level and extreme events that may cause coastal inundation. In New Zealand, storm surges of as much as about 1 m are possible at open-coast locations (Heath, 1979; Bell *et al.*, 1999). Storm surges in tropical Australia can be several meters as a result of tropical cyclonic forcing and shallow continental shelves (Hubbert and McInnes, 1999a,b; McInnes *et al.*, 1999).

The actual height reached by a storm surge depends not only on the location and intensity of the storm but on its timing relative to the tides, coastal bathymetry and topography, and slower variations such as those from ENSO. The latter contribute to significant local sea-level variations around the coasts of Australia (Chiera *et al.*, 1997) and New Zealand (Bell *et al.*, 1999). In addition, any changes in storm intensities, frequencies, and locations will change the average time between surges of a given magnitude at particular locations.

12.1.5.4 New SRES Scenarios

Interim characterizations of regional climate changes to 2100 associated with the SRES emissions scenarios have been provided by Hulme and Sheard (1999) and Carter *et al.* (2000). However, they do not consider aerosol-induced spatial effects, and they use linear scaling of regional patterns of change from seven coupled GCM models, according to a range of global mean warmings generated using MAGICC (Wigley, 1995; Wigley *et al.*, 1997).

Over Australia, these studies show warmings in the 2080s higher than the IS92 scenarios, with similar spatial patterns. In New Zealand, warmings in the 2080s are estimated to be from

0.5 to >2.0°C. Projected precipitation changes are large (>1 standard deviation of the simulated 30-year variability) over much of southern Australia, with a decrease over the mainland in both summer and winter and an increase over Tasmania in winter. Over the South Island of New Zealand, an increase is predicted. For the 2080s, projected decreases in annual rainfall in the southwest of western Australia range from about zero (B1 low scenario) to between 30 and 50% (A2 high scenario). Projected rainfall increases over the South Island of New Zealand of 0–10% (B1) to 10–20% (A2) should be regarded with caution because the AOGCM simulations do not fully incorporate the important influence of the Southern Alps on South Island rainfall patterns.

The SRES scenarios have not yet been applied in any detailed studies of impacts in the region. Unlike parts of the northern hemisphere, high regional concentrations of sulfate aerosols are not expected in the Australasian region under any accepted scenario, so any increase in warming resulting from reduced sulfate aerosols will be less over Australia and New Zealand than in some regions of the northern hemisphere.

To date, impact and vulnerability studies in Australia and New Zealand in general have not taken account of specific socioeconomic scenarios for the future, such as those laid out in the SRES. Thus, vulnerabilities have been based on projected climate change impacts and adaptation, assuming the present socioeconomic situation, in some cases with a qualitative allowance for expected socioeconomic trends (e.g., increased competition for water supplies, increased population and investment in coastal zones).

12.2. Key Regional Concerns

This section summarizes some key regional concerns regarding vulnerability to climate change and impacts in Australia and New Zealand. They have not been prioritized. Supporting details and references are provided in Sections 12.3 through 12.8.

Drought, Flood, and Water Supply: Climate variability is a major factor in the economies of both countries, principally through the flow-on effects of ENSO-related major droughts on agriculture. Farmers in drought-sensitive parts of both countries will be increasingly vulnerable if interannual droughts occur more frequently or are more intense in the future. Less secure water supplies would accentuate competition between users and threaten allocations for environmental flows and future economic growth. Adelaide and Perth are the main cities with water supplies that are most vulnerable to climate change; increasing salinity in the Murray River is an increasing concern for Adelaide. Any increase in flood frequency would adversely affect the built environment. In New Zealand, floods and landslides are natural hazards that could increase in frequency and severity.

Ecosystem Uniqueness and Vulnerability: Australia and New Zealand have been isolated from the rest of the world for millions

of years until relatively recent human settlement. Some species exhibit quite limited ranges of average climate. These two factors leave many of the region's ecosystems vulnerable to climatic change and to invasion by exotic animal and plant species introduced by human activity. This vulnerability has been exacerbated by fragmentation of ecosystems through land-use changes.

Coral Reefs: Australia has one of the greatest concentrations of coral reefs in the world. Rising sea level by itself may not be deleterious. However, the combination of sea-level rise with other induced stresses—notably, increasing atmospheric CO₂ (which leads to a decrease in calcification rates of corals); increasing sea temperatures, leading to coral bleaching; possibly increased riverine outflow events (low salinity and high pollution); and damage from tropical cyclones—may put much of this resource at risk.

Alpine Areas: In Australia, significant warming will raise snowlines, diminish the ski industry, and threaten alpine ecosystems. In New Zealand, snowline changes and the advance or retreat of glaciers also depend on changes in the strength and local orientation of mid-latitude westerlies. Options for relocation of the ski industry are limited by the relatively low altitude of Australia's alpine regions and by rugged terrain and conservation estate regulations in New Zealand.

Agricultural Commodities and Terms of Trade: A major fraction of exports from both Australia and New Zealand are agricultural and forestry products, production of which is sensitive to any changes in climate, water availability, CO₂ fertilization, and pests and diseases. Returns from these commodities could be affected by the projected increase in agricultural production in mid- to high-latitude northern hemisphere countries and resulting impacts on commodity prices and world trade.

Increasing Coastal and Tropical Exposure: Major population and economic growth in coastal areas, especially the tropical and subtropical east coast of Australia, are leading to greatly increased vulnerability to tropical cyclones and storm surges, as well as riverine and estuarine flooding. Rising sea level will accentuate these problems, as would any increase in storm intensities or a more poleward movement of tropical cyclones. Rising sea level also will increase the salinity of estuarine and coastal aquifer groundwater.

Indigenous People: In both countries, indigenous peoples (Aborigines and Torres Straits Islanders in Australia, Maori in New Zealand, as well as Pacific islanders) are among the most disadvantaged members of the population. They generally have lower incomes, and many live in isolated rural conditions or in the sometimes poorly serviced and low-lying margins of large towns and cities. They are more exposed to inadequate water supplies, climatic disasters, and thermal stress and are more vulnerable to an increase in the prevalence of pests and diseases.

12.3. Water Supply and Hydrology

12.3.1. Water Supply

Dry conditions in most parts of Australia tend to be associated with El Niño. The link between rainfall and streamflow and ENSO is statistically significant in most parts of eastern Australia (Chiew *et al.*, 1998; Power *et al.*, 1998). Relationships between river flows and ENSO also have been identified for some seasons in parts of New Zealand (McKerchar *et al.*, 1998). Because of the relatively high variability of Australian rainfall, the storage capacities of Australia's large dams are about six times larger than those of European dams for the same mean annual streamflow and probability of water shortfall. In contrast, New Zealand's hydroelectricity system has a total storage capacity of about 6 weeks of national demand because of its higher and more reliable rainfall (Basher *et al.*, 1998).

The Murray-Darling River basin is the largest in Australia and is heavily regulated by dams and weirs. About 40% of mean annual flow is used for human consumption, principally through irrigation; there is high interannual variability. Application of the CSIRO (1996a) scenarios, with their wide range of rainfall changes as a result of inclusion of both the older slab-ocean GCM and the more recent coupled AOGCM simulations, suggests a possible combination of small or larger decreases in mean annual rainfall, higher temperatures and evaporation, and a higher frequency of floods and droughts in northern Victorian rivers (Schreider *et al.*, 1996). A study of the Macquarie River basin in NSW indicates inflow reductions on the order of 10–30% for doubled CO₂ and reduced streamflows if irrigation demand remains constant or increases (Hassall and Associates *et al.*, 1998). Adelaide and Perth traditionally have been regarded as the most vulnerable metropolitan areas to future water supply problems, including increasing levels of salinity (Schofield *et al.*, 1988; Williams, 1992; PMSEIC, 1998; MDBC, 1999), although Perth recently has decided to spend AU\$275 million for drought-proofing (Boer, 2000). Water supplies are adequate for many coastal regions in Australia. However, drier inland areas are vulnerable to water shortages during the annual dry season and drought.

Studies by Kothavala (1999) and Arnell (1999)—using results from the U.S. National Center for Atmospheric Research (NCAR) Community Climate Model (CCMO) GCM and the HadCM2 and HadCM3 AOGCMs, respectively—show increases in drought across eastern and southern Australia. Kothavala found that the Palmer Drought Index showed longer and more severe drought in northeastern and southeastern Australia. Arnell (1999) found marked decreases in runoff over most of mainland Australia but some increases over Tasmania. For the Murray-Darling basin, he found decreases in mean flow by the 2050s ranging from about 12 to 35%, with decreases in the magnitude of 10-year maximum and minimum monthly runoff.

The only recent water supply study for New Zealand is that by Fowler (1999), based on the RSNZ (1988) and Mullan and Renwick (1990) regional climate change scenarios and three

equilibrium slab-ocean GCM simulations. These models give scenarios of rainfall increases in the Auckland region, leading to the conclusion that changes in water resources most likely would be positive. Scenarios based on recent AOGCM simulations have yet to be evaluated.

Atolls and low-lying islands (e.g., some in the Torres Strait and in association with New Zealand) rely on rainwater or limited groundwater resources for water supplies. These resources are sensitive to climate variations and in some cases already are stressed by increasingly unsustainable demand and pollution caused by human activity. Saltwater intrusion into aquifers might occur through sea-level rise, more frequent storm events, possible reductions in rainfall, and increased water demand as a result of higher temperatures (see Basher *et al.*, 1998; Chapter 17).

12.3.2. Water Allocation and Policy

Until recently, water planning in Australia was driven by demand and controlled by engineers, not by economics (Smith, 1998b). This situation has changed with growing population and demand (rural and urban/industrial), including rapid growth in irrigation of high-value crops such as cotton and vineyards. There also is an increasing awareness of stress on riverine ecosystems as a result of reduced mean flows, lower peak flows, and increasing salinity and algal blooms. Higher temperatures and changed precipitation as a result of climate change generally would exacerbate these problems and sharpen competition among water users (e.g., see Hassall and Associates *et al.*, 1998). In 1995, the Council of Australian Governments reviewed water resource policy in Australia and agreed to implement a strategic framework to achieve an efficient and sustainable water industry through processes to address water allocations, including provision of water for the environment and water-trading arrangements. The Agriculture and Resource Management Council of Australia and New Zealand subsequently commissioned a set of National Principles for the Provision of Water for Ecosystems, with the following stated goal: "To sustain and where necessary restore ecological processes and biodiversity of water-dependent ecosystems." Implementation of water reforms and national principles has resulted in the definition of conceptual frameworks and practical methods for assessing the water requirements of environmental systems.

In Australia, flow recommendations commonly are developed after water infrastructure projects and dams have been in place for some time and environmental flows implemented in river systems that already are experiencing a modified or regulated flow regime (Arthington, 1998; Arthington *et al.*, 1998). This situation is most applicable to adaptation to climate change in existing regulated flow regimes.

The Australian National Principles require that provision of water for ecosystems should use the best scientific information available on the hydrological regimes necessary to sustain aquatic ecosystems. Ideally, environmental flow recommendations are

based on establishment of quantitative relationships between flow characteristics and desired geomorphological, ecological, or water-quality outcomes. Methods are available to estimate flow-related habitat requirements of aquatic invertebrates, fish, and aquatic and riparian plants (e.g., wetted perimeter, transect methods, instream flow incremental methodology (IFIM)—see Kinhill, 1988). However, there are no standard methods for assessing flows that are relevant to maintenance of key life history processes. In the absence of robust biological indicators of response to flow regulation, recent research has advocated the use of statistical descriptors of flow regimes. These methods include maintenance of critical flow characteristics within one or two standard deviations of mean parameters (Richter *et al.*, 1996).

In New Zealand, various pressures on riverine ecosystems have been recognized, including those from agriculture, urban usage and sewage, hydroelectricity and water supply dams, forestry and mining, and introduced pests and weeds. Management of water is covered by the Resource Management Act (RMA) of 1991. Under this Act, the intrinsic values of ecosystems, including their biodiversity and life-supporting capacity, must be considered. The emphasis has changed from multiple-use management to environmentally sustainable management (Taylor and Smith, 1997), and Maori values are explicitly recognized (Ministry for the Environment, 1999). Drought associated with ENSO has placed stress on water supplies in various parts of the country, and it is recognized that climate change could lead to further stresses, especially if there is an increase in the frequency of El Niño events (Taylor and Smith, 1997). The RMA provides a statutory basis for integrated catchment management in that regional Councils control land use, water use, and water quality. Regional plans under which water is allocated have a term of only 10 years, allowing for review to adapt to issues such as river flow changes caused by climate change.

In the context of climate change, it is relevant to ask: How much can critical features of the flow regime be changed before the system becomes seriously stressed? Finding answers to this question for a range of Australian rivers is central to the assessment and management of water allocations to sustain water-dependent systems. Climate change has yet to be systematically injected into this process, but at least the mechanisms are now in place to develop appropriate water allocations and price incentives to use water to the best advantage. There also is scope for increased application of seasonal climate forecasts in water resources management, as a tool to aid adaptation to climate variability.

12.3.3. Inland and Coastal Salinization

Natural salinity and high water tables have been present in Australia for centuries. However, because of changes in land management—notably land clearing and irrigation—salinity is now a major environmental issue in Australia (Ghassemi *et al.*, 1995; MDBC, 1999). About 2.5 Mha are affected in Australia,

with the potential for this to increase to 12.5 Mha in the next 50 years (PMSEIC, 1999). Much of this area covers otherwise productive agricultural land. The area damaged by salinity to date represents about 4.5% of presently cultivated land, and known costs include US\$130 million annually in lost agricultural production, US\$100 million annually in damage to infrastructure (such as roads, fencing, and pipes); and at least US\$40 million in lost environmental assets (Watson *et al.*, 1997; PMSEIC, 1998). The average salinity of the lower Murray River (from which Adelaide draws much of its water supply) is expected to exceed the 800 EC threshold for desirable drinking water about 50% of the time by 2020.

Although climate is a key factor affecting the rate of salinization and the severity of impacts, a comprehensive assessment of the effects of climate change on this problem has not yet been carried out. Revegetation policies and associated carbon credit motivational policies designed to increase carbon sinks are likely to have a significant impact on recharge. However, global warming and dryland salinity policies need to be coordinated to maximize synergistic impacts.

In many coastal areas and oceanic islands, development and management of fresh groundwater resources are seriously constrained by the presence of seawater intrusion. Seawater intrusion is a natural phenomenon that occurs as a consequence of the density contrast between fresh and saline groundwater. If conditions remain unperturbed, the saline water body will remain stationary unless it moves under tidal influences. However, when there is pumping of freshwater, sea-level change, or changing recharge conditions, the saline body will gradually move until a new equilibrium condition is achieved (Ghassemi *et al.*, 1996). If the sea level rises to its "best-guess" or extreme predicted value over the next century, this would significantly increase intrusion of seawater in coastal and island aquifers.

12.3.4. Water Quality

Water quality would be affected by changes in biota, particularly microfauna and flora; water temperature; CO₂ concentration; transport processes that place water, sediment, and chemicals in streams and aquifers; and the timing and volume of water flow. More intense rainfall events would increase fast runoff, soil erosion, and sediment loadings, and further deforestation and urbanization would tend to increase runoff amounts and flood wave speed. These effects would increase the risk of flash flooding, sediment load, and pollution (Basher *et al.*, 1998). On the other hand, increases in plantation and farm forestry—in part for carbon sequestration and greenhouse mitigation purposes—would tend to reduce soil erosion and sediment loads.

Eutrophication is a major water quality problem in Australia (State of the Environment, 1996). This is a natural process, but it has been greatly accelerated in Australia by human activities, including sewage effluent and runoff from animal farms, irrigation, and stormwater. Low flow, abundant light, clear water,

and warmth all encourage algal growth, which affects the taste and odor of water and can be toxic to animals, fish, and humans. Thus, local climate warming and the potential for reduced streamflow may lead to increased risk of eutrophication.

12.4. Ecosystems and Conservation

12.4.1. Introduction

Until recent settlement, Australia and New Zealand were isolated for millions of years, and their ecosystems have evolved to cope with unique climate and biological circumstances (Kemp, 1981; Nix, 1981). Despite large year-to-year climatic variability, many Australian terrestrial species have quite limited ranges of long-term average climate, on the order of 1–2°C temperature and 20% in rainfall (Hughes *et al.*, 1996; Pouliquin-Young and Newman, 1999). Thus, these ecosystems are vulnerable to climatic change, as well as invasion by exotic animals and plants.

Rapid land clearance and subsequent land-use change have been occurring as a result of human activity over the past 500–1,000 years in New Zealand (McGlone, 1989; Wilmshurst, 1997) and, in Australia, subsequent to Aboriginal arrival tens of thousands of years ago—and especially since European settlers arrived 200 years ago. This has led to loss of biodiversity in many ecosystems as well as loss of some ecosystems as a whole. One of the major impacts has been an increase in weedy species in both countries. This is likely to continue and be exacerbated by climate change. Land-use change also has led to fragmentation of ecosystems and to salinization through rising water tables. These trends can inhibit natural adaptation to climate change via the dispersal/migration response. Systems therefore may be more vulnerable, and some might become extinct. For example, Mitchell and Williams (1996) have noted that habitat that is climatically suitable for the long-lived New Zealand kauri tree *Agathis australis* under a 4°C warming scenario would be at least 150 km from the nearest extant population. They suggest that survival of this species may require human intervention and relocation. Similar problems have been identified by Pouliquin-Young and Newman (1999) in relation to fragmented habitat for endangered species in the southwest of western Australia.

Many of the region's wetlands, riverine environments, and coastal and marine systems also are sensitive to climate variations and changes. A key issue is the effect on Australia's coral reefs of greenhouse-related stresses in addition to nonclimatic features such as overexploitation and increasing pollution and turbidity of coastal waters from sediment loading, fertilizers, pesticides, and herbicides (Larcombe *et al.*, 1996).

12.4.2. Forests and Woodlands

In Australia, some 50% of the forest cover in existence at the time of European settlement still exists, although about half of that has been logged (Graetz *et al.*, 1995; State of the Environment, 1996). Pressures on forests and woodlands as a whole are likely

to decrease as a result of recent legislation relating to protection of forests in some Australian states, and as interest in carbon sequestration increases. In New Zealand (Taylor and Smith, 1987), 25% of the original forest cover remains, with 77% in the conservation estate, 21% in private hands, and 2% state owned. Legal constraints on native wood production mean that only about 4% currently is managed for production, and clear-felling without replacement has virtually ceased.

The present temperature range of 25% of Australian Eucalyptus trees is less than 1°C in mean annual temperature (Hughes *et al.*, 1996). Similarly, 23% have ranges of mean annual rainfall of less than 20% variation. The actual climate tolerances of many species are wider than the climate envelope they currently occupy and may be affected by increasing CO₂ concentrations, which change photosynthetic rates and water-use efficiency (WUE) and may affect the temperature response (Curtis, 1996). Such changes from increasing CO₂ would be moderated by nutrient stress and other stressors that are prevalent across Australian forests. Nevertheless, if present-day boundaries even approximately reflect actual thermal or rainfall tolerances, substantial changes in Australian native forests may be expected with climate change. Howden and Gorman (1999) suggest that adaptive responses would include monitoring of key indicators, flexibility in reserve allocation, increased reserve areas, and reduced fragmentation.

In a forested area in western Australia that is listed as one of 25 global “biodiversity hotspots” for conservation priority by Myers *et al.* (2000), Pouliquen-Young and Newman (1999) used the BIOCLIM program (Busby, 1991) to generate a climatic envelope from the present distribution of species. They assessed the effects of three incremental temperature and rainfall scenarios on three species of frogs, 15 species of endangered or threatened mammals, 92 varieties of the plant genus *Dryandra*, and 27 varieties of *Acacia* in the southwest of western Australia. The scenarios were based on the spatial pattern of change from the CSIRO RCM at 125-km resolution, scaled to the IS92 global scenarios. For plant species, suitability of soils also was considered. The results indicate that most species would suffer dramatic decreases in range with climate warming; all of the frog and mammal species studied would be restricted to small areas or would disappear with 0.5°C global-average warming above present annual averages, as would 28% of the *Dryandra* species and one *Acacia*. At 2°C global average warming, 66% of the *Dryandra* species, as well as all of the *Acacia*, would disappear. Adaptation opportunities were considered minimal, with some gain from linking present conservation reserves and reintroducing endangered species into a range of climatic zones.

Studies of the current distribution of New Zealand canopy trees in relation to climate suggest that major range changes can be expected with warming (Whitehead *et al.*, 1992; Leathwick *et al.* 1996; Mitchell and Williams, 1996). Trees in the highly diverse northern and lowland forests (e.g., *Beilschmiedia tawa*) are likely to expand their ranges southward and to higher altitudes. The extensive upland *Nothofagus* forests are likely to be invaded by broad-leaved species. Few tree species are confined to cool

southern climates; those that are have a wide altitudinal range available for adjustment of their distribution, so no extinctions are expected. Most concern centers on the ability of tree species to achieve new distributions rapidly enough in a fragmented landscape, as well as invasion of natural intact forests by exotic tree, shrub, and liana species that are adapted to warm temperate or subtropical climates.

12.4.3. Rangelands

In Australia, rangelands are important for meat and wool production. In their natural state, rangelands are adapted to relatively large short-term variations in climatic conditions (mainly rainfall and temperature). However, they are under stress from human activity, mostly as a result of animal production, introduced animals such as rabbits, inappropriate management, and interactions between all of these factors (Abel *et al.*, 2000). These stresses, in combination with climatic factors, have led to problems of land degradation, salinization, and woody weed invasion and subsequent decreases in food production. In some cases, native dominant species (mostly plants) have been replaced by exotic species, leading to a decrease in population of many native animal species. Woody weed invasion also has changed the fire regime through formation of “thickets” that do not allow fires through, partly as a result of the fire resistance of some species (Noble *et al.*, 1996). Some Australian rangelands also are vulnerable to salinization resulting from rising water tables from irrigation and loss of native vegetation (see Section 12.3).

New Zealand rangelands are used predominantly for sheep grazing. Intensive use of indigenous grasslands and shrublands on land cleared of trees in the 19th century has increased vulnerability to invasion, especially by woody weeds (pine, broom, gorse, etc.) and herbaceous weeds (hawkweed, thistles, and subtropical grasses). Weed invasions are unlikely to further increase the susceptibility of the system to climatic disruptions but could themselves be accelerated by warming or increased climatic variability. Fire is now strictly regulated, although rangeland fires remain a serious problem, especially in ENSO drought years. Rangelands—in particular, in drier areas of eastern South Island—have many problems, including animal and plant pests and declining profitability of farming, leading to a decline in management and fertilizer inputs.

Increased CO₂ is likely to have beneficial effects for native pastures, with possible nitrogen limitation and increased subsoil drainage (Howden *et al.*, 1999d). Runoff and groundwater recharge also could increase (Krysanova *et al.*, 1999). This could lead to increased salinization problems in areas that are susceptible. However, decreases in rainfall in excess of about 10% at the time of CO₂ doubling would dominate over the CO₂ fertilization effect and lead to a decline in pasture productivity. This is more likely in the latest climate change scenarios that are based on coupled AOGCM results. Howden *et al.* (1999d) conclude that a doubling of CO₂ concentrations will result in only limited changes in the distribution of C₃ and C₄ grasses and that such changes will be moderated by warmer temperatures.

12.4.4. Alpine Systems

Basher *et al.* (1998) conclude that alpine systems are among the most vulnerable systems in the region. Despite the fact that they cover only a small area, they are important for many plant and animal species, many of which are listed as threatened. These systems also are under pressure from tourism activity. The Australian Alps are relatively low altitude (maximum about 2,000 m), and much of the Alpine ecosystem area and ski fields are marginal. Most year-to-year variability is related to large fluctuations in precipitation, but interannual temperature variations are small compared to warming anticipated in the 21st century. Studies by Hewitt (1994), Whetton *et al.* (1996b), and Whetton (1998) all point to a high degree of sensitivity of seasonal snow cover duration and depth. For Australia, Whetton (1998) estimates, for the full range of CSIRO (1996a) scenarios, an 18–66% reduction in the total area of snow cover by 2030 and a 39–96% reduction by 2070. This would seriously affect the range of certain alpine ecosystems and species (Bennett *et al.*, 1991). Decreases in precipitation and increased fire danger also would affect alpine ecosystems adversely.

There seems to be little opportunity for adaptation by alpine ecosystems in Australia, which cannot retreat upward very far because of the limited height of Australian hills and mountains. There are various options for the rapidly expanding mountain-based recreation industry, including increased summer recreation and artificial snowmaking. These adaptations would increase stress on alpine ecosystems and water resources.

The New Zealand Alps are of higher altitude (up to 3,700 m); about 9% of the New Zealand landmass is above the treeline. A large number of species (for example, 25% of vascular plants), which often are highly distinctive, grow there. Despite a 0.5°C rise in New Zealand's mean annual temperatures since the 1860s, there has been no significant rise in the treeline or shrubland expansion (Wardle and Coleman, 1992), and it seems unlikely that there will be any significant threat to alpine ecosystems from warming in the medium term.

12.4.5. Wetlands

The Australian State of the Environment Report (1996) states, "Wetlands continue to be under threat, and large numbers are already destroyed." For example, Johnson *et al.* (1999) estimate wetland loss of about 70% in the Herbert River catchment of Northern Queensland between 1943 and 1996. Wetland loss is caused by many processes, including water storage; hydroelectric and irrigation schemes; dams, weirs, and river management works; desnagging and channelization; changes to flow, water level, and thermal regimes; removal of instream cover; increased siltation; toxic pollution and destruction of nursery and spawning or breeding areas (Jackson, 1997); and use of wetlands for agriculture (Johnson *et al.*, 1999). Climate change will add to these factors through changes in inflow and increased water losses.

Specific threats to wetlands from climate change and sea-level rise have been studied as part of a national vulnerability assessment (Waterman, 1996). The best example is provided for Kakadu National Park in northern Australia. There are fears that World Heritage and Ramsar-recognized freshwater wetlands in this park could become saline, given current expectations of sea-level rise and climate change (Bayliss *et al.*, 1997; Eliot *et al.*, 1999). Although this analysis is supported by a large data resource, it is speculative, and efforts to develop more definite monitoring tools are needed. However, it does raise the possibility that many other Australian coastal wetlands could be similarly affected. Some of these wetlands may be unable to migrate upstream because of physical barriers in the landscape.

Many inland wetlands are subject to reduced frequency of filling as a result of water diversion for irrigation, and they also may be seriously affected by reductions in seasonal or annual rainfalls in the catchments as a result of climate change (Hassall and Associates *et al.*, 1998). This may threaten the reproduction of migratory birds (some species of which already are under threat), which rely on wetlands for their breeding cycle (Kingsford and Thomas, 1995; Kingsford and Johnson, 1998; Kingsford *et al.*, 1999). Large decreases in inflow predicted for the Macquarie River and several rivers in northern Victoria by Hassall and Associates *et al.* (1998) and Schreider *et al.* (1996, 1997) for scenarios that are consistent with the latest AOGCM simulations would have major impacts on wetland ecosystems.

Wetlands in New Zealand are the most threatened ecosystems; they have declined by 85% since European settlement (Stephenson, 1983). The vast majority have been drained or irretrievably modified by fire, grazing, flood control works, reclamation, or creation of reservoirs. Eutrophication, weed invasion, and pollution have greatly reduced their biodiversity (Taylor and Smith, 1997). More than 50% of the 73 significant wetlands that meet the Ramsar Convention standards for international wetlands are in coastal districts and will be impacted by rising sea levels. Most important wetlands are in highly urbanized or productive landscape settings and therefore have limited options for adaptation to decreased size or increased salinization.

12.4.6. Riverine Environments

Many Australian river systems, particularly in the southeast and southwest, have been degraded through diversion of water via dams, barrages, channels, and so forth, principally for irrigated agriculture. Many New Zealand rivers have been affected by hydroelectric generation; diversion of water for irrigation; agricultural, manufacturing, and urban pollution; and biotic invasion. Recent research has shown that river ecosystems are particularly sensitive to extremes in flow. Most research has been on the effects of flood flows. Droughts, as opposed to floods, have a slow onset and although recovery from floods by river flora and fauna is relatively rapid, recovery after droughts tends to be slow, may be incomplete, and may lag well behind the breaking of the drought (Lake, 2000). Floods

and droughts interact with nutrient supply (Hildrew and Townsend, 1987; Biggs, 1996), so the effects of any possible changes in their frequency and magnitude need to be evaluated within the context of other human activities and climate-induced land-use change.

Current ranges of scenarios tend to suggest reductions in mean flow in many Australian rivers, similar to or greater than those in Schreider *et al.* (1997) and Hassall and Associates *et al.* (1998). In particular, any tendency toward more frequent or severe El Niño-like conditions beyond that already contained in the CSIRO (1996a) scenarios would further threaten many riverine and inland wetland systems in Australia and New Zealand. Findings of increased drought frequency and severity in eastern Australia under an NCAR CCMO transient simulation (Kothavala, 1999) and 12–35% reductions in mean flow by 2050 in the Murray-Darling basin by the 2050s in Arnell (1999), using results from the HadCM2 and HadCM3 GCM simulations, are cause for concern. Arnell (1999) found reductions in maximum and minimum flows. Walsh *et al.* (2000) found less severe increases in drought in Queensland, based on simulations with the CSIRO RCM nested in the CSIRO Mark 2 GCM.

Implications of these findings for riverine ecosystems and estuaries (Vance *et al.*, 1998; Loneragan and Bunn, 1999) and possible adaptations have yet to be investigated, although reduced diversions from rivers to increase environmental flows is one possibility. This could be achieved through increased WUE, imposition of caps on water diversions, or water pricing and trading, but the latter two measures are controversial and would have strong implications for rural industry (e.g., see ABARE, 1999). Increased efficiency in water delivery for irrigation currently is the favored option for restoring environmental flows in the heavily depleted Snowy River in southeastern Australia.

12.4.7. Coastal and Marine Systems

Australia has some of the finest examples of coral reefs in the world, stretching for thousands of kilometers along the northwest and northeast coasts (Ellison, 1996). Coral reefs in the Australian region are subject to greenhouse-related stresses (see Chapter 6 for a summary), including increasingly frequent bleaching episodes, changes in sea level, and probable decreases in calcification rates as a result of changes in ocean chemistry.

Mass bleaching has occurred on several occasions in Australia's Great Barrier Reef (GBR) and elsewhere since the 1970s (Glynn, 1993; Hoegh-Guldberg *et al.*, 1997; Jones *et al.*, 1997; Wilkinson, 1998). Particularly widespread bleaching, leading to death of some corals, occurred globally in 1997–1998 in association with a major El Niño event. Bleaching was severe on the inner GBR but less severe on the outer reef (Wilkinson, 1998; Berkelmans and Oliver, 1999). This episode was associated with generally record-high SSTs over most of the GBR region. This was a result of global warming trends resulting from the enhanced greenhouse effect and regional summer warming from the El Niño event, the combined effects

of which caused SSTs to exceed bleaching thresholds (Lough, 1999). Three independent databases support the view that 1997–1998 SST anomalies were the most extreme in the past 95 years and that average SSTs off the northeast coast of Australia have significantly increased from 1903 to 1994. Lowered seawater salinity as a result of flooding of major rivers between Ayr and Cooktown early in 1998 also is believed to have been a major factor in exacerbating the effects in the inshore GBR (Berkelmans and Oliver, 1999). Solar radiation, which is affected by changes in cloud cover and thus by El Niño, also may have been a factor (Brown, 1997; Berkelmans and Oliver, 1999).

Although warming in Australia's coral reef regions on average is expected to be slightly less than the global average, according to the SRES global warming scenarios it may be in the range of 2–5°C by 2100. This suggests that unless Australian coral reefs can adapt quickly to these higher temperatures, they will experience temperatures above present bleaching thresholds (Berkelmans and Willis, 1999) almost every year, well before the end of the 21st century (Hoegh-Guldberg, 1999). Hoegh-Guldberg (1999) notes that apparent thresholds for coral bleaching are higher in the northern GBR than further south, suggesting that some very long-term adaptation has occurred. Coral reef biota may be able to adapt, at least initially, by selection for the more heat-tolerant host and symbiont species and genotypes that survived the 1997–1998 summer and by colonization of damaged sites by more heat-resistant genotypes from higher latitudes arriving as planktonic larvae. However, it is generally believed that the rate and extent of adaptation will be much slower than would be necessary for reef biota to resist the frequency and severity of high SST anomalies projected for the middle third of the 21st century (medium to high confidence). The most likely outlook is that mass bleaching, leading to death of corals, will become a more frequent event on Australian coral reefs in coming decades.

Increasing atmospheric CO₂ concentrations will decrease the carbonate concentration of the ocean, thereby reducing calcification rates of corals (Gattuso *et al.*, 1998, 1999; Kleypas *et al.*, 1999). This is complicated, however, by the effects of possible changes in light levels, freshwater discharge, current patterns, and temperature. For example, Lough and Barnes (2000) report a historic growth stimulus for the *Porites* coral that they correlate with increasing average SSTs. Thus, the net effect on Australian reefs up to 1980 appears to have been positive, but it is unclear whether decreased carbonate concentration resulting from rapidly increasing CO₂ concentration will outweigh the direct temperature effect later in the 21st century, especially if regional SSTs reach levels not experienced by the corals of the GBR during the Holocene.

As noted in Chapter 6, expected rates of sea-level rise to 2100 would not threaten healthy coral reefs (most Australian reefs) but could invigorate growth on reef flats. However, decreased calcification rates might reduce the potential ability of the reefs to keep up with rapid sea-level rise. Possible increases in tropical cyclone intensity with global warming also would impact coral

reefs (high confidence), along with nonclimatic factors such as overexploitation and increasing pollution and turbidity of coastal waters by sediment loading, fertilizers, pesticides, and herbicides (Larcombe *et al.*, 1996). Climate change could affect riverine runoff and associated stresses of the reefs, including low-salinity episodes. Coupled with predicted rises in sea level and storminess, bleaching-induced coral death also could weaken the effectiveness of the reefs in protecting the Queensland coast and adversely affect the biodiversity of the reef complex.

On the whole, mangrove processes are less understood than those for coral reefs (Ellison, 1996). Mangroves occur on low-energy, sedimentary shorelines, generally between mean- and high-tide levels. Australian mangroves cover approximately 11,500 km² (Galloway, 1982). It is anticipated that they are highly vulnerable but also highly adaptable to climate change. Studies over glacial/interglacial cycles show that in the past mangroves have moved landward during periods of rising sea level (Woodroffe, 1993; Wolanski and Chappell, 1996; Mulrennan and Woodroffe, 1998). However, in many locations this will be inhibited now by coastal development. Coastal wetlands are thought to be nursery areas for many commercially important fish (e.g., barramundi), prawns, and mudcrabs.

In New Zealand, estuaries are the most heavily impacted of all coastal waters. Most are situated close to or within urban areas (Burns *et al.*, 1990). Most have been modified by reclamation or flood control works and have water-quality problems resulting from surrounding land use. Increasing coastal sedimentation is having a marked effect on many estuaries. This may increase with increased rainfall variability. In the South Island, increased coastal sedimentation has disrupted fish nursery grounds and destroyed weed beds, reef sponges, and kelp forests; in the North Island it has been linked to loss of seagrasses through worsening water clarity (RSNZ, 1993; Turner, 1995).

Over a long period, warming of the sea surface is expected (on average) to be associated with shoaling (thinning) of the mixing layer, lowering of phytoplankton growth-limiting dissolved inorganic nutrients in surface waters (Harris *et al.*, 1987; Hadfield and Sharples 1996), and biasing of the ecosystem toward microbial processes and lowered downward flux of organic carbon (Bradford-Grieve *et al.*, 1999). However, this would be modified regionally by any change in the Pacific Ocean to a more El Niño-like mean state. Warming also may lead to decreased storage of carbon in coastal ecosystems (Alongi *et al.*, 1998).

There is now palaeo-oceanographic evidence documenting environmental responses east of New Zealand to climatic warming, especially the Holocene “optimum” (~6–7 ka) and interglacial optimum (~120–125 ka), when SSTs were 1–2°C warmer than present. Immediately prior to and during those two periods, oceanic production appears to have increased, as manifested by greater amounts of calcareous nanoplankton and foraminifera (e.g., Lean and McCave, 1998; Weaver *et al.*, 1998). Other evidence suggests that storms in the New Zealand region may have been more frequent in warmer epochs (Eden and

Page, 1998), affecting the influx of terrigenous material into the continental shelf (Foster and Carter, 1997). There also may be a relationship between strong El Niño events and the occurrence of toxic algal blooms in New Zealand waters (Chang *et al.*, 1998). Nevertheless, we do not know, over the longer term, how the oceanic biological system in the southwest Pacific will be influenced by the interaction of ENSO events with the overall warming trend.

South of the subtropical front, primary production is limited by iron availability (Boyd *et al.*, 1999), which has varied in the past. It is not known how or whether aeolian iron supply to the Southern Ocean in the southwest Pacific (Duce and Tindale, 1991) may be altered by climate change, although it could be affected by changes in aridity and thus vegetation cover over Australia as well as by strengthening of the westerlies. In any case, Harris *et al.* (1988) demonstrate that the strength of the zonal westerly winds is linked to recruitment of stocks of spiny lobsters over a wide area.

If reduction or cessation of North Atlantic or Antarctic bottomwater formation were to occur (Manabe and Stouffer, 1994; Hirst, 1999), this could lead to significant changes in deep ocean chemistry and dynamics, with wide ramifications for marine life. The common southern hemisphere copepod *Neocalanus tonsus* could be affected because it spends part of the year at depths between 500 and 1,300 m but migrates seasonally to surface waters, becoming the focus of feeding of animals such as sei whales and birds (Bradford-Grieve and Jillett, 1998).

The northern part of New Zealand is at the southern extension of the distribution of marine subtropical flora and fauna (Francis and Evans, 1993). With a warming climate, it is possible that many species would become a more permanent feature of the New Zealand flora and fauna and extend further south.

12.4.8. Landscape Management as a Goal for Conservation and Adaptation

Ecosystems that are used for food and fiber production form a mosaic in a landscape in which natural ecosystems also are represented. Aquatic systems, notably rivers and groundwater, often play a crucial role. Given the issues of fragmentation and salinization in many parts of the region, especially Australia, landscape management as an integrated approach (PMSEIC, 1999) may be one of the best ways of achieving conservation goals and human needs for food and fiber in the face of multiple stresses—of which climate change is only one.

This complex interconnection of issues in land management is evident in most parts of Australia and New Zealand—notably in the tropical coastal zone of Queensland, where rapid population and economic growth has to be managed alongside agricultural land use that impacts soil and riverine discharge into the waters of the GBR, a growing tourist industry, fisheries, indigenous people’s rights, as well as the climatic hazards of tropical cyclones, floods, and droughts. Climate change and

associated sea-level rise are just one of several major issues in this context that may be significant in adding stress to a complex system.

Similar complexities arise in managing other major areas such as the Murray-Darling basin, where control of land degradation through farm and plantation forestry is being considered as a major option, partly for its benefits in controlling salinization and waterlogging and possibly as a new economic option with the advent of incentives for carbon storage as a greenhouse mitigation measure. Similar problems and processes apply in New Zealand, where plantation forestry is regarded as a major option in land use and GHG mitigation.

12.5. Food and Fiber

12.5.1. Introduction

Some 60% of Australia is used for commercial agriculture (Pestana, 1993). Only 2% is used for broad acre and intensive crop production; 4% is sown to pastures. Soil and topography are major constraints on cropping, which produces about 50% of the gross value of farm production—the rest being divided equally between meat production and livestock products such as wool and milk.

Russell (1988) identifies climatic “frontiers” affected by climate change and interdecadal variability in rainfall—namely, the inland limit to agriculture (mean annual rainfall <300 mm in the south and <750 mm in the north), the southern limit of effective summer rainfall; and the lower rainfall limit of high value crops (on the order of 1,000 mm). Temperature also is limiting, with some temperate crops held south of their high-temperature (northern) limit, and other more tropical crops held at their low-temperature (southern or high-altitude) limit. Large areas of the interior and west are desert or very arid rangelands with low yields; much of this land is now returned to Aboriginal management.

There is great interannual variability, especially in the interior and more northern regions, associated mainly with ENSO, convective rainfall, and tropical cyclones. Australia is known as a land of droughts and flooding rains. Secondary factors such as wildfires also account for losses of fodder, animals, and farm infrastructure (sheds, fences, machinery), and hail causes significant crop losses. Accordingly, drought and disaster relief policies are matters of ongoing concern (O’Meagher *et al.*, 1998, 2000; Pittock *et al.*, 1999), as is sustainability in the face of economic pressures and global change (Abel *et al.*, 1997).

In New Zealand, pastoral agriculture provides more than 40% of the country’s export earnings (Statistics New Zealand, 1998). Dairy farming is the major activity in wetter areas; sheep dominate hilly and drier areas, and beef cattle are widely distributed throughout the country. Pastures are highly productive—composed largely of introduced grass and nitrogen-fixing legume species—and support high stock numbers. Rainfall in New Zealand

generally is not strongly seasonal, but high evapotranspiration rates in the summer make pastoral agriculture in the east vulnerable to largely ENSO-related variability in summer rainfall.

12.5.2. Pastoral Farming

Howden *et al.* (1999d) have summarized and updated work by Hall *et al.* (1998), McKeon *et al.* (1998), and Howden *et al.* (1999a,b). They find that although CO₂ increase alone is likely to increase pasture growth, particularly in water-limited environments, there also is strong sensitivity to rainfall, so that a 10% reduction in rainfall would counter the effect of a doubled CO₂ concentration. A 20% reduction in rainfall at doubled CO₂ is likely to reduce pasture productivity by about 15% and live-weight gain in cattle by 12% and substantially increase variability in stocking rates, reducing farm income. The latest scenarios, which have substantial reduction in rainfall in many parts of Australia, would tend to reduce productivity.

Howden *et al.* (1999d) also found that doubled CO₂ concentrations are likely to increase the deep drainage component under pastures, which may increase the risk and rates of salinization where the potential for this problem exists. Doubled CO₂ and increased temperature would result in only limited changes in C₃ and C₄ grass distributions (Howden *et al.*, 1999a).

In New Zealand, productivity of dairy farms might be adversely affected by a southward shift of undesirable subtropical grass species, such as *Paspalum dilatatum* (Campbell *et al.*, 1996). At present, *P. dilatatum* is recognized as a significant component of dairy pastures in Northland, Auckland, Waikato, and the Bay of Plenty. A “user-defined” management threshold for the probability of finding this grass in dairy pasture is predicted by a climate profile technique (Campbell and Mitchell, 1996). This can be considered the point at which adaptive management changes are regarded as necessary. This technique was applied with the IS92a (mid) and IS92e (high) climate change scenarios and the CSIRO4 GCM pattern, using the CLIMACTS integrated assessment model (Kenny *et al.*, 1995, 2000). Results indicate a significant southward shift in the probability of occurrence of *P. dilatatum* with global warming; more southerly geographic thresholds are reached at later dates, but 25–30 years earlier with the higher emissions scenario.

Comprehensive assessment of the response of dairy cattle to heat stress in NSW and Queensland was carried out by Davison *et al.* (1996). Physiological effects of heat stress include reduced food intake, weight loss, decreased reproduction rates, reduction in milk yields, increased susceptibility to parasites, and, in extreme cases, collapse and death. Heat stress can be reduced by the use of shade and sprinklers, and thresholds for their use can be determined. Jones and Hennessy (2000) applied this adaptation to the Hunter Valley in NSW, using probabilistic estimates of temperature and dewpoint changes resulting from climate change for the IS92 range of scenarios to 2100. They then estimated the probabilities of given milk production losses

as a function of time and calculated the economic benefits of provision of shade and sprinklers. They conclude that heat-stress management in the region would be cost-effective. However, such adaptation may not be as cost-effective in a hotter or more humid climate.

Howden and Turnpenny (1997) and Howden *et al.* (1999e) also have looked at heat stress in beef cattle. They find that heat stress already has increased significantly in subtropical Queensland over the past 40 years (where there has been a warming trend) and that it will increase further with greenhouse-induced global warming. They suggest a need for further selection for cattle lines with greater thermoregulatory control, but they point out that this may be difficult because it may not be consistent with high production potential (Finch *et al.*, 1982, 1984).

12.5.3. Cropping and Horticulture

Cropping in Australia recently has undergone great diversification, from predominantly wheat and barley to include a variety of other crops, including rice, cotton, pulses, and oilseeds. Cane sugar is grown extensively in coastal areas of Queensland. Many of these crops are subject to frost limitations on seasons and to water stress in dry spells; some are subject to direct heat stress or deterioration during heat waves. For example, wheat grain protein composition deteriorates after several days above 35°C (Burke *et al.*, 1988; Behl *et al.*, 1993), making it less suitable for high-value uses such as pasta and breadmaking. However, climate warming may allow earlier planting and faster phenological development, resulting in little change in heat shock risk up to a 4°C mean warming (Howden *et al.*, 1999c). Independently, increasing CO₂ can result in a decrease in wheat grain protein content—also leading to a decrease in breadmaking quality (Rogers *et al.*, 1998). A potential complication of these impacts is water stress that results in decreased yield and potentially increased protein.

Howden *et al.* (1999c) report a comprehensive study of global change impacts on Australian wheat cropping. Studies were conducted of changes in wheat yields, grain quality, and gross economic margins across 10 sites in the present Australian wheat belt. Results were scaled up to provide national estimates, with and without varying planting dates. Response surfaces were constructed across the full range of uncertainty in the CSIRO (1996a) scenarios and are shown in bar-graph form in Figure 12-3. The estimated increase in yield resulting from physiological effects of a doubling of actual atmospheric CO₂ is about 24%. The analysis assumes that the regional distribution of cropping is unaffected. (This is not completely accurate, but changes at the margins of present areas would not change the total yield much.) The best variety of wheat is used under each scenario, with current planting dates (a) and optimal planting dates (b) for each scenario. Note that yield reaches a maximum at about 1°C warming with current planting dates but about 2°C with optimal planting dates and that yield drops rapidly with decreases in rainfall. Under the SRES scenarios, warming

in Australian wheat-growing areas would exceed 2°C and could be well in excess of 6°C by 2100; actual CO₂ concentrations could be between 540 and 970 ppm.

Doubling CO₂ alone produced national yield increases of 24% in currently cropped areas, but with a decline in grain nitrogen content of 9–15%, which would require increases in the use of nitrogen-based fertilizer of 40–220 kg ha⁻¹ or increased rotations of nitrogen-fixing plants. Using the mid-range values from the CSIRO (1996a) scenario (which includes both slab-ocean and coupled GCMs and is now superseded—see below), climate change added to CO₂ increase led to national yield increases of 20% by 2100 under present planting practices or 26% with optimum planting dates (Howden *et al.*, 1999c). Regional changes varied widely.

Howden's response surfaces show that for doubled CO₂ but no change from historical rainfall, a 1°C increase in temperature would slightly increase national yield (see Figure 12-3a) when the best variety was used with the current planting window. However, the slope of the temperature curve turned negative

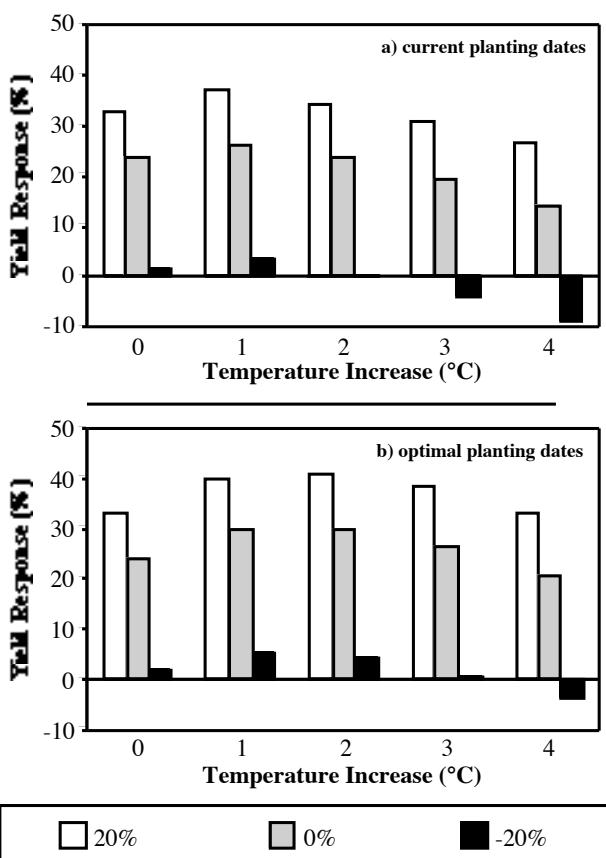

Figure 12-3: Percentage change in average annual total Australian wheat yield for doubling of actual CO₂ (to 700 ppm) and a range of changes in temperature and rainfall. Yield response is shown for rainfall changes of +20% (white), 0 (stippled), and -20% (black), for warmings of 0–4°C.

beyond 1°C, so the yield at 2°C was predicted to be similar to that at present temperatures, and the total yield declined below the current value for greater warmings. Adoption of earlier planting windows with climate change extended the yield plateau to 2°C warming before the slope of the temperature curve became negative (see Figure 12-3b). This was based on the present regional distribution of cropping, although cropping could expand into drier marginal areas with higher CO₂—but this may be countered by substantial reductions in rainfall or land degradation in currently cropped areas. Yield decreases rapidly with decreases in rainfall.

These response surfaces were used by Howden *et al.* (1999d) with the SRES scenarios (see Section 12.1.5.4), which use only recent coupled-ocean GCMs that show reductions in rainfall over most of mainland Australia in summer and winter. Results indicate that for mid-range scenarios (A1-mid and B2-mid) extended to 2100, national yields are reduced 3% without adaptation compared with current yields and increase only 3% with adaptation. Yields decline in western Australia and south Australia but increase in the eastern states. With the A2-high scenario, there are much larger negative impacts, with cropping becoming nonviable over entire regions, especially in western Australia. These results highlight the importance of the more negative rainfall scenarios found with the coupled-ocean GCMs.

In New Zealand, generally drier conditions and reductions in groundwater will have substantial impacts on cereal production in Canterbury (east coast South Island), the major wheat and barley production area of New Zealand. Other grain-producing areas (primarily Manawatu and Southland) are less likely to be affected. Grain phenological responses to warming and increased CO₂ are mostly positive, making grain filling slightly earlier and decreasing drought risk (Pyke *et al.*, 1998; Jamieson and Munro, 1999). Although grain-filling duration may be decreased by warmer temperatures, earlier flowering may compensate by shifting grain filling into an earlier, cooler period.

Maize production is mainly in Waikato (upper middle North Island) and Bay of Plenty and Poverty Bay (east coast North Island), with some production (more likely to be for silage than grain) further south in Manawatu and Canterbury. Rising temperatures make this crop less risky in the south, but water availability may become an issue in Canterbury.

Sweetcorn is grown mostly on the east coast of the North Island (Poverty Bay and Hawke's Bay) but increasingly in Canterbury. Climate warming is decreasing frost risk for late-sown crops, extending the season and moving the southern production margin further south. In the South Island, production is irrigated and is vulnerable to changes in river flows and underground water supply.

Horticulture in Australia includes cool, temperate fruit and vegetables in the south and at higher elevations, extensive areas of tropical fruits in the northeast and in irrigated areas in the northwest, and a rapidly expanding viticulture industry in

cool and warm temperate zones. Many temperate fruits require winter chill or vernalization—which in some cases can be replaced by chemical treatments—and are strongly affected by disease and hail. Other more tropical fruit are subject to disease outbreaks and severe damage from hail, high winds, and heavy rain from tropical storms. These fruits are all likely to be affected by climate change, but few studies have been made (but see Hennessy and Clayton-Greene, 1995; Basher *et al.*, 1998).

In New Zealand, climate change may have mixed results on horticulture. Kiwifruit require some winter chill (Hall and McPherson, 1997a), and studies by Salinger and Kenny (1995) and Hall and McPherson (1997b) suggest that some varieties in some regions will become marginal; warmer summers and extended growing seasons may benefit others but may adversely affect timing for overseas markets.

Chilling requirements for most cultivars of pip-fruit are easily satisfied. However, some common cultivars have shown an adverse reaction to excessively warm conditions, with problems such as sunburn, water-core, and lack of color.

There has been a southern expansion of grapes in New Zealand over the past few decades, sometimes into more climatically marginal land. The New Zealand wine industry to date has shown a largely beneficial response to warm, dry conditions, which are expected to become more dominant in the east, but limitations on groundwater for irrigation may become a problem. Warmer conditions also are assisting expansion of the citrus industry in the north of New Zealand and are particularly beneficial for mandarins. However, this region would be susceptible to any increase in the location-specific frequency of subtropical storms reaching New Zealand.

12.5.4. Forestry

When Europeans arrived in Australia in 1788, there were approximately 70 Mha of forests. Since then, 40% has been cleared and a similar amount has been affected by logging; only about 25% remains relatively unaffected (Graetz *et al.*, 1995; State of the Environment, 1996). Nationally, land clearing still exceeds planting, although this varies greatly across the states, and is occurring mainly in areas defined as woodlands. Plantations have been expanding in Australia at an increasing rate since 1990, currently by more than 50,000 ha yr⁻¹ (National Greenhouse Gas Inventory, 2000). Much of this planting is occurring on farmed land and receives federal government support (Race and Curtis, 1997). Additional plantings are occurring to ameliorate land degradation problems such as erosion, waterlogging, and salinization, and further plantings are associated with the establishment of carbon sinks (Howden *et al.*, 1999d).

Forests cover about 8.1 Mha (29%) of New Zealand's land area. Of this, about 6.4 Mha are in natural forest and 1.7 Mha in planted production forests. New forest establishment increased markedly during the 1990s. Almost all areas of harvested forest

are replanted; during 1998, 52,000 ha of new forest plantings occurred (Statistics New Zealand, 1999).

Climatic factors are well known to influence species distributions (Hughes *et al.*, 1996; Austin *et al.*, 1997) and productivity (Landsberg and Waring, 1997). CO₂ concentrations also have a direct effect (Curtis and Wang, 1998). Kirschbaum (1999a,b) has used a forest growth model to assess response to climate change and CO₂ increases for a site near Canberra.

Howden and Gorman (1999) review this and other work on the impact of global change on Australian temperate forests. Productivity of exotic softwood and native hardwood plantations is likely to be increased by CO₂ fertilization effects, although the amount of increase is limited by various acclimation processes and environmental feedbacks through nutrient cycling. Where trees are not water-limited, warming may expand the growing season in southern Australia, but increased fire hazard and pests may negate some gains. Reduced rainfall in more recent scenarios would have adverse effects on productivity and increase fire risk. Increased rainfall intensity would exacerbate soil erosion problems and pollution of streams during forestry operations. In *Pinus radiata* and Eucalyptus plantations, fertile sites are more likely to have increased productivity for moderate warmings, whereas infertile sites could have decreased production. To date, large uncertainties have lowered the priority of climate change in management considerations.

Despite large year-to-year climatic variability, many Australian native species are confined in their natural climatic range to within 1 or 2°C average mean temperature (Hughes *et al.*, 1996; Pouliquen-Young and Newman, 1999), so without human intervention their survival will be threatened by warmings outside these ranges (see Section 12.4.1).

Of New Zealand's 13 Mha of land used for pastoral farming, at current prices 3–5 Mha of hill country would yield higher returns under forestry. Such land is being converted to plantation forestry at a rate of 40,000 ha yr⁻¹, from an initial rate averaging 60,000 ha yr⁻¹ over the past decade (Statistics New Zealand, 1998); the recent decrease in planting rate reflects current lower wood prices. Carbon trading would facilitate increased planting rates, possibly up to 90,000 ha yr⁻¹ (MAF, 1999). Steep land is particularly uneconomic to manage for pastoral farming and could be converted to forest or scrubland by planting or abandonment and regrowth. Control of possums (a pest introduced from Australia by early European settlers) to minimize transfer of diseases to farm animals has the added benefit of improving the health and regenerative capacity of some indigenous forests (Ministry for the Environment, 1997).

Biomass from forest residues and purpose-grown crops already provides 6% of New Zealand's primary energy supply (EECA, 1996) and significant energy resources for Australia. Biomass use is expected to increase substantially over the next decade (Sims, 1999), partly as a response to constraints on net carbon emissions. This also may encourage increased forestry planting rates.

The direct effects of elevated CO₂ on yield from *radiata* pine plantations are expected to be small in New Zealand. However, regional uncertainties remain with regard to possible increased growth loss under warmer, wetter conditions as a result of existing and new pests and diseases and losses from wind and fire associated with extreme weather events. Biosecurity mechanisms are being improved in New Zealand and abroad to better manage risk. Long-term trends in forest nutritional status are being examined. Indicators of sustainable forestry practices are receiving increasing attention. Risks from fire and wind also are being investigated in New Zealand. Systems to measure and predict effects on carbon sequestration in plantation forests are being improved.

12.5.5. Fisheries

Australia specializes in high-value, low-tonnage fisheries such as lobsters, pearl oysters, prawns, abalone, and tuna. Totaling about AU\$2 billion yr⁻¹ (ABARE, 2000), these fisheries are a significant local primary industry. Tonnage produced is very small by world standards because Australian surface waters generally are low in nutrients as a result of prevailing winds and boundary currents (Kailola *et al.*, 1993). New Zealand's Exclusive Economic Zone (EEZ) is one of the largest in the world (Statistics New Zealand, 1999), and its NZ\$1.23 billion export revenues from fisheries in 1998 constituted 5.5% of total export revenue for that year (Seafood New Zealand, 2000).

For both countries, relationships have been established between recruitment of some fish species and climate variations, suggesting that fisheries in the region will be sensitive to climate change. However, it is uncertain how local winds and boundary currents that advect larvae and affect upwelling of nutrients might respond to GHG-induced climate changes, and downscaling from relevant global climate change model fields has not yet been done. Hence, this section concentrates on reporting studies of observed sensitivities of fisheries in the Australasian region to climate variability. There is insufficient information to date to project the impact of climate change on fisheries productivity.

Understanding of existing processes suggests that if El Niño were to become a more prevalent condition, the Indonesian throughflow and the Leeuwin current (Meyers, 1996) could weaken. If winds were favorable for upwelling, the west coast of Australia could undergo a dramatic shift from a low-production, high-biodiversity ecosystem to a more productive ecosystem typical of temperate shelves.

Australia's single largest fishery is western rock lobster (AU\$260 million yr⁻¹—ABARE 2000). Presently, settlement of larval lobsters (and adult catch rates some years later) is much higher in La Niña years (high coastal sea level, high SST, strong Leeuwin current) than in El Niño years (Pearce and Phillips, 1994). Because the mechanism appears to be through larval advection processes, however, it is unclear whether the species' spawning strategy would adapt to a sustained shift to a weaker Leeuwin current. Many other western Australian

fisheries also correlate (some positively, some negatively) with ENSO (Caputi *et al.*, 1996), through unknown mechanisms. Whether these mechanisms would continue to operate under the combined influence of a sustained weaker Leeuwin current (which tends to reduce temperatures) and a worldwide rise in SST is unknown. Southern bluefin tuna spawn where the Indonesian throughflow enters the Indian Ocean, but the impact of a possibly reduced throughflow also is unknown.

Conditions on the south coast of Australia also are influenced—but to a lesser degree—by the Leeuwin current, which tends to keep near-surface nutrient levels low. In addition, winds are favorable to downwelling, except during some summers, when Australia's only example of strong classical wind-driven coastal upwelling occurs off Portland, Victoria. Small meridional shifts of the subtropical high-pressure ridge modulate summer upwelling. Ecosystem impacts of this are poorly known.

On the east coast of Australia, the East Australian Current (EAC) is a dominant influence on coastal marine ecosystems. The EAC enhances upwelling and primary production (Hallegraeff and Jeffrey, 1993) and presumably fisheries, although this has yet to be demonstrated apart from its effect on the distribution of several tuna species (Lyne *et al.*, 1999). Farther north, Vance *et al.* (1985) report a correlation of catches of banana (but not tiger) prawns with rainfall, probably as a result of runoff-driven export of juveniles from estuary nursery beds.

Post hoc analyses (Smith, 1996) of a dramatic decline in the late 1980s in the Australian gemfish fishery suggest a combination of fishery pressure and poor recruitments as the cause. Recruitment appears to correlate with climatic cycles (Thresher, 1994). Smith (1996) developed a quantitative framework to evaluate management strategies for this and other fisheries.

For New Zealand, there is some evidence that fisheries recruitment may be enhanced by more frequent ENSO events (Harris *et al.*, 1988), although possible negative effects of increased incidence of toxic algal blooms also have been observed (Chang *et al.*, 1998). Changes in ENSO and ocean variability may combine with ocean warming in ways that are poorly understood. Recent New Zealand studies on snapper (Francis 1993, 1994a; Francis *et al.*, 1997), gemfish (Renwick *et al.*, 1998a), and hoki have shown that climatic variations may have a significant impact on spawning success or failure and subsequent recruitment into marine fish populations. Growth rates of juvenile and adult snapper appear to increase when SSTs are warmer (Francis, 1994b). This may have significant effects on the timing and scale of recruitment (e.g., Francis *et al.*, 1997). El Niño appears to have resulted in a westward shift of Chilean jack mackerel in the Pacific and subsequent invasion of this species into New Zealand waters in the mid-1980s (Elizarov *et al.*, 1993). This species now dominates the jack mackerel fishery in many areas. Variations in the abundance and distribution of pelagic large gamefish species in New Zealand may be closely correlated with variability in the ocean climate, with implications for recreational fishers as well as the tourist industry operating from charter boats.

Environmental temperature has a major influence on the population genetics of cold-blooded animals, selecting for temperature-sensitive alleles and genotypes. In New Zealand snapper, differences in allele frequencies at one enzyme marker have been found among year classes from warm and cold summers (Smith, 1979). Such differences could impact survival, growth rates, and reproductive success.

Finally, it should be noted that, if the wildcard of possible reduction or cessation of North Atlantic or Antarctic bottomwater formation were to occur (Manabe and Stouffer, 1994; Hirst, 1999), this could lead to significant changes in deep ocean chemistry, ocean dynamics, and nutrient levels on century time scales. This could have wide, but presently unknown, ramifications for fisheries in Australian and New Zealand waters.

12.5.6. Drought

In the Australia and New Zealand region, droughts are closely related to major drivers of year-to-year and decadal variability such as ENSO, Indian Ocean SSTs, the Antarctic Circumpolar Wave (White and Peterson, 1996; Cai *et al.*, 1999; White and Cherry, 1999), and the Interdecadal Pacific Oscillation (Mantua *et al.*, 1997; Power *et al.*, 1998; Salinger and Mullan, 1999), as well as more or less chaotic synoptic events. These are all likely to be affected by climate change (see Sections 12.1.5 and 12.2.3, and TAR WGI Chapters 9 and 10).

Using a transient simulation with the NCAR CCMO GCM at coarse resolution (R15) (Meehl and Washington, 1996), Kothavala (1999) found for northeastern and southeastern Australia that the Palmer Drought Severity Index indicated longer and more severe droughts in the transient simulation at about $2\times CO_2$ conditions than in the control simulation. This is consistent with a more El Niño-like average climate in the enhanced greenhouse simulation; it contrasts with a more ambivalent result by Whetton *et al.* (1993), who used results from several slab-ocean GCMs and a simple soil water balance model. Similar but less extreme results were found by Walsh *et al.* (2000) for estimates of meteorological drought in Queensland, based on simulations with the CSIRO RCM at 60-km resolution, nested in the CSIRO Mk2 GCM.

A global study by Arnell (1999), using results from an ensemble of four enhanced greenhouse simulations with the HadCM2 GCM and one with HadCM3, show marked decreases in runoff over most of mainland Australia, including a range of decreases in runoff in the Murray-Darling basin in the southeast by the 2050s of about 12–35%. HadCM3 results show large decreases in maximum and minimum monthly runoff. This implies large increases in drought frequency.

The decrease in rainfall predicted for the east of New Zealand by downscaling from coupled AOGCM runs for 2080 and the corresponding increase in temperature are likely to lead to more drought in eastern regions, from East Cape down to Southern Canterbury. Eastern droughts also could be favored

by any move of the tropical Pacific into a more El Niño-like mean state (see Table 3-10). The sensitivity of New Zealand agriculture and the economy to drought events was illustrated by the 1997–1998 El Niño drought, which was estimated to result in a loss of NZ\$618 million (0.9%) in GDP that year. A drought in north and central Otago and dry conditions in Southland associated with the 1998–1999 La Niña resulted in a loss of about NZ\$539 million in GDP (MAF, 2000).

Recurring interest in Australia in policies on drought and disaster relief is evidence of a problem in managing existing climate variability and attempts to adapt (O'Meagher *et al.*, 1998). Present variability causes fluctuations in Australian GDP on the order of 1–2% (White, 2000). Drought and disaster relief helps immediate victims and their survival as producers (e.g., QDPI, 1996) but does not reduce costs to the whole community and in fact may prolong unsuitable or maladapted practices (Smith *et al.*, 1992; Daly, 1994), especially if there is climatic change. Farm productivity models are being used to simulate past and present farm production and to assess causes of and management options for coping with drought (Donnelly *et al.*, 1998). This is contributing to the fashioning of drought assistance and advisory policies.

The potential impact of drought on the Australian economy has declined, in relative economic terms, over time in parallel with the decline in the importance of agriculture to the economy (ABARE, 1997; Wilson and Johnson, 1997). In 1950–1951, the farm sector constituted 26.1% of GDP, whereas currently (1997–1998) it constitutes 2.5%. Similarly, the contribution of the farm sector to Australian exports has fallen from 85.3% (1950–1951) to 19.6% (1997–1998), with a reduction in the total farm sector labor force of about 6%. This despite the fact that farm production has increased over the same period. Thus, drought remains an important issue throughout Australia for social, political, geographical, and environmental reasons (Gibbs and Maher, 1967; West and Smith, 1996; Flood and Peacock, 1999).

Stehlik *et al.* (1999) studied the impact of the 1990 drought on more than 100 individuals from 56 properties in central Queensland and northern NSW to document the social experiences of dealing with drought. They conclude that there is strong evidence that the impact of the extended drought of the 1990s is such that rural Australia will never be the same again: "There is a decline in population: a closing down of small businesses, fewer and fewer opportunities for casual or itinerant work, more and more producers working 'off-farm' and a reduction in available services."

A change in climate toward drier conditions as a result of lower rainfall and higher evaporative demand would trigger more frequent or longer drought declarations under current Australian drought policy schemes, which rely on historical climate data and/or land-use practices on the basis of an expectation of historical climatic variability. A major issue for operational drought schemes is the choice of the most relevant historical period for the relative assessment of current conditions (Donnelly *et al.*, 1998).

Examples of Australian government involvement in rural industries that have been subject to decline in commodity prices over several decades (e.g., wool) suggest that the industries will be supported until the cost to the overall community is too high and the long duration or high frequency of drought declarations is perceived as evidence that the drought policy is no longer appropriate (Mercer, 1991; Daly, 1994). In the case of wool, the shift of government policy from that of support to facilitation of restructuring has involved a judgment about future demand and therefore prices (McLachlan *et al.*, 1999) and has only occurred after an extended period of low prices (Johnston *et al.*, 1999). With a change in climate toward drier conditions, drought policy probably would follow a similar path.

The New Zealand Government response to drought comes under Adverse Climatic Events and Natural Disasters Relief policy that was released in 1995. Government responds only when rare climatic or natural disasters occur on a scale that will seriously impact the national or regional economy and the scale of the response required is beyond the capacity of local resources. The policy is to encourage industry/community/individual response, rather than reliance on government support.

Science has a major role in assessing the probability that recent and current climatic conditions could be the result of natural variability or increased GHGs. At best, these assessments are presented in probabilistic terms (e.g., Trenberth and Hoar, 1997). The public and its representatives will have to judge what constitutes evidence of anthropogenic effects and to what extent future projections and their impacts should be acted on. Because of their impact, future droughts provide a very public focus for assessing the issues of climate change compared to natural variability. Appropriate land-use and management practices can be reassessed by using agricultural system models with CO₂ and climate projections from GCMs (Hall *et al.*, 1998; Howden *et al.*, 1999f; Johnston *et al.*, 1999). However, political judgments between the alternatives of supporting existing land use or facilitating reconstruction are likely to require greater certainty with regard to the accuracy of GCMs than is currently available (Henderson-Sellers, 1993).

One source of adaptation is seasonal and long-lead climate forecasting. This is one area in which climate science already is contributing to better agricultural management, profitability, and, to some extent, adaptation to climate change (Hammer *et al.*, 1991, 2000; Stone and McKeon, 1992; Stone *et al.*, 1996a; Johnston *et al.*, 1999). Indeed, empirical forecasting systems already are revealing the impact of global warming trends (Nicholls *et al.*, 1996b; Stone *et al.*, 1996b), and these systems already are adapting to climate change through regular revision and improvements in forecasting skill.

12.5.7. Pests and Diseases

Cropping, horticulture, and forestry in Australia and New Zealand are vulnerable to invasion by new pests and pathogens for which there are no local biological controls (Sutherst *et al.*,

1996; Ministry for the Environment, 1997). The likelihood that such pests and pathogens—particularly those of tropical or semi-tropical origin—will become established, once introduced to New Zealand, may increase with climate warming.

In-depth case studies are being conducted in Australia to test the performance of pest impact assessment methodologies for estimating the vulnerability of local rural industries to pests under climate change (Sutherst *et al.*, 1996). In New Zealand, pests that already are present may extend their ranges and cause more severe damage. For example, because of the reduced incidence of frosts in the north of New Zealand in recent years, the tropical grass webworm (*Herpetogramma licralis*) has increased in numbers and caused severe damage in some pastures in the far north.

The vulnerability of horticultural industries in Australia to the Queensland fruit fly *Bactrocera (Dacus) tryoni* under climate change was examined by Sutherst *et al.* (2000). Vulnerability was defined in terms of sensitivity and adaptation options. Regional estimates of fruit fly density, derived with the CLIMEX model, were fed into an economic model that took account of the costs of damage, management, regulation, and research. Sensitivity analyses were used to estimate potential future costs under climate change by recalculating costs with increases in temperature of 0.5, 1.0, and 2°C, assuming that the fruit fly will occur only in horticulture where there is sufficient rainfall or irrigation to allow the crop to grow. The most affected areas were the high-altitude apple-growing areas of southern Queensland and NSW and orange-growing areas in the Murrumbidgee Irrigation Area. Apples and pears in southern and central NSW also were affected. A belt from southern NSW across northern Victoria and into South Australia appeared to be the most vulnerable.

Adaptation options were investigated by considering, first, their sustainability under present conditions and, second, their robustness under climate variability and climate change. Bait spraying is ranked as the most sustainable, robust, and hence most promising adaptation option in both the endemic and fruit fly exclusion zones, but it causes some public concern. The sterile insect technique is particularly safe, but there were concerns about costs, particularly with large infestations. Exclusion is a highly effective approach for minimizing the number of outbreaks of Queensland fruit fly in fly-free areas, although it is vulnerable to political pressure in relation to tourism. These three techniques have been given the highest priority.

12.5.8. Sustainability

Ecological and indeed economic sustainability has become a major issue in Australia and New Zealand (e.g., Moffatt, 1992). Australian government policy has been to integrate sustainability issues within a raft of policies and programs relating national heritage, land care, river care, wetlands, and carbon sequestration (Commonwealth of Australia, 1996). In both countries, land-use change and exotic pests and diseases, notably feral animals,

are threatening many native species and ecosystems. In Australia, this is exacerbated by land degradation, notably soil erosion and increasing salinization brought about by loss of vegetative cover and rising water tables resulting from reduced evapotranspiration in catchments and irrigation with inadequate drainage.

These issues have been reviewed in several recent papers and reports, including a paper prepared for the Australian Prime Minister's Science, Engineering and Innovation Council (PMSEIC, 1999). This paper states that continuing degradation is costing Australia dearly in terms of lost production, increased costs of production and rehabilitation, possible damage to a market advantage as a producer of "clean and green" goods, increasing expenditures on building and repairing infrastructure, biodiversity losses, declining air and water quality, and declining aesthetic value of some landscapes.

PMSEIC (1999) states that the Australian community expects the use and management of resources to be economically, environmentally, and socially sustainable, which will require changes in management processes backed by science and engineering innovation. The report emphasizes that individual problems are linked and that an integrated approach is necessary to combat degradation and pursue remediation.

Climate change may exacerbate these problems by increasing opportunities for colonization by exotic species (e.g., woody weeds), by affecting the water balance and water tables, and by increasing erosion rates and flood flows through heavier rain events. Increased fire frequency also may threaten remnant forest and other ecosystems and impact soil degradation.

12.5.9. Global Markets

The impacts of climate change on food and fiber production in Australasia will be direct and indirect, the latter through changing global supply and demand influenced by climatic changes in other parts of the globe. Because a large proportion of food and fiber production in both countries is exported, the effect of commodity prices already is a major influence on the areas and mix of plantings and production, as well as profitability (Stafford Smith *et al.*, 1999). Adaptation in both countries has taken the form of changes in the mix of production between, for example, wool, lamb and beef, dairy products, horticulture and viticulture, and, most recently, farm and plantation forestry, as well as increasing exports of value-added and processed products. Increased variability of production resulting from climate change may restrict expansion of such added-value products. Response to markets has led to rapid changes in some sectors, but this is more difficult for commodities that require longer investment cycles, such as viticulture and forestry. Nevertheless, adaptation to a highly variable environment is a feature of Australian agriculture, and adaptations to climate change also may contribute to exports of agricultural technology. Improved forecasts of commodity prices and longer term trends in supply and demand, taking into account seasonal climate

and ENSO forecasts, are a major means of adaptation. This will be especially important for climate change impacts and will require understanding of global effects.

In New Zealand, there are implications for future wood flows of scenarios for rates of increased areas of forest plantations. Currently, of the 18 million m³ log volume harvested annually in New Zealand, one-third is used for domestic consumption and two-thirds is exported. Using a 50,000 ha yr⁻¹ planting rate, by 2010 the ratio is expected to be 20:80, and by 2025 it is expected to be 5:95. Clearly, there is a need for an export focus. If sufficiently large export markets do not materialize for New Zealand, a major alternative use of wood within New Zealand could be for energy, especially if the economics change as a result of external considerations.

12.5.10. Indigenous Resource Management

Recognition of indigenous land rights in both countries recently has caused a much greater proportion of both countries to come back under the management control of Aboriginal and Maori peoples (Coombs *et al.*, 1990; Langton, 1997). In many situations, this has led to less intense economic exploitation, with more varied land use, (e.g., for low-intensity farming and pastoralism, combined with some horticulture, fishing, and ecotourism). Europeans in both countries have much to learn from traditional indigenous knowledge of land management, including the traditional custodianship ethic—particularly with regard to climatic fluctuations, extreme events, and sustainability. Indigenous knowledge may well lead to greater exploitation of indigenous species for nutritional and medicinal purposes. On the other hand, the indigenous people also have much to gain from greater economic and technical expertise related to markets and new technologies and products.

For example, Aboriginal traditional fire management regimes permitted reproduction of fire-dependent floral species and widespread savannas suitable for grazing. Through the creation of buffer zones, these regimes protected fire-intolerant communities such as monsoonal forests (Langton, 2000). Removal of Aboriginal groups into settlements led to areas where wildfires, fueled by accumulated biomass, cause extensive damage. Research in collaboration with traditional Aboriginal owners recently has played a key role in joint management of National Parks where customary Aboriginal burning is promoted to conserve biodiversity.

Andersen (1999) looks at the commonly accepted contrast between European (“scientific”) and Aboriginal (“experiential”) perspectives in fire management and concludes that in fact, European fire managers often lack clear land management goals and are no more “scientific” than Aboriginal fire managers. He argues that the task now is to introduce scientific goals into both European and Aboriginal fire management. This may be particularly applicable in adapting to changing vegetation patterns and increased fire danger in a changing climate.

12.6. Settlements and Industry

12.6.1 Infrastructure

Climate change will affect settlements and industry through changes in mean climate and changes in the frequency and intensity of extreme events. Obviously, changes in average climate affect design and performance, including variables such as heating and cooling demand, drainage, structural standards, and so forth. However, in many cases average climate is only a proxy for design standards that are developed to cope with extreme demands or stresses such as flooding rains, gale-force wind gusts, heat waves, and cold spells.

If the severity, frequency, or geographic spread of extreme events changes, the impact of such changes on infrastructure may be severe. For instance, movement of tropical cyclones further south into areas where infrastructure is not designed to cope with them would have significant consequences.

The rate and nature of degradation of infrastructure is directly related to climatic factors. Computer models to predict degradation as a function of location, materials, and design and construction factors have been developed (Cole *et al.*, 1999a,b,c,d). Because buildings and infrastructure that are being constructed now will have projected lives until 2050, placement, design, and construction changes to guarantee this life against climate change are needed. Moreover, the effects of degradation and severe meteorological events may have an unfortunate synergy. Increase in the rate of degradation as a result of climate change may promote additional failures when a severe event occurs. If the intensity or geographical spread of severe events changes, this effect may be compounded.

In New Zealand, a Climate Change Sustainability Index (CCSI) developed by Robinson (1999) rates the impact of climate change on a house and the contribution to climate change of GHG emissions from the house. The index includes GHG emissions from heating and cooling, comfort, tropical cyclone risk, and coastal and inland flooding. Basically, the closer the house is to sea level and/or a river or waterway, the lower the CCSI. Higher temperatures and rainfalls in general will shorten the life span of many buildings.

The impact of extreme climatic events already is very costly in both countries. This has been documented for Australia in Pittock *et al.* (1999), where it is shown that major causes of damage are hail, floods, tropical cyclones, and wildfire. In New Zealand, floods and landslides are the most costly climatically induced events, with strong winds and hail also important. The International Federation of Red Cross and Red Crescent Societies (1999) report estimates damages from a combination of drought, flood, and high wind (including cyclones, storms, and tornadoes) in Oceania (Australia, New Zealand, and the Pacific islands) to be about US\$870 million yr⁻¹ over the years 1988–1997. This figure apparently does not include hail damage, which is a major cost. Insured losses from a single severe hailstorm that struck Sydney in April 1999 were

estimated at about AU\$1.5 billion (roughly US\$1 billion) (NHRC, 1999).

A scoping study for Queensland Transport (Queensland Transport *et al.*, 1999) has identified vulnerabilities for the Queensland transport infrastructure that will require adaptation. Infrastructure considered include coastal highways and railways, port installations and operations (as a result of high winds, sea-level rise, and storm surges), inland railways and roads (washouts and high temperatures), and some airports in low-lying areas. Key climate variables considered were extreme rainfall, winds, temperatures, storm surge, flood frequency and severity, sea waves, and sea level. Three weather systems combining extremes of several of these variables—tropical cyclones, east coast lows, and tropical depressions—also were assessed.

Regional projections for each of these variables were created, with levels of confidence, for four regions of Queensland for 2030, 2070, and 2100. Overall, the potential effects of climate change were assessed as noticeable by 2030 and likely to pose significant risks to transport infrastructure by 2070, if no adaptation were undertaken. Setting new standards, in the form of new design criteria and carrying out specific assessments in prioritized areas where infrastructure is vulnerable, was recommended for roads and rail under threat of flooding, bridges, and ports. Detailed risk assessments for airports in low-lying coastal locations were recommended.

Many ports and coastal communities already suffer from occasional storm-surge flooding and wave damage. A series of studies identifies particular vulnerabilities in some Queensland coastal cities (Smith and Greenaway, 1994; AGSO, 1999). Inland

and coastal communities also are vulnerable to riverine flooding (Smith *et al.*, 1997; Smith, 1998a). A key feature of these studies is the nonlinear nature of damage response curves to increased magnitude and frequency of extreme events. This is partly because of exceedance of present design standards and the generally nonlinear nature of the damage/stress relationship, with the onset of building collapse and chain events from flying or floating debris (Smith, 1998a).

A study by McInnes *et al.* (2000; see also Walsh *et al.*, 2000) estimates the height of storm tides at the city of Cairns, in northern Queensland, for the present climate and for an enhanced greenhouse climate in which—based on the findings of Walsh and Ryan (2000)—the central pressure of tropical cyclones was lowered by about 10 hPa and the standard deviation of central pressure (a measure of variability) was increased by 5 hPa but the numbers were unchanged. Cairns is a low-lying city and tourist center, with a population of about 100,000 that is growing at about 3% yr⁻¹. Under present conditions, McInnes *et al.* (2000) found that the 1-in-100-year event is about 2.3 m in height; under the enhanced greenhouse conditions, it would increase to about 2.6 m, and with an additional 10- to 40-cm sea-level rise, the 1-in-100-year event would be about 2.7–3.0 m (see Figure 12-4). This would imply greatly increased inundation and wave damage in such an event, suggesting a possible need for changes in zoning, building regulations, and evacuation procedures.

Urban areas also are vulnerable to riverine flooding (Smith, 1998a) and flash floods exacerbated by fast runoff from paved and roofed areas (Abbs and Trinidad, 1996). Considerable effort has gone into methods to improve estimates of extreme

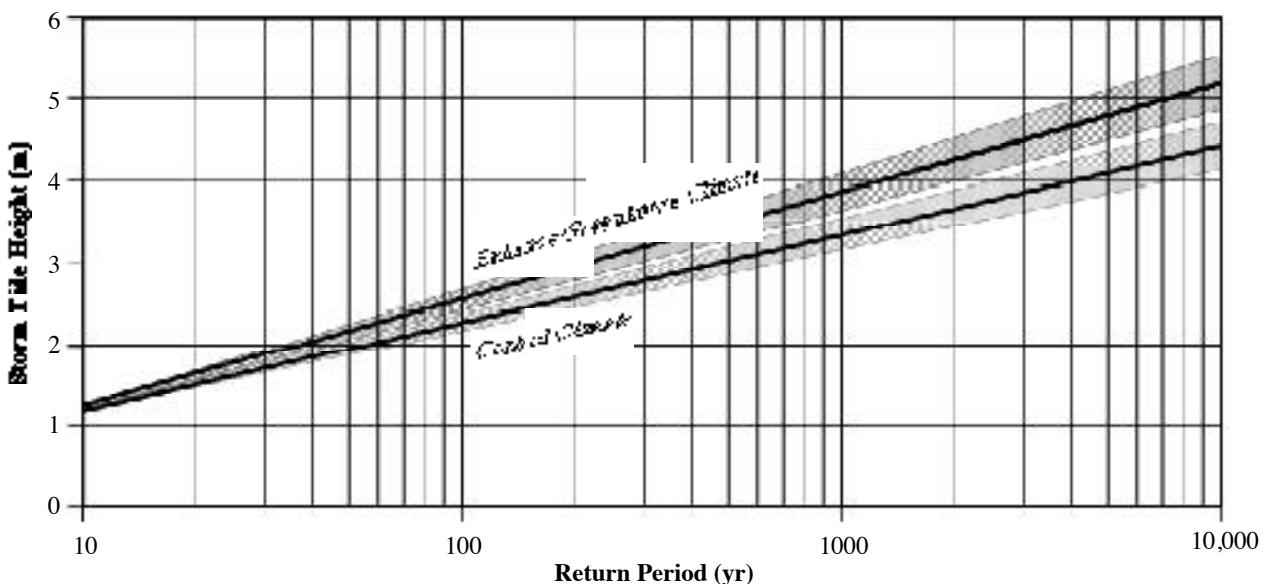

Figure 12-4: Simulated return periods (average time between events) of storm tides in Cairns, Queensland, for present climate (lower curve), and for enhanced greenhouse climate (upper curve), assuming 10 hPa lowering of central pressures and increased variability (additional 5 hPa standard deviation) of tropical cyclones. Anticipated mean sea-level rise should be added to these estimates. Uncertainty ranges of simulations are shown via grey shading (Walsh *et al.*, 2000).

precipitation under present conditions (Abbs and Ryan, 1997; Abbs, 1998). Schreider *et al.* (2000) applied a rainfall-runoff model to three different catchments upstream of Sydney and Canberra under doubled-CO₂ conditions. They found increases in the magnitude and frequency of flood events, but these effects differed widely between catchments because of the different physical characteristics of each catchment.

The safety of publicly owned and private dams also is a major issue (ANCOLD, 1986; Webster and Wark, 1987; Pisaniello and McKay, 1998) that is likely to be exacerbated by increases in rainfall intensity and probable maximum precipitation (Pearce and Kennedy, 1993; Fowler and Hennessy, 1995; Abbs and Ryan, 1997; Hennessy *et al.*, 1997).

Vulnerability depends not only on the severity of the potential impacts but on hazard mitigation measures put in place (including time- and location-specific hazard prediction), crisis management capability, and policies that avoid or minimize the hazard. These matters are discussed in Smith (1998a), Handmer (1997), and Kouzmin and Korac-Kakabadse (1999).

12.6.2. Investment and Insurance

According to Pittock *et al.* (1999), based on Insurance Council of Australia figures, major climatic catastrophe insurance losses from 1970 through 1996 averaged AU\$208 million yr⁻¹. Of these losses, nearly half were from tropical cyclones; one-quarter were from hail. Other flooding and storm damage accounted for most of the rest; losses from fire were less than 10% of the total. Figures provided by the Insurance Council of New Zealand show that insurance industry payouts for New Zealand climatic catastrophes averaged NZ\$23.5 million yr⁻¹ (inflation-adjusted) between 1980 and 1998.

In an Australian study of insurance and climate change, Leigh *et al.* (1998a) examined four major climatic disasters: the Brisbane floods of 1974, the South Australian bushfires of 1983, the Nyngan floods of 1990, and the New South Wales bushfires of 1994. Total estimated damage from these four events was AU\$178 million, \$200–400 million, \$47 million, and \$168 million, respectively; however, the insurance industry bore only 39, 31, 9, and 33% of the cost, respectively. Government relief assistance was roughly equal to that from the insurance industry, and about 70–90% of that was provided by the federal government.

Leigh *et al.* (1998b) have reported on the potential for adaptation to climate change by the insurance industry in Australia by setting out an array of reactive and proactive options. Responses include reducing insurers' exposure or controlling claims through risk management to encourage disaster mitigation measures. The latter has the advantage of reducing overall losses to the community, rather than merely redistributing them among stakeholders. Natural disaster insurance can be more selective, so that good risks are rewarded and poor risks are penalized. Such rate-based incentives can motivate stakeholders to plan to

more effectively minimize exposure to disasters. However, some individuals and businesses may have difficulties if some previously insurable properties become uninsurable against flood because of an increase in location-specific flood frequency. Government intervention and possible co-insurance between government and insurers also were canvassed. Cooperation between insurers and governments to ensure development and enforcement of more appropriate building codes and zoning regulations was regarded as desirable.

12.6.3. Energy and Minerals

Energy demand, essentially for air conditioning, is likely to increase in the summer and in more tropical parts of Australia and New Zealand (Lowe, 1988). However, winter demand for heating will similarly decrease in the winter and in cooler areas. Thus, increasing population in tropical and subtropical parts of Australia may combine with climate change to increase overall energy demand.

The other major uses of energy in Australia are transport and manufacturing. Transport demand generally will increase because of population growth but may be significantly affected by the changing distribution of growth across the continent, which in turn may be affected by climate change.

In general, warming will slightly reduce energy efficiency in most manufacturing, including electricity generation, but this is relatively minor compared with possible technological improvements in efficiency. Any decrease in water supply (see Section 12.3.1), such as is expected in the Murray-Darling basin in Australia, would impact adversely on hydroelectric generation and cooling of power stations, especially where there already is competition between water uses. Fitzharris and Garr (1996) predict benefits for hydroelectricity schemes in New Zealand's Southern Alps because they expect less water will be trapped as snow in the winter, which is the time of peak energy demand for heating.

12.6.4. Coastal Development and Management, Tourism

Economic development is proceeding rapidly in many coastal and tropical areas of Australia and New Zealand. This is fueled partly by general economic and population growth, but it is amplified in these regions by resource availability, shipping access for exports, attractive climates and landscapes, and the growth of the tourism industry. This selective growth in investment is leading to greater community risk and insurance exposure to present and future hazards, while many classes of hazard are expected to increase with global warming (see Table 3-10). Thus, present development trends are likely to make the impacts of climate change worse, especially for sea-level rise and increasing intensity of tropical cyclones. Particular attention should be paid to the implications for the risk to life and property of developments in coastal regions, as well as ways to reduce vulnerability to these hazards. Possible adaptations

include improved design standards, zoning, early warning systems, evacuation plans, and emergency services.

Management of waste and pollution from settlements and industry will become more critical because of the potential for flood and waste discharge to impinge on water quality, including inland and coastal algal blooms, as well as adverse effects on ecotourism associated with damage to coral reefs (see Section 12.4.7). Sediment and pollution fluxes into the GBR lagoon already are a major concern (Larcombe *et al.*, 1996). This could be exacerbated by greater flood flows (see Sections 12.1.5.3 and 12.6.1) and increasing population and development. Higher temperatures will accentuate algal blooms.

The other major tourism and recreation sector that is likely to be seriously affected by climate change is the ski industry, which will be faced with significant reductions in natural snow cover (see Sections 12.2 and 12.4.4) and limited acceptance of artificial snow (Konig, 1998). Also, as the potential ranges of certain agricultural pests such as the fruit fly (see Section 12.5.7) and disease vectors such as mosquitos (see Section 12.7.1) increase, possible transfer of such pests and diseases through tourism may become an increasing issue.

12.6.5. Risk Management

As a result of the large uncertainties associated with possible future climate, as well as the stochastic nature of extreme events, there is great need for a risk management approach to development planning and engineering standards. In accordance with the precautionary principle, uncertainty should not be allowed to stand in the way of risk reduction measures, which in any case often will have other benefits such as protection of coastal and riverine environments.

Australia and New Zealand have jointly developed a risk management standard (Standards Australia and Standards New Zealand, 1999) that is designed to provide a consistent vocabulary and assist risk managers by delineating risk management as a four-step process that involves risk identification, risk analysis, risk evaluation, and risk treatment. Beer and Ziolkowski (1995) specifically examined environmental risk management and produced a risk management framework.

Examples of the application of a risk analysis approach are given in Sections 12.5.2 for pastures in New Zealand, 12.6.1 for storm surges, and 12.8.4 for irrigation water demand.

12.7. Human Health

12.7.1. Diseases and Injuries

Impacts of climate and climate change on health can be direct or indirect. Direct effects that are readily attributed to climate include heat stress and the consequences of natural disasters. However, the resulting burden of disease and injury may be

less than that from indirect effects such as disrupted agriculture and reduced food security. Positive and negative effects can be anticipated, but there is insufficient evidence to state confidently what the balance will be (see Chapter 9). We have not attempted to estimate the overall economic costs of climate change impacts on health in the Australia-New Zealand region because there is considerable debate about the derivation and interpretation of monetary costs (see Chapter 19).

Guest *et al.* (1999) compared heat-related deaths in the five major Australian cities in the period 1977–1990 with those expected under different climate change scenarios (CSIRO, 1996a) for the year 2030. They estimate that greenhouse-induced climate change would increase climate-related deaths in the summer by a small amount, but this would be more than balanced by a reduction in climate-related deaths in the winter. Overall, this resulted in a decrease of 8–12% in climate-attributable mortality under the CSIRO “high” scenario compared to a scenario with no climate changes (but expected population changes).

The only study in New Zealand to date of elevated temperatures and mortality was conducted by Hales *et al.* (2000). Daily numbers of deaths in Christchurch were compared with measures of weather and ambient particulate pollution from June 1988 to October 1993. Above the third quartile (20.5°C) of summer maximum temperatures, an increase of 1°C was associated with a 1.3% increase (95% confidence interval, 0.4–2.3%) in all-cause mortality and a slightly greater increase in mortality from respiratory conditions. There was no evidence of interaction between the effects of temperature and particulate air pollution. Greater than expected numbers of deaths also occurred during winter days of low temperature, although this was not statistically significant. This suggests that cold-related deaths will be less common in a warmer climate. However, the mechanisms that explain excess winter mortality are not well understood.

The effects of solar ultraviolet (UV) radiation on skin cancer, skin aging, and cataracts of the eye are particularly important in New Zealand and Australia, which already have the highest skin cancer rates in the world (Marks *et al.*, 1989). The etiology of skin cancer is not fully understood, and factors other than sun exposure undoubtedly are involved. However, UV-B is a key factor. Present levels of UV radiation in this region are relatively high and have been increasing in the past 20 years (McKenzie *et al.*, 1999). It is expected with a high degree of confidence that if UV flux at ground level increases at a faster rate as a result of greenhouse-related cooling in the upper stratosphere and subsequent slowdown in the breakdown of ozone-depleting substances, the incidence of melanomas and other skin cancers will increase (Armstrong, 1994; Longstreth *et al.*, 1998). Australians and New Zealanders of pale-skinned European descent will be particularly vulnerable to these effects. This topic is discussed in more detail in Chapter 9.

The numbers of notified cases of arbovirus infections (illnesses caused by insect-borne viruses) have increased in Australia in recent years (Russell, 1998), and exotic insect species such as *Aedes albopictus* and *Aedes camptorhynchus* that are competent

vectors of viruses such as dengue and Ross River virus have been detected at New Zealand borders (Hearnden *et al.*, 1999).

There is good evidence that the frequency of mosquito-borne infections in this region is sensitive to short-term variations in climate. For example, outbreaks of Ross River fever and Murray Valley encephalitis in southeast Australia tend to follow heavy rainfall upstream in the Murray-Darling catchment (Nicholls, 1993; Maelzer *et al.*, 1999). In other parts of Australia where the predominant vector is the coastal mosquito *A. camptorhynchus*, variations in sea level also contribute to outbreaks of illness from Ross River virus (Mackenzie *et al.*, 1994). No quantitative estimates have been made of the possible impact of long-term climate change on rates of vector-borne infections. However, present climate change scenarios suggest that parts of Australia and New Zealand will experience conditions that are more favorable to breeding and development of mosquitoes (Bryan *et al.*, 1996). In these areas, warmer conditions will tend to extend the range of reservoir hosts, decrease the extrinsic incubation period of arboviruses, and encourage outdoor exposure of humans (Weinstein, 1997). Therefore, it is expected with a high degree of confidence that the potential for insect-borne illness will increase. Whether this potential is translated into actual occurrence of disease will depend on many other factors, including border security, surveillance, vector eradication programs, and effectiveness of primary health care.

Endemic malaria was present in North Queensland and the Northern Territory until early in the 20th century (Ford, 1950; Black, 1972). Vectors to transmit the disease still are present in that part of Australia, and climate change will favor the spread of these mosquitoes southward (Bryan *et al.*, 1996). The disease-limiting factor at present is the effectiveness of local health services that ensure that parasitemic individuals are treated and removed from contact with mosquitoes. Therefore, climate change on its own is unlikely to cause the disease to return to Australia, unless services are overwhelmed. In New Zealand there currently are no mosquitoes that are capable of transmitting malaria; even under global warming scenarios, the possibility of an exotic vector becoming established is considered to be slight (Boyd and Weinstein, 1996).

Studies of the prevalence of asthma in New Zealand have shown an association with average temperature (Hales *et al.*, 1998). Electorates with lower mean temperatures tend to have lower levels of asthma, after adjusting for confounding factors. The reason is not clear but may be related to exposure to insect allergens. If this were so, warming may tend to increase the frequency of asthma, but too little is known about the causes of the disease to forecast the impact of climate change on asthma in Australia and New Zealand.

Climate change may influence the levels of several outdoor air pollutants. Ozone and other photochemical oxidants are a concern in several major Australian cities and in Auckland, New Zealand (Woodward *et al.*, 1995). In Brisbane, Australia, current levels of ozone and particulates have been associated with increased hospital admission rates (Petroeshevsky *et al.*,

1999) and daily mortality in persons ages 65 and over (Simpson *et al.*, 1999). Outdoor particulate pollution in the winter (largely generated by household fires) has been associated with increased daily mortality in Christchurch, New Zealand (Hales *et al.*, 2000). Formation of photochemical smog is promoted in warmer conditions, although there are many other climatic factors—such as windspeed and cloud cover—that are at least as important as temperature but more difficult to anticipate. A rise in overnight minimum temperatures may reduce the use of fires and hence emissions of particulates, but it is not known how this might affect pollution and population exposures.

Toxic algal blooms may affect humans as a result of direct contact and indirectly through consumption of contaminated fish and other seafood. At present this is not a major public health threat in Australia or New Zealand, but it is an economic issue (because of effects on livestock and shellfish). It could affect very large numbers of people (Oshima *et al.*, 1987; Sim and Wilson, 1997). No work has been carried out in Australia or New Zealand relating the health effects of algal blooms to climate. Elsewhere in the Pacific, it has been reported that the incidence of fish poisoning (resulting from ingestion of fish contaminated with ciguatoxins) is associated with ocean warming in some eastern islands, but not elsewhere (Hales *et al.*, 1999). It is uncertain whether these conditions will become more common in Australia and New Zealand with projected climate change.

Since 1800, deaths specifically ascribed to climatic hazards have averaged about 50 yr⁻¹ in Australia (Pittock *et al.*, 1999), of which 40% are estimated to be caused by heat waves and 20% each from tropical cyclones and floods. Although this is not necessarily representative of present conditions because of changing population, statistical accounting, and technologies, it is an order of magnitude estimate. This suggests that if heat waves, floods, storm surges, and tropical cyclones do become more intense, some commensurate increase in deaths and injuries is possible. Whether this will occur will depend on the adequacy of hazard warnings and prevention. Statistics from other developed countries with larger populations indicate a recent trend toward increasing damages but decreasing death and injury from climatic hazards. Thus, hazard mitigation is possible, although it must more than outweigh increased exposure resulting from larger populations in hazardous areas.

12.7.2. Vulnerability

Climate impacts are determined not just by the magnitude of environmental change but also by the vulnerability of exposed populations. Examples of biophysical vulnerability are the susceptibility of pale-skinned populations to the effects of UV radiation and the vulnerability of isolated island ecosystems such as New Zealand's to invasion by exotic species (including disease vectors). Another example is infections spread to humans from animals, such as cryptosporidiosis. New Zealand has relatively high rates of notified cases of this infection (Russell *et al.*, 1998). This may be related to the conjunction of

high densities of livestock and unprotected human drinking water supplies. In such a setting, increased rainfall intensity would promote transmission of the pathogen (by washing animal excreta containing the organism into the water supply).

Woodward *et al.* (1998) reviewed social determinants of vulnerability to health effects of climate change in the Pacific region. Australia and New Zealand are two of the wealthiest countries in the region, with relatively low population densities and well-developed social services. For these reasons, Australia and New Zealand are likely to be less vulnerable overall to many of the threats to health from climate change than neighboring countries. However, within both countries there are groups that are particularly susceptible to poor health. Sources of disadvantage include poverty, low housing standards, high-risk water supplies, lack of accessible health care, and lack of mobility. These factors tend to be concentrated in particular geographical locations and ethnic groups (Crampton and Davis, 1998) and carry with them increased vulnerability to most of the hazards that are associated with climate variability and climate change.

There have been no studies in New Zealand or Australia that have attempted to quantify vulnerability to disease and injury. Some work has been carried out on indices of environmental vulnerability (e.g., Kaly *et al.*, 1999). These studies have focused on measures of the resilience and integrity of ecosystems; with further development, they may assist in future forecasts of the impacts of climate change on human health.

12.7.3. Complexities of Forecasting Health Effects

There is no opportunity to study directly, in a conventional controlled fashion, the effects on health of climate change. Research to date in Australia and New Zealand has concentrated on the association of climate variability, at relatively restricted spatial and temporal scales, with the incidence of disease. It is not simple to extrapolate from these findings to long-term climate change. This problem is not particular to Australia and New Zealand, but there are informative local examples in the literature. These include analyses of roles of climate-related variables other than temperature (e.g., the critical effects of wind on air pollution, rainfall density on mosquito breeding, and humidity on heat stress); interactions with local ecosystems (e.g., the potential for amplification of certain arboviruses in New Zealand wildlife); and human behaviors that influence exposures (such as changing patterns of skin protection and the implications for UVexposures) (Hill *et al.*, 1993; Russell, 1998b).

12.7.4. Public Health Infrastructure

A major challenge in Australia and New Zealand is how to protect and improve public health systems that deal with threats to health such as those that will potentially accompany climate change. Examples include border controls to prevent introduction of pathogens (including those from livestock and

animal imports), measures required to ensure safe food and clean water, and primary health care services that reach the most disadvantaged and vulnerable members of the community. Threats to these systems include restrictions on government spending, increasing demands, and fragmented systems of purchase and provision of services.

With vector-borne diseases, the major challenge in Australia will be to control the expansion and spread of diseases that already are present in the country, such as Ross River virus and Murray Valley encephalitis—which are strongly influenced by climatic events. Introduction of new pathogens from close neighbors such as Papua New Guinea also is possible. Imported Japanese encephalitis and malaria remain serious threats, influenced principally by the numbers of people moving across the Torres Strait and the effectiveness of health services in the far north of Australia.

In New Zealand, the key issue for the health sector is how to prevent the introduction of vector-borne disease, particularly arboviruses carried by mosquitoes. Competent vectors for conditions such as Ross River virus and dengue have been detected frequently at entry points in recent years. This is likely to be a result of increasing trade and passenger traffic between New Zealand and other countries, as well as heightened awareness and better reporting. Eradication programs are expensive, and they are feasible only when the spread of exotic mosquitoes is confined. With repeated incursions and/or dispersion, the emphasis is likely to shift to control strategies.

12.7.5. Design of Human Environments

Several measures can be taken to better design human environments to cope with potential health stresses resulting from climate change. These measures include:

- Air conditioning and other measures to reduce exposure to heat
- Limiting exposure to disease vectors by measures such as use of screens on doors and windows and restriction of vector habitats (especially near waterways and urban wetlands)
- Land-use planning to minimize ecological factors that increase vulnerability to potential climate changes, such as deforestation, which increases runoff and the risk of flood-related injury and contamination of water supplies; animal stock pressures on water catchments; and settlement of marginal or hazardous areas such as semi-tropical coastal areas that are prone to storms and close to good vector breeding sites.

12.7.6. Vulnerable Populations, including Indigenous and Poor

Woodward *et al.* (1998) have argued that the effects of climate change on health will be most severe in populations that

already are marginal. For these populations, climate change and sea-level rise impacts will be one more cause for “overload.” In general, indigenous people in Australia and New Zealand are vulnerable to the effects of climate change because they tend to be excluded from mainstream economic activity and modern technological education and experience higher levels of poverty, lower rates of employment, and higher rates of incarceration than the overall population. These factors have widespread and long-term impacts on health (Braaf, 1999).

For example, Northern Territory health data for 1992–1994 show that the mortality rate for indigenous people was 3.5–4 times greater than that for nonindigenous people. Life expectation at birth was 14–20 years lower for indigenous Australians than for nonindigenous Australians (Anderson *et al.*, 1996). The indigenous population displays diseases and health problems that are typical of developed and developing nations. This includes high rates of circulatory diseases, obesity, and diabetes, as well as diarrheal diseases and meningococcal infections. High rates of chronic and infectious diseases affect individual and community well-being and reduce resilience to new health risks (Braaf, 1999).

A changing climate has implications for vector-borne and waterborne diseases in indigenous communities. In the “Top End” of the Northern Territory during the wet season, hot and humid conditions are conducive for vectors of infectious diseases endemic in the region. Vectors include flies, ticks, cockroaches, mites, and mosquitoes. Flies can spread scabies and other diseases. Mosquitoes are vectors for Australian encephalitis and endemic polyarthritis. Giardia and shigella are water-borne diseases that are common among indigenous children in the region. Both can be spread from infected people to others through consumption of infected food and untreated water. Existing and worsening overcrowded housing conditions, poor sanitation, and poor housing materials create breeding grounds for infection. Climate changes and sea-level rise—which create conditions that are suitable for new vectors (such as malaria) or expand distributions of existing vectors—may expose such vulnerable populations to increased risks.

In New Zealand, the gap between the health of indigenous people and the remainder of the population is less marked than in Australia but is substantial nevertheless. In 1996, life expectancy at birth was 8.1 years less for Maori females than for non-Maori females and 9.0 years less for Maori males than for non-Maori males (Statistics New Zealand, 1998a). As in Australia, this difference is associated with and partly caused by poorer economic circumstances and lack of appropriate, effective services (Durie, 1994). Consequently, Maori are at greater risk of health problems related to climate variability and climate change. An example is the lack of reticulated water supplies in the East Cape of the North Island, an area in which the population is predominantly Maori and in many cases cannot afford to truck in water in times of drought.

Impact assessments that consider only biophysical relationships between climate and health will be inadequate in evaluating

indigenous health outcomes. The possibility—or, indeed, likelihood—that people may have very different views concerning what makes them vulnerable to climate change, which impacts may be significant, and what responses may be implemented also will need to be considered (Braaf, 1999).

The present social circumstances of indigenous peoples provide a poor basis on which to build adaptation responses to climate change threats. Thus, policies that aim to improve resilience to climate change impacts could encompass efforts to reduce relevant social liabilities—poverty, poor education, unemployment, and incarceration—and support mechanisms that maintain cultural integrity. Adaptive strategies could pursue economic development of these communities while sustaining the environments on which these populations are dependent (Howitt, 1993).

In other parts of the Pacific, there are many countries that are particularly susceptible to the effects of climate change—especially low-lying island states, which are likely to be severely affected by sea-level rise and increases in storm activity. Australia and New Zealand have close relations with many of the Pacific island states. For example, New Zealand has particular responsibilities for Niue, the Cook Islands, and Tokelau and contains substantial expatriate communities from most of the islands. Climate-related threats to these islands (see Chapter 17) would impact immediately on Australia and New Zealand.

12.8. Adaptation Potential and Vulnerability

12.8.1. Adaptation and Possible Benefits of Climate Change

It has not been assumed that all the impacts of climate change will be detrimental. Indeed, several studies have looked at possible benefits. Moreover, adaptation is a means of maximizing such gains as well as minimizing potential losses.

However, it must be said that potential gains have not been well documented, in part because of lack of stakeholder concern in such cases and consequent lack of special funding. Examples that have not been fully documented include the possible spread of tropical and subtropical horticulture further poleward (but see some New Zealand studies, on kiwi fruit, for example—Salinger and Kenny, 1995; Hall and McPherson, 1997b). In southern parts of Australia and New Zealand, notably Tasmania, there could be gains for the wine industry, increased comfort indices and thus tourism, and in some scenarios increased water for hydroelectric power generation.

Guest *et al.* (1999) have documented possible decreases in winter human mortality alongside possible increased summer mortality (see Section 12.7.1), and Howden *et al.* (1999d) have shown that Australian wheat yields may increase for 1 or 2°C warming, before showing declines at greater warmings (see Section 12.5.3 and Figure 12-3). A similar situation may apply to forestry (see Section 12.5.4). Such studies take account of gains from increased CO₂ concentrations. Changes in overseas

production and thus in markets in some cases also could lead to greater demand and higher prices for Australian and New Zealand primary products (see Section 12.5.9), but only if such changes do not disrupt world trade in other ways (e.g., lower capacity to pay).

Vulnerability and adaptation to climate change must be considered in the context of the entire ecological and socioeconomic environment in which they will take place. Indeed, adaptations will be viable only if they have net social and economic benefits and are taken up by stakeholders. Adaptations should take account of any negative side effects, which would not only detract from their purpose but might lead to opposition to their implementation (PMSEIC, 1999).

Adaptation is the primary means for maximizing gains and minimizing losses. This is why it is important to include adaptation in impact and vulnerability studies, as well as in policy options. As discussed in Chapter 18, adaptation is necessary to help cope with inevitable climate change, but it has limits; therefore, it would be unwise to rely solely on adaptation to solve the climate change problem.

In some cases adaptation may have co-benefits. For example, reforestation to lower water tables and dryland salinization or to reduce storm runoff may provide additional income and help with mitigation (reduction of GHG emissions). However, other potential adaptations may be unattractive for other reasons (e.g., increased setbacks of development in coastal and riverine environments). These considerations have particular application in Australia and New Zealand. Studies of adaptation to climate change in Australia and New Zealand are still relatively few and far between. They are summarized in the remainder of this section.

12.8.2. Integrated Assessments and Thresholds

Over the past decade there have been several national and regional assessments of the possible impacts of climate change. A regional assessment for the Macquarie River basin was done by Hassall and Associates *et al.* (1998, reported in Basher *et al.*, 1998); Howden *et al.* (1999d) made a national assessment for terrestrial ecosystems (see Section 12.5). Two other preliminary regional assessments cover the Hunter Valley in NSW (Hennessy and Jones, 1999) and the Australian Capital Territory (Baker *et al.*, 2000). The former was based on a stakeholder assessment of climate change impacts that identified heat stress in dairy cattle as a subject for a demonstration risk assessment. Thresholds for heat stress and the probability of their being exceeded were evaluated, as were the economic value of adaptation through installation of shade and sprinklers (see Section 12.5.2; Jones and Hennessy, 2000). Baker *et al.* (2000) made a preliminary qualitative assessment of the impacts of scenarios on the basis of the CSIRO RCM at 60-km resolution (Hennessy *et al.*, 1998) on a wide range of sectors and activities.

However, most integrated studies in Australia and New Zealand have been “one-off” assessments, have lacked a time

dimension, cannot readily be repeated to take account of advances in climate change science, and often have not placed the problem in its socioeconomic context. Several groups are collaborating on integrated modeling systems that overcome these drawbacks. In New Zealand this is called CLIMPACTS (Kenny *et al.*, 1995; Warrick *et al.*, 1996; Kenny *et al.*, 1999, 2000), and an Australian system called OZCLIM has been based on it. These integrated models contain a climate change scenario generator, climate and land surface data, and sectoral impact models. They provide a capacity for time-dependent analyses, a flexible scenario approach, a capability for rapid updating of scenarios; and inclusion of models for different sectors. One application is reported in Section 12.5.2.

OZCLIM contains regional climate patterns for monthly temperature and rainfall over Australia from several GCMs and the CSIRO RCM. They can be forced or scaled by the latest emission scenarios, and variables include potential evapotranspiration and relative humidity. It is being adapted to produce projected ranges of impact variables and to assess the risk of exceeding critical thresholds (CSIRO, 1996b; Jones, 2000; Pittock and Jones, 2000).

There are different levels and styles of integration in impact and adaptation assessment, and several of these have been attempted in Australia and New Zealand. Bottom-up integration was done for a range of climate change scenarios in the water supply, pasture, crop, and environmental flow sectors for the Macquarie River basin study by Hassall and Associates *et al.* (1998). It also has been done in a more probabilistic way to take account of uncertainty, with a focus on the probability of exceeding a user-defined threshold for performance and the need for adaptation (Jones, 2000).

Top-down integration has been attempted via the use of global impacts assessment models with some regional disaggregation—such as a regional analysis based on the Carnegie Mellon University ICAM model, which was used to examine adaptation strategies for the Australian agricultural sector (Graetz *et al.*, 1997). The principal conclusions were that climate matters and that the best strategy is to adapt better to climate variability.

Another top-down approach, based on an Australian regionalization of the DICE model of Nordhaus (1994), is that of Islam (1995). An initial application of this model to quantifying the economic impact of climate change damages on the Australian economy gave only a small estimate, but the authors expressed reservations about model assumptions and the need to better quantify climate impacts (Islam *et al.*, 1997). Others have examined the structure and behavior of the Integrated Model to Assess the Greenhouse Effect (IMAGE) but to date have not applied this to climate change impacts in Australia (Zapert *et al.*, 1998; Campolongo and Braddock, 1999).

A spatially explicit modeling system known as INSIGHT is being developed to evaluate a wide range of economic, social, environmental, and land-use impacts that could affect large areas (Walker *et al.*, 1996). It can map and summarize key

social, economic, and environmental outcomes in annual steps to the year 2020. The need for such a system was identified through workshops involving potential stakeholders, and the system could factor in scenarios resulting from climate change.

As pointed out in PMSEIC (1999), much of Australia is subject to multiple environmental problems, of which climate change is only one. This leads to a logical emphasis on regional integrated assessments, which look for adaptations and policies that help to ameliorate more than one problem and have economic benefits.

12.8.3. Natural Systems

A large fraction of the region is composed of unmodified or nonintensively managed ecosystems where adaptation will depend mostly on natural processes. Vulnerability will occur when the magnitude or rate of climate variations lies outside the range of past variations. In some cases, adaptation processes may be very accommodating, whereas in others adaptation may be very limited. Ecosystems in the region handle a wide variety of climatic variability, in some cases with very large swings, but generally this variation occurs on short time scales—up to a few years. This does not necessarily confer adaptability to long-term changes of similar magnitude.

An important vulnerability identified by Basher *et al.* (1998) is the problem of temperatures in low to mid-latitudes that reach levels never before experienced and exceed the available tolerances of plants and animals, with no options for migration. The southwest of western Australia is a case in point (see Section 12.4.2). Another potential vulnerability arises from changes in the frequency of events. Examples include a climatic swing of duration exceeding a reproductive requirement (e.g., water birds in ephemeral lakes—Hassall and Associates *et al.*, 1998) and damaging events occurring too frequently to allow young organisms to mature and ecosystems to become reestablished.

Vulnerability also is expected to exist where species or ecosystems already are stressed or marginal, such as with threatened species; remnant vegetation; significantly modified systems; ecosystems already invaded by exotic organisms; and areas where physical characteristics set constraints, such as atolls, low-lying islands, and mountain tops. Coral reefs, for instance, may be able to survive short periods of rising sea level in clear water but are less likely to do so in turbid or polluted water or if their growth rates are reduced by acidification of the ocean (Pittock, 1999). Vulnerability of coastal freshwater wetlands in northern Australia to salinization resulting from increasing sea level and the inability of some of these wetlands to migrate upstream because of physical barriers in the landscape is described in Sections 12.4.5 and 12.4.7.

Unfortunately, there is relatively little specific information about the long-term capacity for and rates of adaptation of ecosystems in Australia and New Zealand that can be used to predict likely outcomes for the region. Therefore, a large

degree of uncertainty inevitably exists about the future of the region's natural ecosystems under climate change.

12.8.4. Managed Systems

In the region's agriculture, many farming systems respond rapidly to external changes in markets and technology, through changes in cultivars, crops, or farm systems. Mid-latitude regions with adequate water supplies have many options available for adaptation to climate change, in terms of crop types and animal production systems drawn from other climatic zones. However, at low latitudes, where temperatures increasingly will lie outside past bounds, there will be no pool of new plant or animal options to draw from, and the productivity of available systems is likely to decline.

Adaptation options will be more limited where a climatic element is marginal, such as low rainfall, or where physical circumstances dictate, such as restricted soil types. Even where adaptations are possible, they may be feasible only in response to short-term or small variations. At some point, a need may arise for major and costly reconfiguration, such as a shift from or to irrigation or in farming activity. Indeed, one adaptation process already being implemented in Australia to cope with existing competition for water is water pricing and trading, which is likely to lead to considerable restructuring of rural industries (see Section 12.4.6).

Management of climate variability in Australia currently involves government subsidies in the form of drought or flood relief when a specific level of extreme that is classified as exceptional occurs (Stafford Smith and McKeon, 1998; see also Section 12.5.6). An adaptive measure being applied in Australia and New Zealand is to improve seasonal forecasting and to help farmers optimize their management strategies (Stone and McKeon, 1992; Stone *et al.*, 1996a; White, 2000), including reducing farm inputs in potentially poor years.

However, if a trend toward more frequent extremes were to occur, such measures might not allow farmers to make viable long-term incomes because there may be fewer good years. The question arises whether this is merely a string of coincidental extremes, for which assistance is appropriate, or whether it is part of an ongoing trend resulting from climate change. The alternative policy response to the latter possibility may well be to contribute to restructuring of the industry.

The PMSEIC (1999) report notes that there are opportunities for new sustainable production systems that simultaneously contribute to mitigation objectives through retention of vegetation and introduction of deeper rooted perennial pasture. Tree farming in the context of a carbon-trading scheme would provide additional opportunities, and this strategy could be linked to sustainability and alleviation of dryland salinity.

Nevertheless, the report recognizes that totally new production systems may be required for sustainability. These systems will

need to capture water and nutrients that otherwise would pass the root zone and cause degradation problems. The design of such systems will entail research into rotating and mixing configurations of plants; manipulating phenology; modifying current crops and pastures through plant breeding, including molecular genetics; and possibly commercializing wildlife species and endemic biological resources. The report concedes, however, that there probably still will be agricultural areas where attempts to restore environmental and economic health will meet with little success.

Vulnerability and the potential for adaptation can be investigated quantitatively if a system and the climate change impacts on that system can be modeled. This was done by Pittock and Jones (2000) and Jones (2000) for climatically induced changes in irrigation water demand on a farm in northern Victoria. Here a window of opportunity is opened for adaptation via identification of a future time when adaptation would be necessary to reduce the risk of demand exceeding irrigation supply.

Jones (2000) used a model that was based on historical irrigation practice. Seasonal water use was used to estimate an annual farm cap of 12 Ml ha^{-1} , based on the annual allocated water right. Water demand in excess of this farm cap in 50% of the years was taken to represent a critical threshold beyond which the farmer cannot adapt. Conditional probabilities within projected ranges of regional rainfall and temperature change were utilized, combined with a sensitivity analysis, to construct risk response surfaces (see Figure 12-5). Monte Carlo sampling was used to calculate the probability of the annual farm cap being exceeded across ranges of temperature and rainfall change projected at intervals from 2000 to 2100. Some degree of adaptation was indicated as desirable by 2030, although the theoretical critical threshold was not approached until 2050, becoming probable by 2090 (see Figure 12-6).

In a full analysis, this example would need to be combined with an analysis of the likelihood of changes in water supply (e.g., Schreider *et al.*, 1997) affecting the allocated irrigation cap and an evaluation of possible adaptation measures.

12.8.5. Human Environments

The most vulnerable human environments in Australia and New Zealand are those that are subject to potential coastal or riverine flooding, landslides, or tropical cyclones and other intense storms. Adaptation to natural variability in these cases usually takes the form of planning zones, such as setbacks from coasts and flood levels of particular return periods or engineering standards for buildings and infrastructure. Many of these settlements and structures have long lifetimes—comparable to that of anthropogenic climate change. This means that many planning zones and design standards may become inappropriate in a changing climate.

Adaptation in these circumstances depends on costs and benefits, the lifetime of the structures, and the acceptability of redesigned

measures or structures (e.g., seawalls). Thus, responses will depend in part on aesthetic and economic considerations; poorer communities, such as many indigenous settlements, will be particularly vulnerable. Conflicts will arise between investors with short time horizons and local government or other bodies who think on longer time scales and may bear responsibility for planning or emergency measures. Complex jurisdictional arrangements often will add to the difficulties of adopting rational adaptation measures (Waterman, 1996).

In an attempt to meet these problems for the Australian coastline, a guide has been developed for response to rising seas and climate change (May *et al.*, 1998), as well as good practice and coastal engineering guidelines (Institution of Engineers, 1998; RAPI, 1998).

Local governments in some parts of Australia and New Zealand are identifying measures they could implement to adapt to climate change. For example, the Wellington Regional Council is required by its Regional Policy Statement to periodically

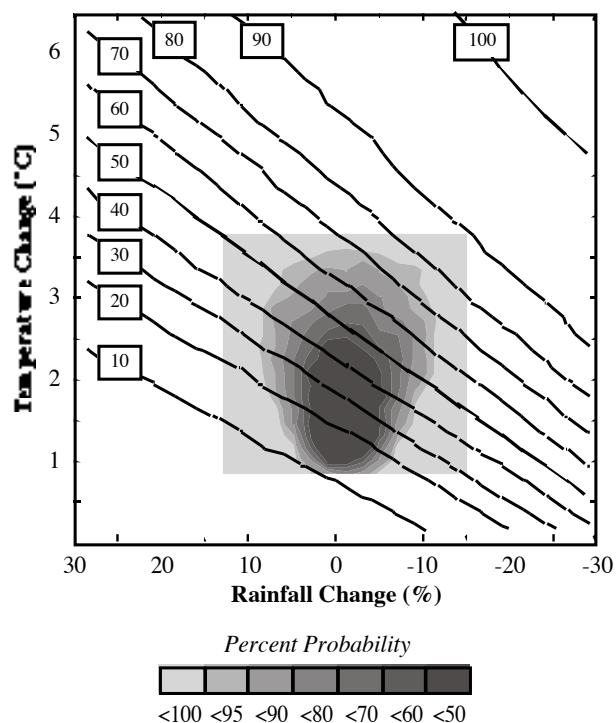

Figure 12-5: Risk response surface incorporating cumulative probability plots (in shaded box) for climate change magnitudes as indicated on x- and y-axes. Indicated percentage probabilities are probabilities of climate change in northern Victoria in 2070 lying within each shaded area (thus, there is a 100% probability of climate within the shaded square, and a 50% probability of climate within the innermost region). Probability (in percent) of irrigation water demand exceeding farm supply cap in any one year, for indicated climate change, is indicated by oblique lines. Critical threshold (heavy line) is set at a 50% chance of exceeding the cap (Jones, 2000).

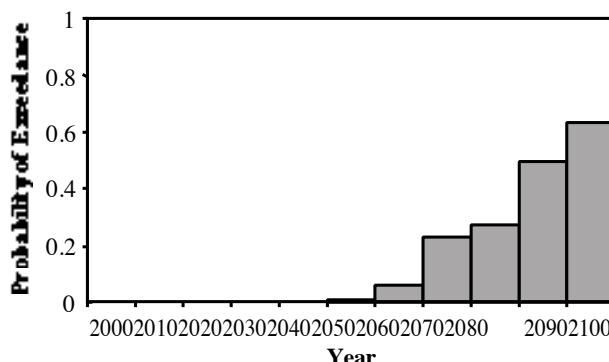

Figure 12-6: Change in probability of exceeding critical threshold (exceeding farm cap in 50% of all years) over time. Note that if farm cap were reduced through reductions in irrigation supply under climate change, the probability of the cap being exceeded would be increased (Jones, 2000).

review current knowledge on climate change and possible effects on natural hazards; the Council already allows for climate-induced variability in its flood protection activities (Green, 1999).

The region's health infrastructure is quite strong, and numerous existing adaptations, such as quarantine and eradication of disease vectors, are available to deal with the main changes expected. However, there is concern that already disadvantaged communities, especially indigenous people, may not have equitable access to adaptation measures. Another issue is the question of adaptations to deal with a climatic impact that may cause secondary effects. Examples include adaptations that require more energy production or higher water use, and vector controls that result in reduced population immunity to the disease carried.

12.8.6. Indigenous People

Traditional indigenous societies in the region have lived in a close and conscious relationship with their environment (Tunks, 1997; Skerlchly and Skerlchly, 2000). Australian Aborigines have modified and managed the landscape through the controlled use of low-intensity fire (Kohen, 1995). They have lived in Australia for at least 40,000 years. Thus, they have a long history of adaptation to sea-level rise, which rose by 130 m from the last glacial maximum 18,000 years ago until the present level was reached 6,000 years ago. Memories of these traumatic events are found in oral traditions recorded by early European settlers (Mulvaney and Kamminga, 1999).

With the recognition of indigenous land rights, indigenous people in both countries are now major land managers (Coombs *et al.*, 1990; Langton, 1997) and hence are impacted by and responsible for managing climatic impacts. The importance of their participation in the development of policy and response strategies to climate change is discussed in New Zealand

Climate Change Programme (1990) and Tunks (1997), but to date their involvement has been minimal. This is a result partly of greater emphasis in Australia and elsewhere on mitigation of climate change rather than adaptation (Cohen, 1997), lack of indigenous community involvement in climate change research, and the array of other more pressing social issues for such communities (Braaf, 1999).

12.8.7. Extra-Regional Factors

Basher *et al.* (1998) draw attention to the vulnerability of the region to external influences arising from climate change—in particular, from likely changes in terms of trade (see also Stafford Smith *et al.*, 1999). Increased risk of invasion by exotic pests, weeds, and diseases and possible immigration from neighboring territories rendered uninhabitable by rising sea level are other factors. These issues exist independent of climate change but are likely to be exacerbated by climate change. A variety of adaptations to deal with each problem exist and can be strengthened, but the costs involved and remaining impacts could be considerable.

12.9. Synthesis

12.9.1 Introduction

Many activities and ecosystems in Australia and New Zealand are sensitive to climate change, with positive and negative effects. Much climate sensitivity information is still qualitative, and there are substantial uncertainties in predictions of regional-to local-scale climate changes—especially rainfall changes and changes in extreme events. Thus, comprehensive, quantitatively based cross-sectoral estimates of net Australasian costs of climate change impacts are not yet available. Confidence remains very low in the impact estimate for Australia and New Zealand of –1.2 to –3.8% of GDP for an equivalent doubling of CO₂ concentrations (Basher *et al.*, 1998). This estimate is based on climate change scenarios that are now outdated; does not include some potentially important impacts, including changes in weeds, pests and diseases, storm surges, and urban flooding; and does not account for possible adaptations to climate change.

Despite the uncertainties, there is a large body of knowledge and more agreement on changes than often is realized (e.g., between different coupled ocean-atmosphere climate models on the sign of the change in rainfall over large areas of Australia; see Section 12.1.5.1). There also is qualitative agreement on reduced water supplies in large agricultural regions of Australia (see Sections 12.3.1 and 12.5.6).

Potential net impacts on grazing, crops, and forests critically depend on the balance between the competing effects of warmings, positive or negative rainfall changes, direct physiological effects of higher CO₂ concentrations, and spatial and temporal variations in soil fertility. We expect with medium to high confidence that beneficial physiological effects of higher CO₂ concentration

will become less dominant with time and effects of warming will become more damaging, especially given the expected tendency toward greater aridity over much of Australia. Impacts (and thus climate change benefits or damages) will not scale linearly with increasing GHG concentrations.

The following subsections draw together material from this chapter that is pertinent to the “policy-relevant questions” identified by the IPCC Bureau, as well as regional policy concerns.

12.9.2. Observed Consequences of Past and Current Climate Variability in the Region

Regional consequences documented in this chapter from floods, droughts, and temperature changes associated with recent ENSO events include losses in the pastoral agriculture sector from droughts (Australia, 1–2% of GDP; New Zealand, NZ\$422 million estimated farm-gate costs from 1997 to 1999) and impacts on streamflow, water supply, stream ecology, horticulture, some commercial fisheries, and toxic algal blooms. Parts of the GBR have suffered mass coral bleaching from high SSTs (possibly related to ENSO and recent warming trends) and/or lowered salinity as a result of floods. Storms in the New Zealand region may have been more frequent in past warm epochs, leading to a greater influx of terrigenous material

onto the continental shelf. Oceanic productivity east of New Zealand apparently increased immediately prior to and during warm periods 6,000–7,000 years ago and 120,000–125,000 years ago.

Extreme climatic events resulting from natural climatic variability in the past century have caused major damage and loss of life in Australia and New Zealand (see Sections 12.1.5.3 and 12.6.2). These extremes are expected to change in intensity, location-specific frequency, and sequence as a result of climate change (see Table 3-10 and Section 12.1.5.3), with major impacts on infrastructure and society unless strong adaptation measures are adopted.

12.9.3. Factors Influencing Vulnerability

12.9.3.1. Abrupt or Nonlinear Changes in Impacts

Several potential abrupt or nonlinear responses to climate change are listed in Table 12-1. In some cases, they involve a reversal of the sign of the effect with greater climate change; in others they result from the onset or acceleration of a biophysical or socioeconomic process that occurs or greatly accelerates beyond some threshold of climate change. Such thresholds can be quite location- and system-specific and need to be identified in collaboration between climatologists and stakeholders. The

Table 12-1: Nonlinear or rapid climate change responses identified in this chapter.

System	Description of Change	Certainty and Timing	Section
Great Barrier Reef	Reef death or damage from coral bleaching	Medium to high, next 20–50 years	12.4.7
Deep ocean	Chemical, dynamical, and biological changes from reduction in bottomwater formation	Low to medium, century time scale	12.4.7
Southwest of western Australia	Rapid loss of species with narrow annual mean temperature ranges	High, next 20–50 years	12.4.2
Australian alpine ecosystems	Loss of species as a result of warming and reduced snow cover	Medium to high, next 50 years	12.4.4
Insect-borne disease spread	Conditions more favorable to mosquitoes and other disease vectors	High potential, growing vulnerability	12.7.1
Agriculture	Shift from net profit to loss as a result of increased frequency of bad years	High potential in some places, next 20–50 years	12.8.4
Agriculture	Shift from positive to negative balance between benefits of increased CO ₂ and losses from increasing aridity	High potential in parts of Australia, 50–100 years	12.5.2, 12.5.3
Built infrastructure	Change in magnitude and frequency of extremes to exceed design criteria, leading to rapid increases in potential damages to existing infrastructure	Medium to high in tropical coastal and riverine situations, next 30–50 years	12.6.1

frequency with which thresholds are exceeded often is used in engineering in the form of design criteria to withstand an event with a certain “return period,” or average time between occurrences. It also can manifest itself as a change from an average profit to an average loss for a given enterprise such as a farm.

12.9.3.2. Interactions with Other Environmental and Social Factors

Some of the region’s ecosystems are extremely vulnerable to invasion by exotic animal and plant species because of relative isolation before European settlement. Land-use changes have left some systems and areas more vulnerable to added stresses from climate changes, as a result of salinization or erosion, and because of ecosystem fragmentation, which lessens adaptation options for movement of species threatened by changing habitats (see Section 12.4.8).

Increasing human populations and development in coastal areas and on floodplains cause increasing vulnerability to tropical cyclones, storm surges, and riverine flooding episodes (see Sections 12.4.7 and 12.6.4), which may become more frequent with climatic change. Development has reduced the area and water quality of many estuaries, increasing the vulnerability of their ecosystems to sea-level rise and climate changes. Pressures on coral reefs including the GBR include increased coastal development, fisheries, tourism, and runoff of nutrients, chemicals, and sediment from land, as well as climate-related stresses such as rising sea level, rising temperatures, changes in tropical storm frequency, and acidification of the ocean from increasing CO₂ concentrations (see Section 12.4.7).

Poorer communities, including many indigenous settlements, are more vulnerable to climate-related natural hazards and stresses on health (see Section 12.7.6) because they often are in exposed areas and have less adequate housing, health, and other resources for adaptation.

Capacity to adapt is a function not only of the magnitude and critical nature of the climatic change but also of the demographics, economy, institutional capacity, and technology of a society. Thus, alternative socioeconomic futures will lead to different capacities to adapt. This has hardly been explored to date in Australia and New Zealand in relation to climate change.

12.9.3.3. Regional-Global Interactions

Reliance on exports of agricultural and forest products makes the region sensitive to changes in commodity prices produced by changes in climate elsewhere (see Section 12.5.9) and to increases in global forests as a result of carbon sink policies. Other extra-regional factors include increased risks of invasion by exotic pests, weeds, and diseases; pressures from immigration from neighboring low-lying Pacific island territories impacted by sea-level rise (see Section 12.7.6); and international agreements

that constrain net emissions of GHGs. In an era of increasing globalization, these issues may assume more importance, although this report hardly touches on them.

12.9.4. Impacts for Differing Emissions Scenarios and Stabilization Pathways

Quantitative cross-sectoral impact assessments for differing scenarios are not yet available for Australia and New Zealand. Regional impacts will vary nonlinearly with time before and after stabilization of GHG concentrations. Warming will continue to increase after stabilization, but the beneficial effects of CO₂ on plants will no longer increase. Moreover, regional patterns of rainfall change, particularly in southern Australian and New Zealand areas, will tend to reverse after stabilization of GHGs (see Section 12.1.5.1). These complexities, together with the continuing post-stabilization rise in sea level, mean that estimated impacts at the time of stabilization may not be sufficient to determine whether the level of stabilization is a safe one.

12.9.5. Uncertainties and Risk Management

Given that some of the climate sensitivities listed in Section 12.9.6, and especially in Table 12-2, already have been observed for natural climate variations (such as El Niño), confidence is high that a range of impacts will occur in Australia and New Zealand as a result of climate change over the coming decades. This level of certainty, and the possibility that the early stages of greenhouse-related changes already may be occurring, justify prudent risk management through initiation of appropriate mitigation and adaptation strategies. Probabilistic assessments of risk, which account for the uncertainties, are regarded as a way forward. These assessments attempt to quantify the various sources of uncertainty to provide a conditional probability of climate change that would cause critical system performance thresholds to be exceeded and require adaptation or result in losses. Stakeholders may define their own subjective levels of acceptable risk and plan accordingly to adapt before or when the threshold is exceeded. Some examples for Australia and New Zealand are presented in this chapter (see Sections 12.5.2, 12.6.1, 12.8.2, and 12.8.4), but more are needed.

12.9.6. Vulnerability and Adaptability in Australia and New Zealand

The key regional concerns identified in this chapter regarding vulnerability to climate change impacts are ecosystem uniqueness, isolation, and vulnerability; agricultural commodities and terms of trade; droughts, floods, and water supply; increased coastal and tropical exposure to climate hazards; impacts on indigenous peoples and their involvement in adaptation planning; coral reefs; and Australian alpine areas.

Major expected impacts, vulnerability, and adaptability are summarized in Table 12-2. Note that although Australian and

Table 12-2: Main areas of vulnerability and adaptability to climate change impacts in Australia and New Zealand. Degree of confidence that tabulated impacts will occur is indicated by a letter in the second column (VH = very high, H = high, M = medium, L = low, VL = very low). These confidence levels, and the assessments of vulnerability and adaptability, are based on information reviewed in this chapter and assume continuation of present population and investment growth patterns.

Sector	Impact	Vulnerability	Adaptation	Adaptability	Section
Hydrology and water supply	<ul style="list-style-type: none"> – Irrigation and metropolitan supply constraints, increased salinization—H – Saltwater intrusion into some island and coastal aquifers—H 	High in some areas High in limited areas	<ul style="list-style-type: none"> – Planning, water allocation, and pricing – Alternative water supplies, retreat 	Medium Low	12.3.1, 12.3.2 12.3.3
Terrestrial ecosystems	<ul style="list-style-type: none"> – Increased salinization of dryland farms and some streams (Australia)—M – Biodiversity loss, notably in fragmented regions, Australian alpine areas, and southwest of WA—H – Increased risk of fires—M – Weed invasion—M 	High Medium to high in some areas Medium Medium	<ul style="list-style-type: none"> – Changes in land-use practices – Landscape management; little possible in alpine areas – Land management, fire protection – Landscape management 	Low Medium to low Medium Medium	12.3.3 12.4.2, 12.4.4, 12.4.8 12.1.5.3, 12.5.4, 12.5.10 12.4.3
Aquatic ecosystems	<ul style="list-style-type: none"> – Salinization of some coastal freshwater wetlands—M – River and inland wetland ecosystem changes—M – Eutrophication—M 	High Medium Medium in inland Aus. waters	<ul style="list-style-type: none"> – Physical intervention – Change water allocations – Change water allocations, reduce nutrient inflows 	Low Low Medium to low	12.4.7 12.4.5, 12.4.6 12.3.4
Coastal ecosystems	<ul style="list-style-type: none"> – Coral bleaching, especially Great Barrier Reef—H – More toxic algal blooms?—VL 	High Unknown	<ul style="list-style-type: none"> – Seed coral? – 	Low –	12.4.7 12.4.7
Agriculture, grazing, and forestry	<ul style="list-style-type: none"> – Reduced productivity, increased stress on rural communities if droughts increase, increased forest fire risk—M – Changes in global markets as a result of climate changes elsewhere—H, but sign uncertain – Increased spread of pests and diseases—H – Increased CO₂ initially increases productivity, but offset by climate changes later—L 	Location-dependent, worsens with time High, but sign uncertain Medium Changes with time	<ul style="list-style-type: none"> – Management and policy changes, fire prevention, seasonal forecasts – Marketing, planning, niche and fuel crops, carbon trading – Exclusion, spraying – Change farm practices, change industry 	Medium Medium Medium –	12.5.2, 12.5.3, 12.5.4 12.5.9 12.5.7 12.5.3, 12.5.4
Horticulture	– Mixed impacts (+ and -), depends on species and location— H	Low overall	– Relocate	High	12.5.3

Table 12-2 (continued)

Sector	Impact	Vulnerability	Adaptation	Adaptability	Section
Fish	– Recruitment changes (some species)— L	Unknown net effect	– Monitoring, management	—	12.5.5
Settlements and industry	– Increased impacts of flood, storm, storm surge, sea-level rise— M	High in some places	– Zoning, disaster planning	Moderate	12.6.1, 12.6.4
Human health	– Expansion and spread of vector-borne diseases— H – Increased photochemical air pollution— H	High Moderate (some cities)	– Quarantine, eradication, or control – Emission controls	Moderate to high High	12.7.1, 12.7.4 12.7.1

(to a lesser extent) New Zealand farmers have adapted, at least in part, to existing El Niño-related droughts, they depend on good years for recovery. Thus, despite their adaptability, they are quite vulnerable to any increase in the frequency of drought or to a tendency for droughts to last for a longer period. This vulnerability flows through to the rural communities that service them (see Section 12.5.6).

Several of these vulnerabilities are likely to interact synergistically with each other and with other environmental stresses. Moreover, vulnerability is a result of exposure to hazard and capacity to adapt. Thus, vulnerability will be greatly affected by future changes in demography, economic and institutional capacity, technology, and the existence of other stresses.

There have been no rigorous studies for Australia or New Zealand that have taken all of these variables into account. Thus, Table 12-2 is based largely on studies that assume that the society that is being impacted is much like that of today. It should not be assumed, however, that socioeconomic changes in the future necessarily will reduce vulnerability in Australia and New Zealand. Indeed, many existing socioeconomic trends may exacerbate the problems. For instance, the bias toward population and economic growth in coastal areas, especially in the tropics and subtropics, by itself will increase exposure to sea-level rise and more intense tropical cyclones. If such trends are not to increase vulnerability, they will need to be accompanied by a conscious process of planning to reduce vulnerability by other means (e.g., changes in zoning and engineering design criteria). Thus, vulnerability estimates are based on present knowledge and assumptions and can be changed by new developments, including planned adaptation.

12.9.7. Knowledge Gaps

Significant knowledge gaps have become apparent during this assessment. These gaps mean that the net cost or benefit of unmitigated climate change in Australia and New Zealand is highly uncertain (see Section 12.9.1) and cannot be compared objectively with the cost of mitigation. Without this knowledge

base, policymaking regarding adaptation and mitigation cannot be soundly based on economic considerations. Research priorities follow.

Indicators of climate impacts: Although long-term monitoring programs are in place for physical indicators (such as climate variables and sea level), work is still desirable on designing and implementing long-term monitoring programs that cover vulnerable animals, plants, and ecosystems and systematically examining them for the effects of climate changes. Flora and fauna with presently restricted or marginal climatic ranges would be most appropriate (see Section 12.4). (Candidate indicators for the UK are presented in Cannell *et al.*, 1999.)

Underpinning physical knowledge and improved scenarios: Improved impact assessments will depend on better understanding of how climate change may influence factors such as the frequency and intensity of El Niños and related droughts, the intensity and location-specific frequency of tropical cyclones, and return periods for heavy rainfalls, floods, high winds, and hail. Oceanic issues include understanding differences between observed and modeled lag in warming of the Southern Ocean (see Section 12.1.5.2), possible impacts of cessation of bottomwater formation (see Section 12.4.7), and determining the influence of greenhouse warming on currents, upwelling, and nutrient supply. More knowledge is needed about influences of GHG-related cooling in the stratosphere on ozone depletion and regional UV radiation levels (see Section 12.7.1). All of this knowledge is needed to improve scenarios of regional climate (including ocean behavior).

Underpinning biological knowledge: The sensitivities of many plant and animal species and ecosystems in this region to climate changes, as well as the potential threats to biodiversity, are still unknown (see Section 12.4). Knowledge is required for assessment of potential impacts and for development of conservation strategies. This is important for marine and coastal environments, including coastal freshwater wetlands (see Section 12.4.7), as well as for terrestrial systems. Identification of relevant climatic thresholds for biological (and other) systems is needed (see Section 12.8.2). The effects of

the time-varying balance between the beneficial physiological effects of increasing CO₂ concentrations and climate change on natural (indigenous) and managed ecosystems needs to be better understood, especially in light of recent regional scenarios.

Underpinning social knowledge: Better knowledge is required about the vulnerability of particular population groups (including indigenous people), about how people and organizations have adapted to past climate variability and changes, and about public attitudes to adaptation and mitigation options. Work is needed to understand how different socioeconomic futures (demography, economic capacity, and technological change) (see Section 12.1.5.4) would affect vulnerability (see Sections 12.8 and 12.9.2.2) and on socioeconomic thresholds for change, such as economic nonviability and unacceptable risk.

Fisheries: There is insufficient information to enable confident predictions of changes in fisheries productivity from climate change (see Section 12.5.5). This requires better knowledge of physical and biological processes in the ocean (as above) and improved information on the climate sensitivities of many species.

Health: Continuing work is needed on the potential for introduction (New Zealand) and spread (Australia) of significant disease vectors, including sensitivity to climate, population shifts, and effectiveness of health services and biosecurity procedures (see Section 12.7.4). Other health issues should be addressed, including potential effects of threats to water supply on remote communities (see Section 12.7.6).

Regional effects and integration: Better quantitative sectoral knowledge is required about, for example, influences of climate change on water supply and demand (see Section 12.3.1), salinization (see Section 12.3.3), and some crops and farming practices (see Sections 12.5.2 and 12.5.3). Because various sectors (e.g., agriculture, ecosystems, infrastructure, and hydrology) interact at the regional and national levels, continued work is needed on integrated assessment approaches and models that synthesize sectoral knowledge and draw on the social sciences (see Section 12.8.2), in rural and urban settings. Models of the physical economy that track fluxes and pools of materials, energy, land, and water are required for national analyses.

Global interactions: More understanding is needed of the interaction of global climate change impacts, and of mitigation policies, on Australian and New Zealand markets, sectoral change, and land use (see Sections 12.5.9 and 12.8.7).

Adaptation: Further objective studies are required, in close collaboration with stakeholders, on adaptation options and their acceptability, costs, co-benefits, side effects, and limits (see Section 12.8). Adaptation should be regarded as a means to maximize gains and minimize losses, with a greater exploration of opportunities (see Section 12.8.1).

Costing: More comprehensive and realistic costings are needed for impacts and adaptation options, taking account of human behavior and using up-to-date scenarios.

Communication of policy-relevant results: If climate change issues are to be addressed by decisionmakers, there will need to be better communication of results from research. This will come partly from consultation with decisionmakers and other stakeholders to ensure that the right policy-relevant questions are addressed (see Sections 12.8.2 and 12.9) and partly from effective communication of what is known, as well as the uncertainties. A risk-assessment approach geared to particular stakeholders seems likely to be most effective (see Section 12.9.5).

EXECUTIVE SUMMARY

- The adaptation potential of socioeconomic systems in Europe is relatively high because of economic conditions (high gross national product and stable growth); a stable population (with the capacity to move within the region); and well-developed political, institutional, and technological support systems. However, adaptation potential for natural systems generally is low. [very high confidence]
- Present-day weather conditions have effects on natural, social, and economic systems in Europe in ways that reveal sensitivities and vulnerabilities to climate change in these systems. Climate change may aggravate such effects. [very high confidence, well-established evidence]
- Vulnerability to climate change in Europe differs substantially between subregions; it is particularly high in the south and in the European Arctic. This has important equity implications. More marginal and less wealthy areas will be less able to adapt. [very high confidence, established but incomplete evidence]
- Water resources and their management in Europe are under pressure now, and these pressures are likely to be exacerbated by climate change [high confidence]. Flood hazard is likely to increase across much of Europe, except where snowmelt peak has been reduced, and the risk of water shortage is projected to increase particularly in southern Europe [medium to high confidence]. Climate change is likely to widen water resource differences between northern and southern Europe. [high confidence, well-established evidence]
- Soil properties will deteriorate under warmer and drier climate scenarios in southern Europe. The magnitude of this effect will vary markedly between geographic locations and may be modified by changes in precipitation. [medium confidence, established but incomplete evidence]
- Natural ecosystems will change as a result of increasing temperature and atmospheric concentration of carbon dioxide (CO₂). Permafrost will decline, trees and shrubs will encroach northern tundra, and broad-leaved trees may encroach coniferous forests. Net primary productivity in ecosystems is likely to increase (also as a result of nitrogen deposition). Diversity in nature reserves is under threat from rapid change. Loss of important habitats (wetlands, tundra, and isolated habitats) would threaten some species (including rare/endemic species and migratory birds). Faunal shifts as a result of ecosystem changes are expected in marine, aquatic, and terrestrial ecosystems. [high confidence, established but incomplete evidence]
- In mountain regions, higher temperatures will lead to an upward shift of biotic and cryospheric zones and perturb the hydrological cycle. There will be redistribution of species, with, in some instances, a threat of extinction. [high confidence]
- Timber harvest will increase in commercial forests in northern Europe [medium confidence, established but incomplete evidence], but reductions are likely in the Mediterranean, with increased drought and fire risk. [high confidence, well-established evidence]
- Agricultural yields will increase for most crops as a result of increasing atmospheric CO₂ concentration. This effect would be counteracted by the risk of water shortage in southern and eastern Europe and by shortening of growth duration in many grain crops as a result of increasing temperature. Northern Europe is likely to experience overall positive effects, whereas some agricultural production systems in southern Europe may be threatened. [medium confidence, established but incomplete evidence]
- Changes in fisheries and aquaculture production from climate change embrace faunal shifts affecting freshwater and marine fish and shellfish biodiversity. These changes will be aggravated by unsustainable exploitation levels and environmental change. [high confidence]
- The insurance industry faces potentially costly climate change impacts through the medium of property damage, but there is great scope for adaptive measures if initiatives are taken soon. [high confidence]
- Transport, energy, and other industries will face changing demand and market opportunities. Concentration of industry on the coast exposes it to sea-level rise and extreme events, necessitating protection or removal. [high confidence]
- Recreational preferences are likely to change with higher temperatures. Outdoor activities will be stimulated in northern Europe, but heat waves are likely to reduce the traditional peak summer demand at Mediterranean holiday destinations, and less reliable snow conditions could impact adversely on winter tourism. [medium confidence]

- A range of risks is posed for human health through increased exposure to heat episodes (exacerbated by air pollution in urban areas), extension of some vector-borne diseases, and coastal and riverine flooding. Based on current evidence, climate change would result in a reduction in wintertime deaths, at least in temperate countries. [medium confidence]
- In coastal areas, the risk of flooding, erosion, and wetland loss will increase substantially—with implications for human settlement, industry, tourism, agriculture, and coastal natural habitats. Southern Europe appears to be more

vulnerable to these changes, although the North Sea coast already has high exposure to flooding. [high confidence]

The foregoing conclusions are broadly consistent with those expressed in the IPCC *Special Report on Regional Impacts of Climate Change* (1998) and the Second Assessment Report (1996). This survey incorporates much more information than previously reported, corroborating previous conclusions (with which it is broadly consistent) but extending knowledge into other sectors. It is more specific about subregional effects and includes new information concerning adaptive capacity.

13.1. The European Region

13.1.1. Previous Work

Western Europe was the subject of the first multi-country assessment of climate change impacts using general circulation model (GCM)-derived climate scenarios (Meinl and Bach, 1984). This included assessment of impacts on the agricultural, water, and energy sectors in the European Union (EU). Since that time, most assessments have been of single sectors or single countries. Most countries in Europe have now conducted climate impact studies, though these studies generally are based on expert reviews rather than new research. EU-wide assessments have been completed for water (Arnell *et al.*, 1999), agriculture (Harrison *et al.*, 1995a), forestry (Kellomäki, 1999), and coastal regions (European Commission, 1999).

The IPCC synthesis of regional impacts in its *Special Report on Regional Impacts of Climate Change* (RICC) captured some of the important likely effects—for example, on water resources, coastal regions, and agriculture—but drew no conclusions concerning effects on ecosystems, soils, forestry, insurance, and mountain regions (IPCC, 1998). The present survey refers to a much more extensive literature base (about three times as much as in RICC) and is able to cover additional fields and draw more specific conclusions. The main differences between the current assessment and the previous one are its coverage of the additional sectors noted above; the distinction it is able to draw between effects on different parts of Europe, particularly between northern and southern Europe; the greater degree of quantification achieved; and its evaluation of the adaptive capacity of different sectors to climate change impacts. This assessment draws substantially on the work of a 3-year review of impacts in Europe funded by the Commission of the European Communities, with extensive additional input of material for non-EU countries (Parry, 2000).

13.1.2. What is Different about the European Region?

13.1.2.1. Geography, Population, Environment

Europe, a continent with an area of 10.5 million km², extends from the Atlantic Ocean in the west to the Eastern Ural Mountains, the River Ural, and the Caspian Sea in the east and from the Arctic Sea in the north to the Caucasus Mountains, the Black Sea, and the Mediterranean Sea in the south.

Europe consists of large areas with low relief, including one of the world's largest uninterrupted plains: the European Plain. There are several mountain ranges; the highest peak is 5,642 m (Elbrus in the Caucasus Mountains). The continent is well-watered, with numerous permanent rivers, many of which flow outward from the central part of the continent.

There are five essential types of climate in Europe: maritime, transitional, continental, polar, and Mediterranean. The five major vegetation types are tundra, coniferous taiga (boreal forest),

deciduous-mixed forest, steppe, and Mediterranean. A relatively large proportion of Europe is farmed, and about one-third of the area is arable; cereals are the predominant crop.

Europe has a total population of 720 million; it has a higher population density and lower birth rate than any other continent. In several countries of central and eastern Europe, population growth is negative at present, even as low as -1.2% (World Bank, 1999). High life expectancy and low infant mortality are results of advances in health care. Life expectancy at birth is among the highest in the world, in some countries reaching more than 75 years for men and more than 80 years for women (World Bank, 1999). European nations are aging faster than those of any other continent.

Key environmental pressures that are significant at the European scale are identified in the Dobris Report (Stanners and Bourdeau, 1995). They relate to areas such as biodiversity, landscape, soil and land degradation, forest degradation, natural hazards, water management, and recreational environment, among others. Most ecosystems in Europe are managed or semi-managed; they often are fragmented and under stress from pollution and other human impacts. Social concerns include issues such as competitiveness, employment, income, and social mobility (Parry, 2000). The relative importance of these issues varies across Europe. Southern Europe, mountains, and coastal zones have their own sets of environmental concerns, some of which will be aggravated by climate change.

13.1.2.2. Economy

The pattern of wealth distribution in the European region is strongly nonhomogeneous. Values of gross national product (GNP) per capita range from US\$540 to 44,320 in Moldova and Switzerland, respectively (World Bank, 1999).

The 15 states that belong to the European Union (EU) are developed countries with stable economies and high levels of productivity. Their industry is based on modern high technology. The EU has reached a high degree of integration and common economic policy.

Until 1990, several countries in central and eastern Europe (CEE) had centrally planned economies dominated by heavy industry. Since late 1989, the CEE has undergone dramatic economic and political changes toward market economy and democracy. CEE countries labeled as "economies in transition" have been overhauling outdated, ineffective, energy- and raw material-consuming and highly polluting industries. This has been a difficult and long-term process; as a result, in 1990–1992, a large drop in GNP was noted in all CEE countries. Subsequently, some countries have managed to achieve solid growth. Poland, for instance, has now experienced nine consecutive years of growth, and its mean annual GNP rise for 1990–1997 is 3.9% (World Bank, 1999). Yet for some other countries, mean annual GNP growth for 1990–1997 has been negative.

After the fall of the former political system in CEE, ties between these countries ceased to exist and new subregional links are being built, such as the Vysehrad Group created by Poland, the Czech Republic, Slovakia, and Hungary and the Central European Free Trade Agreement (CEFTA). Yet the tendency for many countries of CEE now is to seek access to Western institutions. Three countries—the Czech Republic, Hungary, and Poland—joined the North Atlantic Treaty Organization (NATO) in March 1999. Five countries (Czech Republic, Estonia, Hungary, Poland, and Slovenia) have started negotiations that are expected to lead to full access to the EU in a few years. Among the macro-level pressures in some countries are within-country ethnic tensions and difficulties of transition toward a democratic system with a market economy.

13.1.3. Recent Climate Variability in Europe, including Recent Warming

The climate of Europe exhibits large differences from west (maritime) to east (continental) and from north (Arctic) to south (Mediterranean). The climatic effects of the distribution of land and ocean are further complicated by numerous high mountain ranges, which act as physical barriers to atmospheric circulation and often introduce large precipitation gradients within small regions (e.g., Frei and Schär, 1998). There is no synoptic consistency to the behavior of the European atmosphere across such a heterogeneous climatic domain.

Europe possesses long instrumental data records. The central England temperature series, for example, commences in 1659 (Jones and Hulme, 1997). Reconstruction of regional climates in Europe with proxy data sets identifies the magnitudes of natural temperature variability that have occurred on even longer multi-century time scales: 1,400 years of summer temperatures from tree growth in Fennoscandia (Briffa *et al.*, 1990), 460 years of monthly temperature and precipitation patterns from hydrological and biological evidence in central Europe (Pfister, 1992), and 500 years of annual temperatures from ice cores in Greenland (Fischer *et al.*, 1998). Direct sea-level measurements are available from the 18th century. There have been several attempts at deciphering the remote past, based on proxy data (e.g., Velichko *et al.*, 1998; Zelikson *et al.*, 1998).

13.1.3.1. Temperature

Most of Europe has experienced increases in surface air temperature during the 20th century that, averaged across the continent, amount to about 0.8°C in annual temperature (see Figure 13-1) (ECSN, 1995; Beniston *et al.*, 1998; EEA, 1998). This warming has been largest over northwestern Russia and the Iberian peninsula (Nicholls *et al.*, 1996; Onate and Pou, 1996) and stronger in winter than in summer (Maugeri and Nanni, 1998; Brunetti *et al.*, 2000). An exception is Fennoscandia, which has recorded cooling in mean maximum and mean minimum temperature during 1910–1995 in winter

but warming in summer (Tuomenvirta *et al.*, 1998). The past decade in Europe (1990–1999) has been the warmest in the instrumental record, annually and for winter. Increases in growing-season length also have been observed in Europe—for example, in western Russia (Jones and Briffa, 1995) and in Fennoscandia (Carter, 1998). Trends in the intensity of the growing season as measured by growing degree days, however, are more ambiguous in both of these studies. The evidence for longer growing seasons in Europe also is supported by phenological data collected in central Europe (Menzel and Fabian, 1999). These data point to increases of about 10 days in average growing-season length since the early 1960s. Other biological indicators of a changing growing season in Europe include poleward shifts of 35–240 km during this century in entire ranges of 34 different butterfly species (Parmesan *et al.*, 1999) and earlier breeding times for several species of amphibians and migratory birds during the past few decades (Forchhammer *et al.*, 1997).

Warming in annual mean temperature has occurred preferentially as a result of nighttime rather than daytime temperature increases (Brazdil *et al.*, 1996; Easterling *et al.*, 1997; Tuomenvirta *et al.*, 1998), reflecting similar tendencies to those in other world regions. There has been some evidence that this reduction in the diurnal temperature range (DTR) has been associated with increased cloudiness. This is especially true over parts of the former Soviet Union (FSU—Abakumova *et al.*, 1996; Groisman *et al.*, 1996), Fennoscandia (Kaas and Frich, 1995; Tuomenvirta *et al.*, 1998), and Switzerland, where Rebetez and Beniston (1998) found that a 20th-century decrease in DTR of about 1.5°C was strongly correlated with increased cloudiness, except at high elevations. In Italy (Brunetti *et al.*, 2000), daytime warming is higher than nighttime temperature rise, with a consequent increase in DTR.

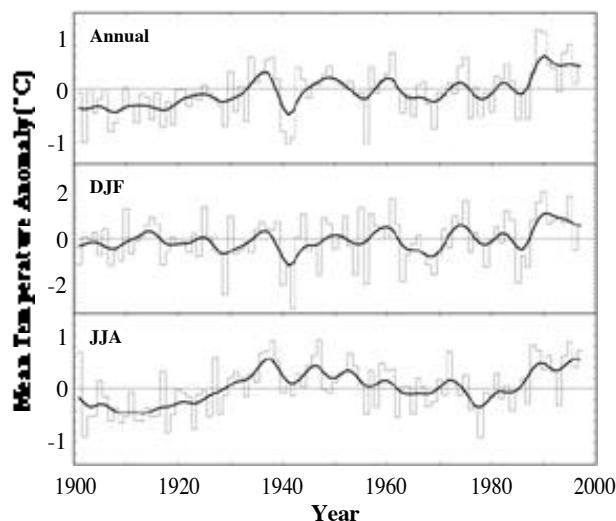

Figure 13-1: European annual mean temperature anomalies over land, 1901–1995, for the region 35°N to 75°N and 30°W to 50°E, with respect to 1961–90 mean. 10-pt filter applied. Data from IPCC Data Distribution Centre.

13.1.3.2. Precipitation

Trends in annual precipitation differ between northern Europe (wetting) and southern Europe (drying), reflecting a wider hemispheric pattern of contrasting zonal-mean precipitation trends between high and low latitudes (Dai *et al.*, 1997; Hulme *et al.*, 1998). Precipitation over northern Europe has increased by 10–40% in the 20th century, whereas some parts of southern Europe have dried by as much as 20% (see Figure 13-2). Romero *et al.* (1999) show that the numbers of days with precipitation over the Spanish southern coast and the Pyrenees region have decreased by 50 and 30%, respectively, in 1964–1993. In Italy, total precipitation in the 20th century has decreased by about 5% in the north and by about 15% in the south (Buffoni *et al.*, 1999; Brunetti *et al.*, 2001). Analysis of moisture extremes over Europe, using the Palmer Drought Severity Index (PDSI—Briffa *et al.*, 1994) showed strong decadal-scale variability in drought frequency; the 1940s and early 1950s experienced widespread and severe droughts—a pattern repeated in 1989 and 1990.

13.1.3.3. Extreme Events

Analyses of trends in extreme weather events in Europe generally have been limited to national studies, making it difficult to provide a continent-wide overview of changes in hot/cold day frequencies, precipitation intensities, or gale frequencies. Gruza *et al.* (1999) analyzed data over the whole of Russia, the western third of which falls into our definition of Europe, and found a slight increase over the 20th century in the Climate Extremes Index (CEI), which combines daily temperature, daily precipitation, and drought extremes. Analysis of 85 long-term maximum 1-day precipitation records in the Nordic countries indicates that there is a maximum in the 1930s and a tendency of increasing values during the 1980s and 1990s—decades with relatively high regional summer temperatures. In western Norway, the past 2 decades have been exceptional, with substantial increases in orographic precipitation during autumn, winter, and spring (Førland *et al.*, 1998). Elsewhere, daily precipitation intensities over the UK have increased in winter over recent decades (Osborn *et al.*, 1999), although not in other seasons. This increase in UK winter precipitation intensities has been paralleled by a marked decrease in the frequency of cold winter days in the UK (Jones *et al.*, 1999). Changes in storminess over the northeast Atlantic have been analyzed by Schmidt *et al.* (1998) and WASA (1998); they show that although storminess has increased in recent decades, storm intensities are no higher than they were early in the 20th century. Wave heights around the shores of northwest Europe also show large decadal variability, but no long-term trends emerge.

13.1.3.4. North Atlantic Oscillation

One important cause for interannual and perhaps interdecadal climate variability in Europe, particularly in winter, is the North Atlantic Oscillation (NAO). NAO is a measure of the strength

of the westerly flow over the North Atlantic; records go back to the early 19th century (Jones *et al.*, 1997). Over the past 4 decades, the NAO pattern gradually has altered from the most extreme and persistent negative phase in the 1960s to the most extreme positive phase during the late 1980s and early 1990s—a trend that has been responsible for relatively mild and wet winters during the latter period over much of northwest Europe (Hurrell and van Loon, 1997) and can help explain the observed narrowing in DTR (Tuomenvirta *et al.*, 1998). Following its long period of amplification, the NAO index underwent a sharp decrease to a short-lived minimum in the winter of 1995–1996, with radical recognizable changes in the North Atlantic. It should be noted that the NAO appears to exert significant control on the export of ice and freshwater from the Arctic to the open Atlantic (WCRP, 1998). Since that temporary minimum, a recovery toward positive values of the NAO has been observed. NAO certainly is a more important influence on European climate than the El Niño-Southern Oscillation (ENSO), although several studies have explored the influence of ENSO on European precipitation variability, and links between NAO and ENSO are being sought. Evidence for such an influence is weak and shows phase differences through the continent (Fraedrich and Müller, 1992; Fraedrich *et al.*, 1992; Rodo *et al.*, 1997; Price *et al.*, 1998).

13.1.4. Key Sensitivities to Climate and Weather Now

The response of human activities and the natural environment to current weather perturbations provides a guide to where critical sensitivities to future climate change may lie. Even if adaptation may modify the response, analysis of present-day sensitivities helps us understand the likely impact of future climate changes on our environment and lifestyle.

The principal sensitivities in Europe to current climate and weather conditions are to:

- Extreme seasons
 - Exceptionally hot, dry summers
 - Mild winters
- Short-duration hazards
 - Windstorm (possibly associated with tidal surges)
 - Heavy rain leading to river-valley flooding and flash floods
- Slow, long-term change
 - Coastal squeeze.

Sensitivities vary across Europe as a result of differences in climate and topography, as well as the socioeconomic environment, but all of Europe is sensitive to the foregoing anomalous conditions.

13.1.4.1. Extreme Seasons

13.1.4.1.1. Exceptionally hot, dry summers

Extremely hot and dry summers were experienced in 1995 throughout much of western Europe (Palutikof *et al.*, 1997)

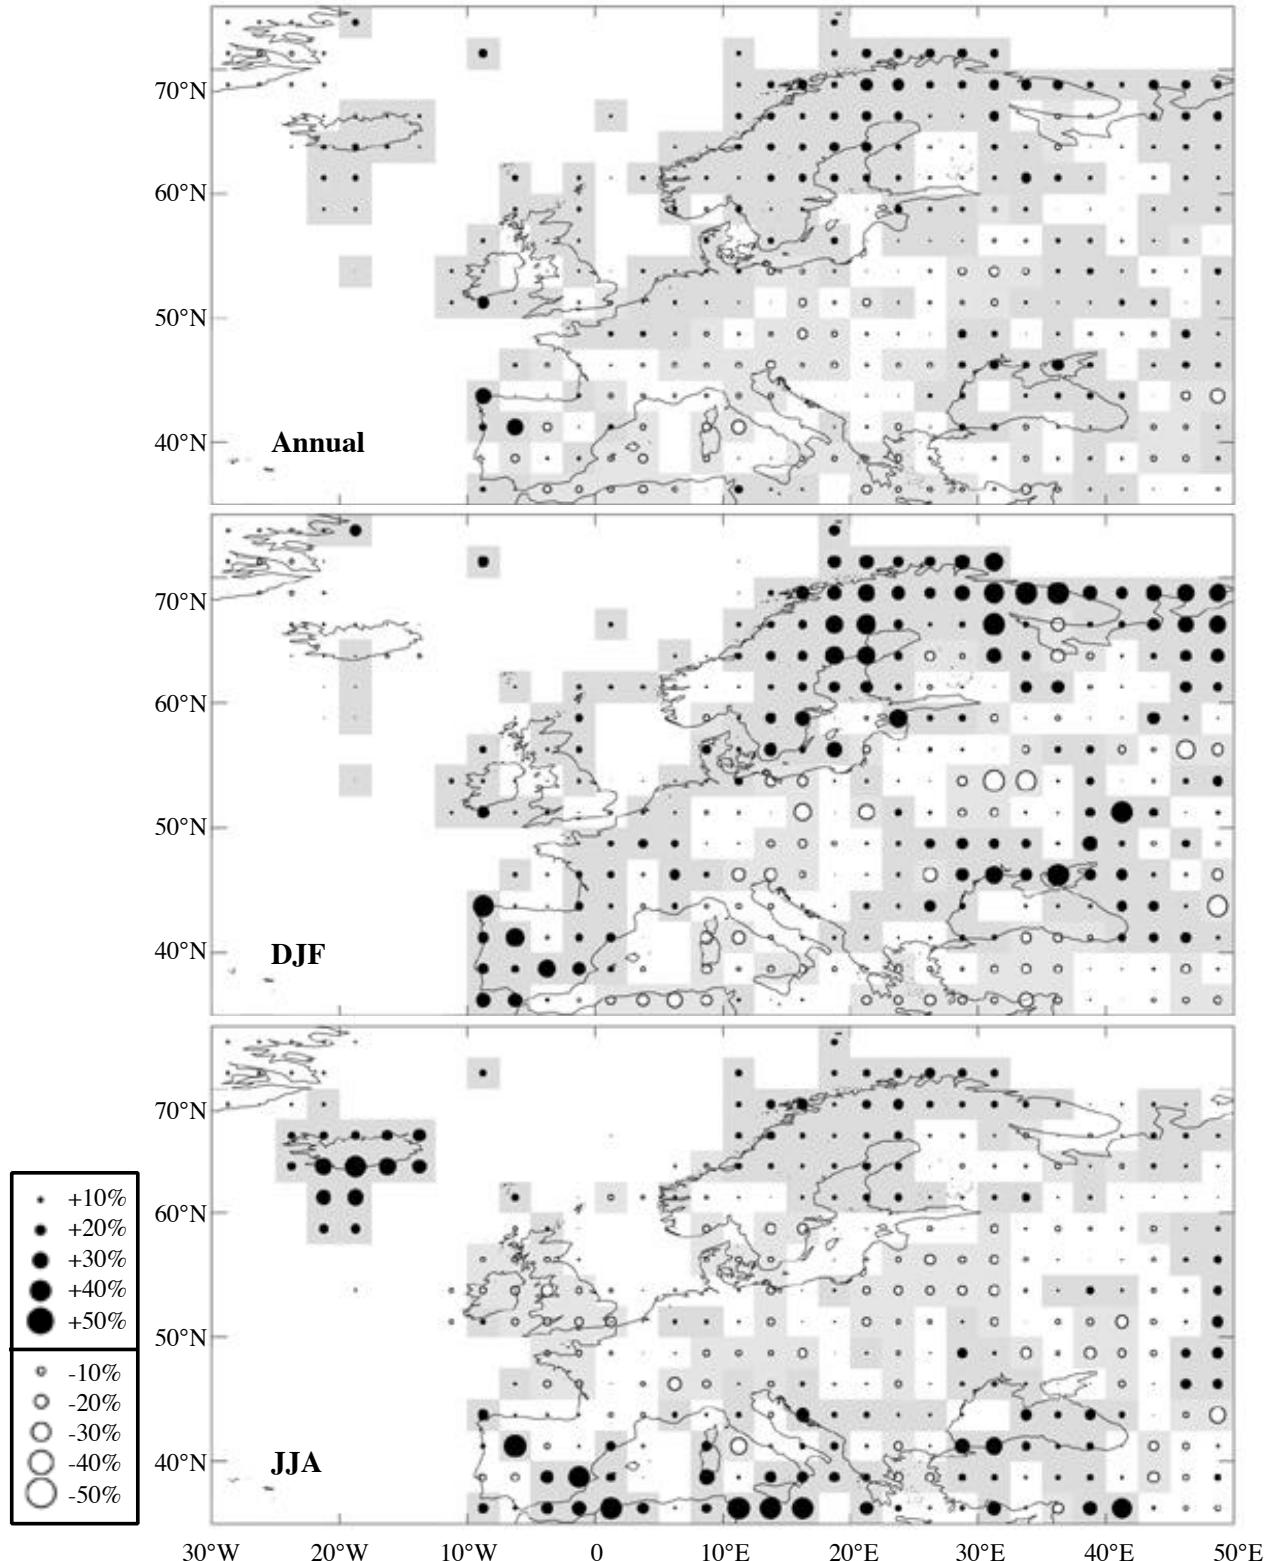

Figure 13-2: Trends in annual (top), winter (middle), and summer (bottom) precipitation expressed as % per century and calculated on 2.5° grid. Black circles denote wetting and white circles denote drying. Magnitude of trend is related to circle size. Shaded trends are significant at 90% (data from New *et al.*, 1999).

and in 1992 in CEE (Schellnhuber *et al.*, 1994). Summer drought conditions can have a devastating impact on the natural environment, particularly by reducing the availability of water for flora and fauna. Pollution levels may rise to high levels in the subsiding anticyclonic air, with add-on effects for human health in terms of increased numbers of asthma attacks and associated hospitalizations. High water temperatures often lead to algal blooms, which may make water bodies unusable for recreational purposes.

Agriculture and water supply are the two economic sectors that may be most severely affected by exceptional heat and drought in summer. Large proportions of the working populations in Mediterranean countries are engaged in agriculture, and even in "normal" years water shortages may be a limiting factor. These countries, therefore, appear to be more vulnerable to exceptional summer weather. An increased frequency of hot, dry summers is likely to reduce tree growth and affect timber yield and quality. Reduced tree vigor often favors outbreaks of pests and pathogens, and hot and dry conditions trigger wildfire.

13.1.4.1.2. Mild winters

Milder winters exert a major impact on the natural environment. Overwintering of species is more successful. However, failure to kill off pests and diseases that prey on wildlife, as well as failure to cull weaker members of the species—which then compete for food in the following springs and summers—in the end may be counterproductive. Cannell and Pitcairn (1993) show that during two mild winters in the UK, various life events occurred earlier—for example, insects and other animals moved about and fed more actively, causing widespread aphid damage on oak and mite damage on lime. Milder winters can affect fulfillment of chilling requirements in some plant species, which would have an impact on the formation of leaf and flower buds (e.g., Murray *et al.*, 1989). This could lead to regeneration failure; some susceptible species are common across much of Europe today (e.g., *Picea abies*) (Sykes and Prentice, 1996).

The skiing industry in Europe is vulnerable to variations in snowfall—that is, too little or too much snow. Many European ski resorts have suffered severe shortfalls in earnings when snow cover was not sufficiently deep during Christmas and winter school holidays. If temperatures remain below freezing, a more active hydrological cycle might lead to more episodes of heavy snowfall; the winter of 1998–1999 is a good proxy for this situation. Although the number of cold spells generally has decreased over the past few decades, cold spells still have a range of impacts on agriculture, settlements, the built environment, and transport.

13.1.4.2. Short-Duration Hazards

Severe windstorms affected Europe in the 1990s. The January 1990 storm (Daria) caused insured losses of about US\$5.7 billion

(at 1997 prices) and 95 deaths; in the following month, the storm of 26 February (Vivian) caused a further US\$3.9 billion in insured losses (Swiss Re, 1998) and 64 deaths. The UK experienced a severe windstorm at Christmas 1997, causing 13 deaths and losses of US\$500 million (Swiss Re, 1998).

The major impact of windstorm on the natural environment is on trees, woodland, and forest. It is estimated that 15 million trees (5 months' production of coniferous wood and 2 years' production of broadleaf timber production—see Quine, 1988) were blown down in the UK during the October 1987 storm.

Windstorm associated with tidal surge is a particularly deadly combination for low-lying coastal areas, as epitomized by the event of 1953. Severe northerly winds combined with an exceptionally high spring tide caused overtopping in The Netherlands and much of East Anglia, resulting in more than 2,000 deaths. Since then the policy has been to keep the sea out at all costs, and in fact several storm surges of similar size have occurred with no loss of life.

Several devastating river floods, of high severity, occurred in Europe in the 1990s (Kundzewicz and Takeuchi, 1999). Among the flood events to hit the headlines was the Odra flood in the summer of 1997, during which historic flow records were broken. The deluge caused more than 100 deaths and economic damage in excess of US\$5 billion (Kundzewicz *et al.*, 1999).

13.1.4.3. Coastal Squeeze

Coastal squeeze occurs when coastal habitats are "squeezed" between rising sea level and fixed hard defenses (Bijlsma *et al.*, 1996). It is occurring in most northwest European countries, and it already is a coastal management issue (Rigg *et al.*, 1997). It is considered in more detail in Sections 13.2.1.3 and 13.3.5.

13.1.5. Climate Scenarios for the Future

Most of the impact studies evaluated in this chapter have attempted to characterize the future climate of a study region by using climate change scenarios. General reviews of the development and application of climate change scenarios are provided in Chapter 3 and in TAR WGI Chapter 13. It also should be noted that many recent impact studies in Europe have followed published guidelines concerning the use of scenarios (Carter *et al.*, 1994; USCSP, 1994; Smith and Hulme, 1998). This review offers a brief summary first of the types of scenario information provided in European impact assessments and second of research to improve this information.

13.1.5.1. Scenario Provision

One or more of three broad classes of climate change scenario generally have been adopted: synthetic scenarios, palaeoclimatic analogs, and scenarios that are based on outputs from GCMs.

The impacts of these scenario changes conventionally are assessed relative to conditions under a reference or “baseline” climate that represents present-day conditions (commonly 1961–1990).

Synthetic or incremental scenarios describe techniques whereby particular climatic (or related) elements are changed by a realistic but arbitrary amount, often according to an interpretation of climate model simulations for a region. They are simple to use

and can offer a useful tool for exploring the sensitivity of an exposure unit to a plausible range of climatic variations. They commonly are applied prior to the adoption of more detailed GCM-based scenarios. For example, national assessments in CEE conducted as part of the U.S. Country Studies Program adopted adjustments of present-day temperatures by +1, +2, +3, and +4°C and baseline precipitation by ±5, +10, +15, and +20% (e.g., Smith and Pitts, 1997; Kalvová, 1995; Alexandrov, 1997).

Box 13-1. Some Key Features of Climate Scenarios for Europe

Temperature

- Annual temperatures over Europe warm at a rate of between 0.1 and 0.4°C per decade. This warming of future annual climate is greatest over southern Europe (Spain, Italy, Greece) and northeast Europe (Finland, western Russia) and least along the Atlantic coastline of the continent.
- In winter, the continental interior of eastern Europe and western Russia warms more rapidly (0.15–0.6°C per decade) than elsewhere. In summer, the pattern of warming displays a strong south-to-north gradient, with southern Europe warming at a rate of between 0.2 and 0.6°C per decade and northern Europe warming between 0.08 and 0.3°C per decade.
- Winters currently classified as cold (occurring 1 year in 10 during 1961–1990) become much rarer by the 2020s and disappear almost entirely by the 2080s. In contrast, hot summers become much more frequent. Under the 2080s scenario, nearly every summer is hotter than the 1-in-10 hot summer as defined under the present climate.
- The agreement between models about these future temperature changes is greatest over southern Europe in winter. In summer, however, this region shows the greatest level of disagreement between model simulations. All model simulations show warming in the future across the whole of Europe and in all seasons.

Precipitation

- The general pattern of future change in annual precipitation over Europe is for widespread increases in northern Europe (between +1 and +2% per decade), smaller decreases across southern Europe (maximum –1% per decade), and small or ambiguous changes in central Europe (France, Germany, Hungary, Belarus).
- There is a marked contrast between winter and summer patterns of precipitation change. Most of Europe gets wetter in the winter season (between +1 and +4% per decade); the exception is the Balkans and Turkey, where winters become drier. In summer, there is a strong gradient of change between northern Europe (wetting of as much as +2% per decade) and southern Europe (drying of as much as –5% per decade).
- The areas, however, where these changes are greater than the 2-standard deviation estimate of natural 30-year time scale climate variability are limited to the later periods (2050s and 2080s) and to the scenarios with the larger rates of global warming (B2, A1, and A2).
- Only for the A2-high scenario are there substantial areas in Europe (Fennoscandia and northwest Europe) where precipitation changes by the 2020s are larger than what might occur as a result of natural climate variability. Even for this scenario with rapid global warming, not all regions in Europe have well-defined precipitation signals from GHG-induced climate change by the 2080s.
- The intermodel range of seasonal precipitation changes generally is larger than the median change, implying that sign differences frequently exist between the precipitation changes simulated by different climate models. The largest intermodel differences tend to occur in southern and northern Europe. Intermodel differences are smallest across much of central Europe.

Weather Extremes

- The scenarios do not explicitly quantify changes in daily weather extremes. However, it is very likely that frequencies and intensities of summer heat waves will increase throughout Europe; likely that intense precipitation events will increase in frequency, especially in winter, and that summer drought risk will increase in central and southern Europe; and possible that gale frequencies will increase.

Sea Level

- Global-mean sea level rises by the 2050s by 13–68 cm. These estimates make no allowance for natural vertical land movements. Owing to tectonic adjustments following the last glaciation, there are regional differences across Europe in the natural rates of relative sea-level change.

Scenarios based on GCM simulations are the most widely adopted in impact studies reported from Europe. Some of these studies employ scenarios that are based on equilibrium 2xCO₂ model simulations that were conducted during the 1980s (e.g.,

Smith *et al.*, 1996; Tarand and Kallaste, 1998). The performance of some of these GCMs at simulating current climate over Europe was examined by Smith and Pitts (1997) and Kalvová and Nemesová (1997). Among the models considered, they

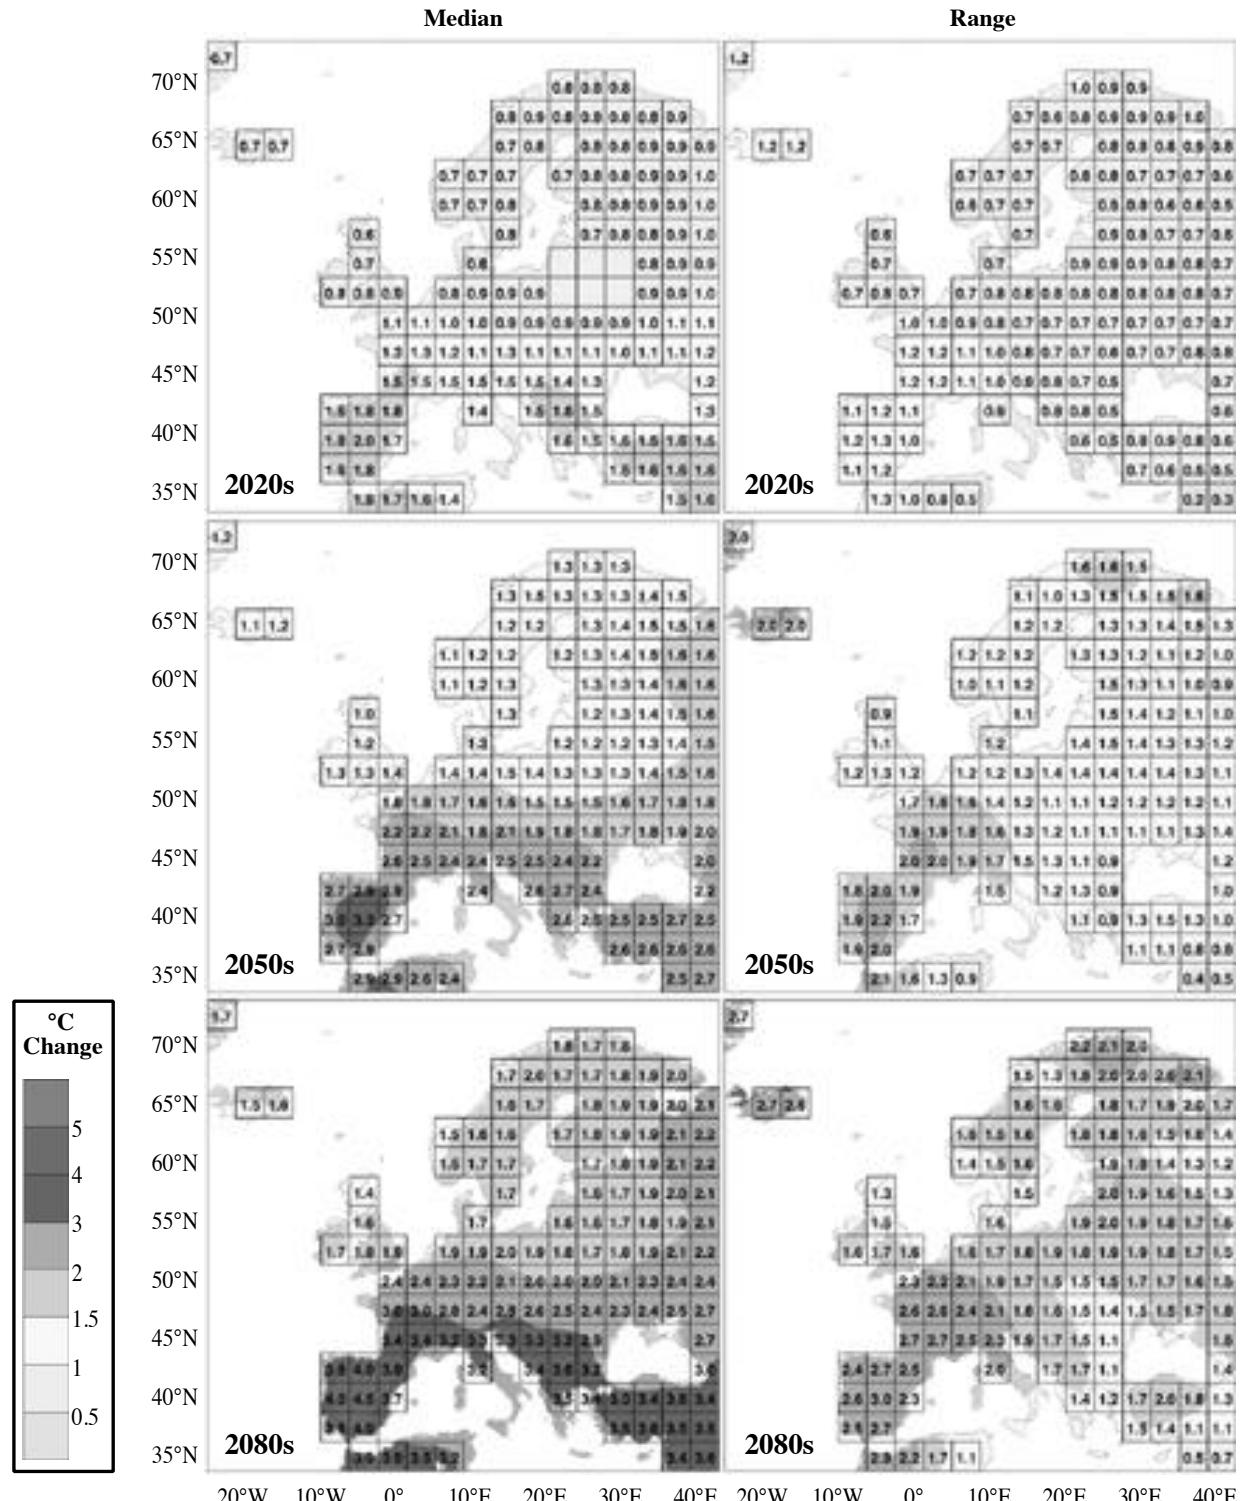

Figure 13-3: ACACIA B2 summer scenario maps (B2-mid, JJA) for mean temperature.

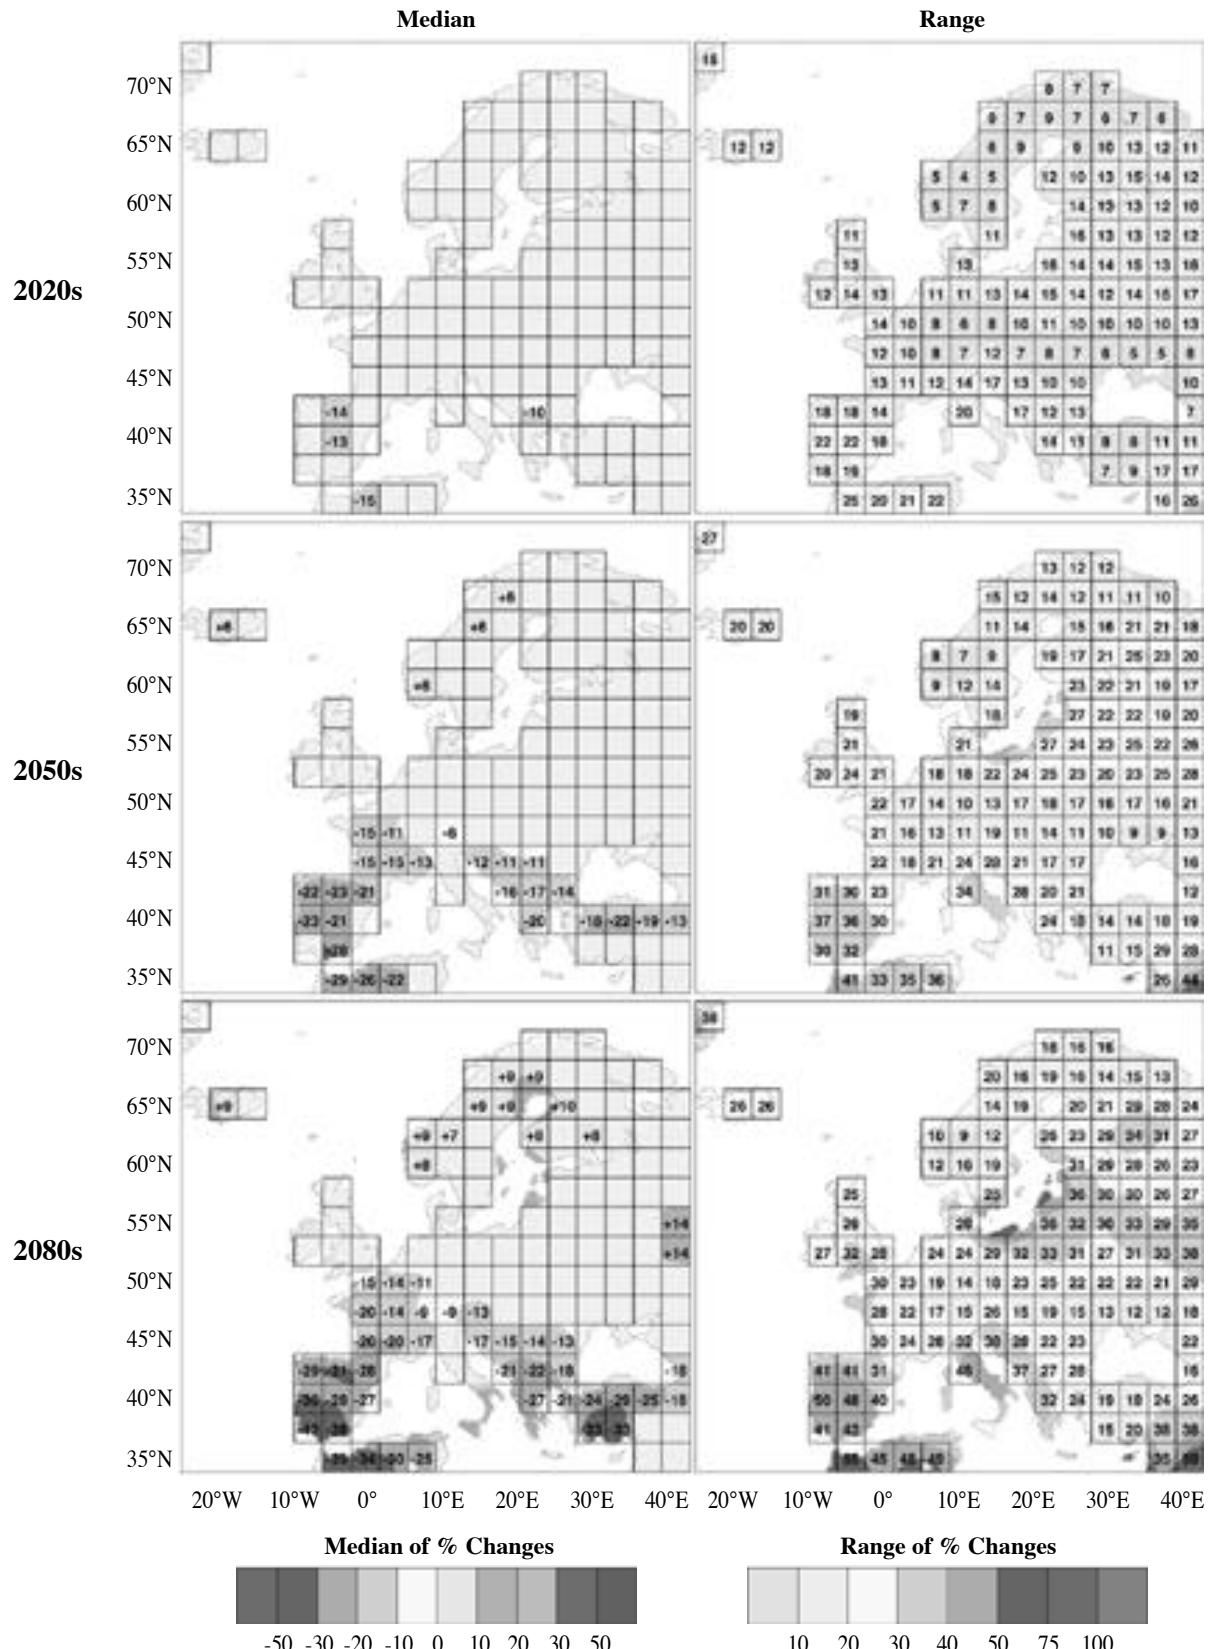

Figure 13-4: ACACIAB2 summer scenario maps (B2-mid, JJA) for precipitation.

found that the Goddard Institute for Space Studies (GISS) and Canadian Centre for Climate Modeling and Analysis (CCCM) models best simulated current temperature, whereas the GISS and UK89 models best simulated precipitation in northern regions and the CCCM model best simulated precipitation in southern regions.

Scenarios from the earliest transient-response experiments with coupled atmosphere-ocean GCMs (AOGCMs), which ignored historical greenhouse gas (GHG) forcing, were adopted in several studies that used direct model outputs (e.g., Harrison *et al.*, 1995b) or modified the outputs to account for historical forcing, using simple climate models (e.g., Carter *et al.*, 1996a; UK Department of the Environment, 1996). Scenarios from transient-response experiments that explicitly account for historical forcing have been adopted in the most recent impact studies (e.g., Arnell, 1999; Harrison and Butterfield, 1999; Hulme *et al.*, 1999). Some of these scenarios also incorporate aerosol effects, ensemble simulations, and multidecadal climatic variability. Many of these GCM results are lodged with the IPCC Data Distribution Centre (DDC) and were used in developing the European scenarios of A Concerted Action Towards A Comprehensive Climate Impacts and Adaptations Assessment for the European Union (ACACIA).

13.1.5.2. Scenarios for Europe

The climate change scenarios summarized here originally were prepared for the European ACACIA project and subsequently developed further for the IPCC (Hulme and Carter, 2000). The method by which they were developed is briefly described in Chapter 3 of this volume and more fully in Carter *et al.* (2000). These scenarios define a range of future European climates that embrace some of the major uncertainties in future climate prediction. The scenarios were placed in the context of model estimates of the natural variability of European climate. The baseline period selected was 1961–1990; changes in mean 30-year climates were calculated for the periods centered on the 2020s (2010–2039), the 2050s (2040–2069), and the 2080s (2070–2099). Each climate scenario is based on one of the four preliminary SRES98 marker emissions scenarios from the IPCC *Special Report on Emissions Scenarios* (SRES) (Nakicenovic, 2000).

For each scenario, season, variable, and time-slice, two maps were constructed (see Figures 13-3 and 13-4). One map shows the median change from the sample of eight standardized and scaled GCM responses; the other map shows the absolute range of these eight responses. The idea of signal-to-noise ratios in these regional responses was introduced by comparing median scaled-GCM changes against an estimate of natural multidecadal variability derived from the 1,400-year unforced climate simulation made with the HadCM2 model (Stott and Tett, 1998). In the maps showing median changes, only values exceeding the 2-standard deviation estimate of natural multidecadal variability are plotted. Figures 13-3 and 13-4 show an example of this information for the B2-mid scenario

for summer temperature and precipitation. A complete set of illustrations appears in the report of the European ACACIA project (Hulme and Carter, 2000).

To condense this scenario information further, national-scale summary graphs for each European country or groups of countries have been calculated (see Figure 13-5 for an example covering Spain, Sweden, and Poland). Each country graph shows—for either winter or summer and for either the 2020s, the 2050s, or the 2080s—the distribution of mean changes in mean temperature and precipitation for each GCM simulation and for each scenario. As with the maps, these changes are compared with the natural multidecadal variability of temperature and precipitation extracted from the HadCM2 1,400-year unforced simulation. These graphs provide a quick assessment at a national scale of the likely range and significance of future climate change and the extent to which different GCMs agree with regard to their regional response to a given magnitude of global warming.

A contrasting future climate for Europe—the result of a rapid, nonlinear response of the climate system—has been suggested. This involves an abrupt collapse of the thermohaline circulation in the North Atlantic and consequent cooling in Europe at least for the first half of the 21st century (e.g., Alcamo *et al.*, 1994). Although this event has not been ruled out on theoretical grounds (see TAR WGI Chapter 11), it has not been simulated by any AOGCM (see TAR WGI Chapter 9) and therefore has not been included in this assessment.

13.1.6. Socioeconomic Scenarios for Europe

The four socioeconomic global futures (or SRES scenarios) described in Chapter 3 of this assessment have been characterized for Europe in the European ACACIA study (Jordan *et al.*, 2000), and are summarized below:

- Under a “World Market” (A1) scenario, the world becomes increasingly globalized, and materialist-consumerist social values predominate. Global societal values are primarily technocentric and short-termist. Nature therefore is assumed to be largely resilient to human stress. The emphasis is on pursuing economic growth in the narrow sense rather than sustainable development. Although rising income levels will make everyone in Europe richer, the poorest will gain relatively little. The EU functions as a single interconnected market, functionally integrated with other regional markets (e.g., in Asia and North America).
- Under a “Global Sustainability” (B1) scenario, Europe is run along more communitarian lines and within environmental resource limits. There is a strong emphasis on finding international solutions to globally interconnected problems. Thus, EU member states pool more and more of their sovereignty to address common environmental problems, the causes of which are considered to lie in the basic structure of

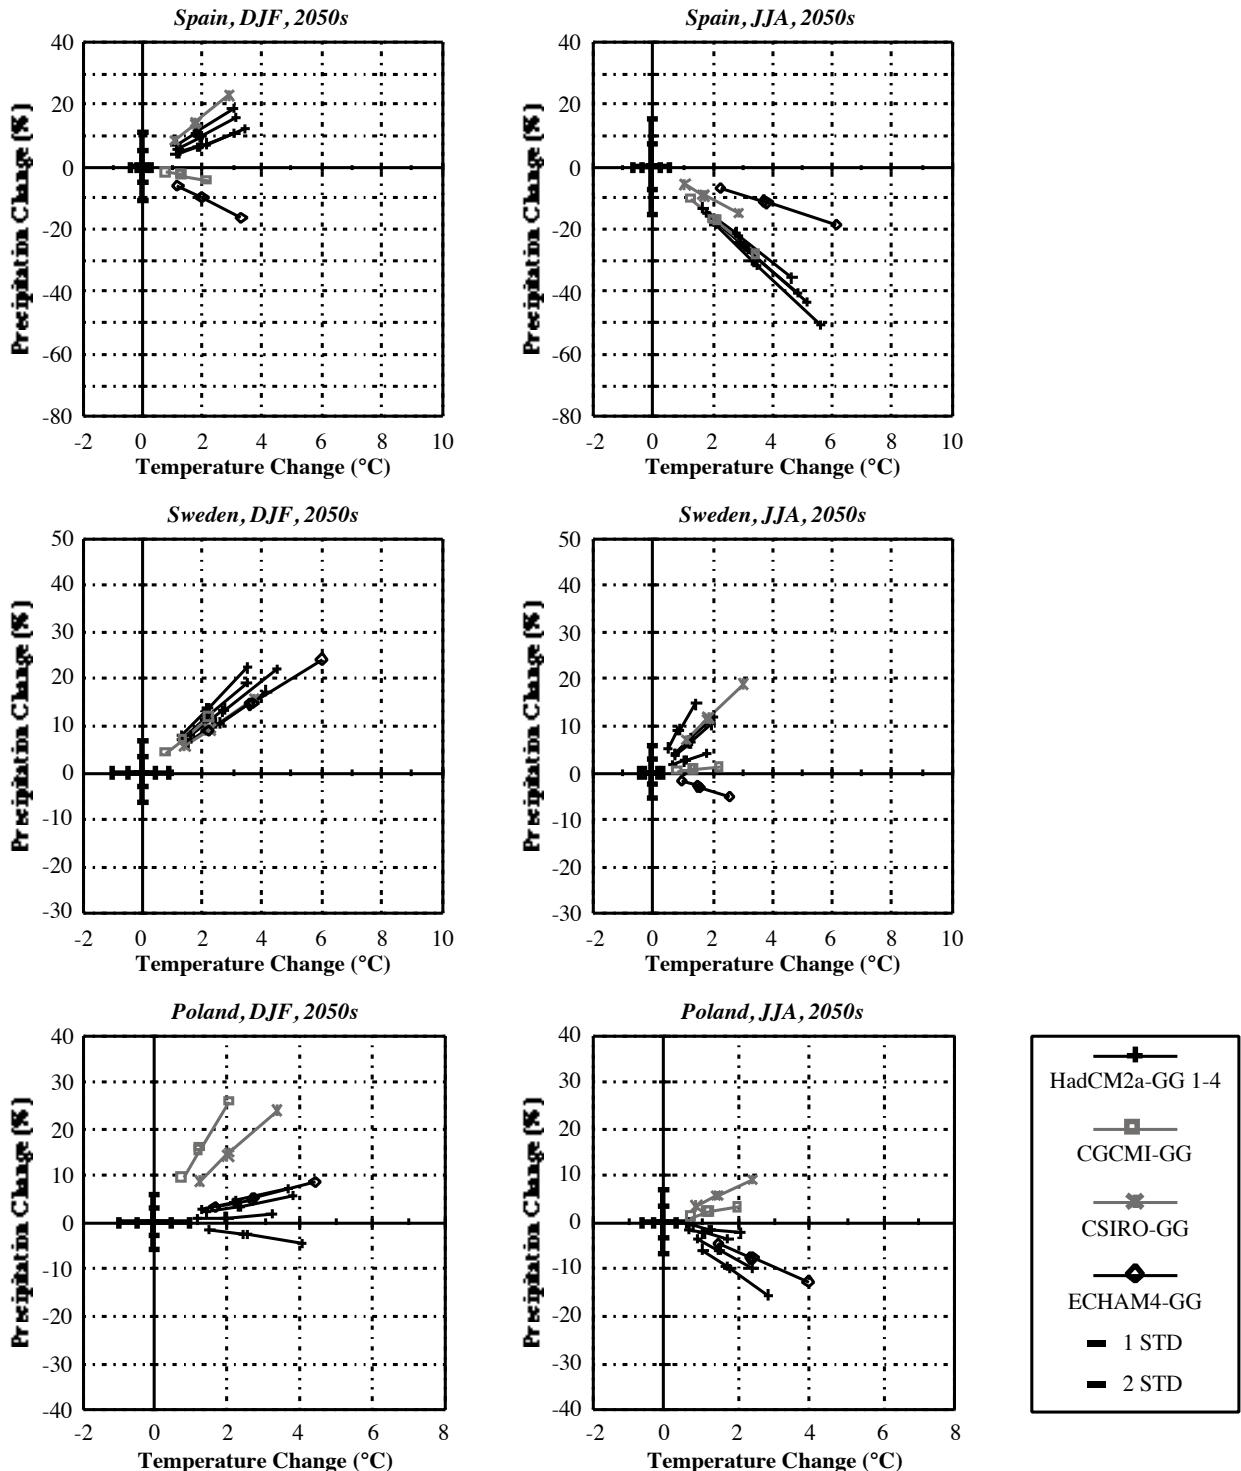

Figure 13-5: Scatter plot depicting scaled outputs of mean winter (left panels) and summer (right panels) temperature and precipitation change over land grid boxes representing Spain (top), Sweden (middle), and Poland (bottom) from each of seven GCM simulations (GFDL simulations are not shown because they extend only to 2025). Lines connect four points for each GCM simulation, each point representing standardized regional changes in climate from the GCM, linearly scaled according to global warming from each of the four ACACIA scenarios. The order of points along a line from the origin is the same for all plots: B1-low, B2-mid, A1-mid, A2-high. Also plotted are 1 and 2 standard deviation limits from 1,400-year HadCM2 unforced simulation, which is used to indicate natural multi-decadal variability.

society. The role of international institutions, including the EU, will extend from simply regulating environmental problems to tackling social inequality and social exclusion through adoption of social programs.

- In a “Provincial Enterprise” (A2) scenario, Europe is much more heterogeneous. Increasingly, the organization of society is dictated by short-term consumerist values. More policy decisions are taken at a national and subnational level. Europe adopts more protectionist economic and trade policies, which constrain innovation and stifle economic development, particularly in developing countries. Growth in global GDP is more modest than under the A1 scenario, and global inequality grows. Declining equity within and between member states of the EU produces tension and social exclusion. This typifies the uneasy tension in this scenario between the simultaneous desire for “free markets” (consumerist values) and protection of national state sovereignty. Politicians prioritize demands such as protecting the national economy and meeting short-term consumer demands for growth over environmental quality.
- In a “Local Sustainability” (B2) scenario, Europe is more committed to solving environmental problems by applying solutions that are attuned to local needs and circumstances. Thus, the dominant value system is more communitarian and ecocentric in nature, with greater commitment to longer term, strategic planning. In a sense, the shift in governance down to the local level accords with the principle of *subsidiarity*. National governments therefore are left to perform residual functions that cannot be undertaken at the subnational level. Small firms thrive under these conditions, whereas multinationals struggle to realign themselves to local needs. Overall, the world (including Europe) is more heterogeneous. Because of the lack of coordinated regional action, however, relative inequality may increase as local problems receive higher priority than those in other regions. Significantly, the environment benefits under this scenario, but not nearly as much as under B1 because of the limited extent of spatial coordination.

13.2. Key Regional Concerns

13.2.1. Water and Land Resources

13.2.1.1. Water Resources

Europe has a very diverse hydrological background, reflecting its varied climate and topography. In the south there is very significant variation in flow through the year, with long, dry summers. To the west there is less extreme variation, and in catchments underlain by absorbent aquifers flows remain reasonably constant through the year. In the north and east, much precipitation falls as snow, so much flow occurs during the spring snowmelt period. Major rivers such as the Rhine,

Rhone, Po, and Danube distribute water from the “water tower” of the Alps. Superimposed on this varied hydrological base is a wide variety of water uses, pressures, and management approaches. Asuccession of floods and droughts has illustrated Europe’s vulnerability to hydrological extremes. There are many other water-related pressures on Europe’s environment, however (see the Dobris Assessment—Stanners and Bourdeau, 1995), such as increasing demand for water, particularly in the south, and subsequent increases in abstractions. River ecosystems and wetlands are increasingly at risk. The quality of Europe’s rivers, lakes, and groundwater is being threatened by the discharge of sewage and industrial waste (often a legacy from past industrial development) and by excessive application of pesticides and fertilizers. At the same time, the institutional aspects of water resources management are changing. There is a shift in many countries from “supply-side” solutions to a “demand-side” approach, aimed at reducing demand for water or exposure to risk. Water managers in many European countries have adopted (at least in principle) a sustainable approach, and forthcoming EU directives are likely to encourage this further. Environmental demands are being taken increasingly seriously across most of Europe. Climate change adds another set of potential pressures on European water resources and their management.

13.2.1.1.1. Changes in hydrological cycle

Climate and land-use change influence the structure of the water balance (Ryszkowski and Kedziora, 1987; Ryszkowski *et al.*, 1990; Olejnik and Kedziora, 1991). Calculations at the European scale (Arnold, 1999) indicate that under most climate change scenarios, northern Europe would see an increase in annual average streamflow, but southern Europe would experience a reduction in streamflow. In much of mid-latitude Europe, annual runoff would decrease or increase by about 10% by the 2050s, but the change resulting from climate may be smaller than “natural” multidecadal variability in runoff. To the south and north, it may be substantially larger (Hulme *et al.*, 1999). Table 13-1 lists catchment-scale studies into potential hydrological changes in Europe that have been conducted since the IPCC’s Second Assessment Report (SAR).

The consequences of climate change for the variation of flow through the year vary across Europe. In Mediterranean regions, climate change is likely to exaggerate considerably the range in flows between winter and summer. In maritime western Europe, the range also is likely to increase, but to a lesser extent. In more continental and upland areas, where snowfall makes up a large proportion of winter precipitation, a rise in temperature would mean that more precipitation falls as rain and therefore that winter runoff increases and spring snowmelt decreases. The timing of streamflow therefore alters significantly. Further east and at higher altitudes, most of the precipitation continues to fall as snow, so the distribution of flow through the year is altered little (Arnold, 1999). The substantial projected change in flow regime resulting from reduction in snowfall and snowmelt across large parts of CEE has been noted widely

Table 13-1: Catchment-scale studies into effects of climate change on runoff regimes in Europe (since SAR).

(e.g., Hladny *et al.*, 1996; Kasparék, 1998; Hlavcová and Cunderlík, 1998; Starosolszky and Gauzer, 1998).

Low-flow frequency generally will increase across most of Europe (Arnell, 1999), although in some areas where the minimum occurs during winter the absolute magnitude of low flows may increase because winter runoff increases: The season of lowest flow shifts toward summer. An implication of simulated changes in streamflow is that riverine flood risk generally would increase across much of Europe and that in some areas, the time of greatest risk would move from spring to winter. Effects on groundwater recharge (a major resource for many Europeans) are less clear because the general increase in winter rainfall may be offset by a reduction in the recharge season. Studies in the UK (Arnell and Reynard, 1999) and Estonia (Jarvet, 1998) indicate that groundwater recharge could be increased by climate change.

Implications of climate change for river water quality have been less well studied, but an increase in water temperature and

widespread reductions in flow during summer are likely to lead to deterioration in many determinants of water quality (particularly dissolved oxygen concentrations). Jansons and Butina (1998) estimate nitrate and phosphate loads in a catchment in Latvia from streamflow; they use the relationships to infer an increase in nitrate and phosphate loads in winter (when flow increased) and a decrease in spring. Their model, however, did not account for possible temperature-related effects on nitrate and phosphate concentrations. Higher water temperatures are likely to increase the risk of blue-green algal blooms in rivers and lakes (e.g., Zalewski and Wagner, 1995).

13.2.1.1.2. Water management

The impacts of climate change on European water resources and their management depend not only on the change in hydrology but also (perhaps more particularly) on characteristics of the water management system. In general terms, the more stressed the system is under current conditions, the more sensitive it will be to climate change. Table 13-2 summarizes the key potential impacts on European water resources. These impacts should be considered against the background of other pressures and drivers on European water. Most of the potential impacts are self-explanatory.

Changes in the water resource base affect many sectors within Europe, including agriculture, industry, transport, power generation, the built environment, and ecosystems. Similarly, changes in many of these sectors will affect hydrology and the resource base. Changes in agricultural practices resulting from climate change, for example, will affect volumes and, more likely, quality of streamflow.

In many European countries, industrial water use has declined as a result of legislation, environmental protection, and economic change. The warmer climate may lead to significant increase in water demands in southern Europe—leading to possible overexploitation of groundwater resources, decrease of baseflow, and environmental degradation. Climate change is but one of the pressures facing European water managers. They will be played out against varying socioeconomic backgrounds, political demands for environmental improvements, and new trends in integrated water management. More detail on this and the foregoing conclusions appear in the water chapter of the European ACACIA report (Arnell, 2000).

13.2.1.2. Soils and Land Resources

Climate change will impact directly and, through land-use change, indirectly on a wide range of soil processes and properties that will determine the future ability of land to fulfill key functions that are important for all terrestrial ecosystems, as well as several socioeconomic activities, that underpin the well-being of society. The following subsections summarize key effects. Further information is summarized in the section on soils in the European ACACIA report (Rounsevell and Imeson, 2000).

Table 13-2: Key impacts of climate change on European water resources.

Sector	Potential Impacts	Sample Reference
Public water supply	<ul style="list-style-type: none"> – Reduction in reliability of direct river abstractions – Change in reservoir reliability (dependent on seasonal change in flows) – Reduction in reliability of water distribution network 	Kaczmarek <i>et al.</i> (1996), Dvorak <i>et al.</i> (1997)
Demand for public water supplies	<ul style="list-style-type: none"> – Increasing domestic demand for washing and out-of-house use 	Herrington (1996)
Water for irrigation	<ul style="list-style-type: none"> – Increasing demand – Reduced availability of summer water – Reduced reliability of reservoir systems 	Kos (1993), Alexandrov (1998)
Power generation	<ul style="list-style-type: none"> – Change in hydropower potential through the year – Altered potential for run-of-river power – Reduced availability of cooling water in summer 	Grabs (1997), Sælthun <i>et al.</i> (1998)
Navigation	<ul style="list-style-type: none"> – Change (reduction?) in navigation opportunities along major rivers 	Grabs (1997)
Pollution risk and control	<ul style="list-style-type: none"> – Increased risk of pollution as a result of altered sensitivity of river system 	Mänder and Kull (1998)
Flood risk	<ul style="list-style-type: none"> – Increased risk of loss and damage – Increased urban flooding from overflow of storm drains 	Grabs (1997)
Environmental impacts	<ul style="list-style-type: none"> – Change in river and wetland habitats 	

13.2.1.2.1. Soil physical properties

Soil water contents respond rapidly to variability in the amounts and distribution of precipitation or the addition of irrigation. Temperature changes affect soil water by influencing evapotranspiration, and plant water use is further influenced by elevated CO₂ concentrations, leading to lower stomatal conductance and increased leaf photosynthetic rates (Kirschbaum *et al.*, 1996). Soil water contents are highly variable in space (Rounsevell *et al.*, 1999), so it is difficult to generalize about specific climate impacts.

Climate change can be expected to modify soil structure through the physical processes of shrink-swell (caused by wetting and drying) and freeze-thaw, as well as through changes in soil organic matter (SOM) contents (Carter and Stewart, 1996). Compaction of soils results from inappropriate timing of tillage operations during periods when the soil is too wet to be workable. Soil workability has a strong influence on the distribution and management of arable crops in temperate parts of Europe (Rounsevell, 1993; Rounsevell and Jones, 1993). Therefore, wet areas with heavy soils could benefit from climate change (MacDonald *et al.*, 1994; Rounsevell and Brignall, 1994). In a similar way, grassland systems can suffer poaching by grazing livestock (i.e., damage caused by animal hooves) (Harrod, 1979). Thus, drier soil conditions for longer periods of the year would affect the distribution of intensive

agricultural grassland in temperate Europe (Rounsevell *et al.*, 1996a) and may result in intensification of currently wet upland grazing areas.

Soils with large clay contents shrink as they dry and swell when they become wet again, forming large cracks and fissures. Drier climatic conditions will increase the frequency and size of crack formation in soils, especially those in temperate regions of Europe, which currently do not reach their full shrinkage potential (Climate Change Impacts Review Group, 1991, 1996). Soils that shrink and swell cause damage to building foundations through subsidence, creating a problem for householders and the housing insurance industry (Building Research Establishment, 1990). Crack formation also results in more rapid and direct movement of water and solutes from surface soil to permeable substrata or drainage installations through bypass flow (Armstrong *et al.*, 1994; Flurry *et al.*, 1994). This will decrease the filtering function of soil and increase the possibility of nutrient losses and water pollution (Rounsevell *et al.*, 1999).

13.2.1.2.2. Land degradation processes

Accumulation of salts in soils (salinization) results from capillary movement and dispersion of saline water because evapotranspiration is greater than precipitation and irrigation

(Värallyay, 1994). Such conditions, which are widespread throughout the warmer and drier regions of southern Europe, will be exacerbated by temperature rise coupled with reduced rainfall. Climate change also will increase flood incidence and salinity along coastal regions, through the influence of sea-level rise (Nicholls, 2000).

A decrease in precipitation and/or increase in temperature increases oxidation and loss of volume in lowland peat soils that are used for agriculture. It has been suggested that under climate change, the volume of peats in agricultural use will shrink by 40% (Kuntze, 1993). Some peat soils in western Europe are associated with acid sulfate conditions (Dent, 1986); strong acidity largely precludes agricultural use (Beek *et al.*, 1980). Soil acidification also can result from depletion of basic cations through leaching (Brinkman, 1990) where the soil is well drained and structurally stable and experiences high rainfall amounts and intensity—as in many upland areas of Europe. In wetter climate, soil acidification could increase if buffering pools become exhausted, although for most soils this will take a very long time.

Climate change is likely to increase wind and water erosion rates (Rosenberg and Tutwiler, 1988; Dregne, 1990; Botterweg, 1994), especially where the frequency and intensity of precipitation events grows (Phillips *et al.*, 1993). Erosion rates also will be affected by climate-induced changes in land use (Boardman *et al.*, 1990) and soil organic carbon contents (Bullock *et al.*, 1996). Relatively small changes in climate may push many Mediterranean areas into a more arid and eroded landscape (Lavee *et al.*, 1998) featuring decreases in organic matter content, aggregate size, and stability and increases in sodium adsorption ratio and runoff coefficient. However, increased erosion in response to climate change cannot be assumed for all parts of Europe. For example, in upland grazed areas, erosion rates will be reduced as a result of better soil surface cover and topsoil stability arising from higher temperatures that extend the duration of the growing season and reduce the number of frosts (Boardman *et al.*, 1990).

13.2.1.2.3. Biologically mediated soil properties

Climate change will impact directly on SOM through temperature and precipitation (Tinker and Ineson, 1990; Cole *et al.*, 1993; Pregitzer and Atkinson, 1993) and indirectly (and possibly more importantly) through changing land use (e.g., Hall and Scurlock, 1991). SOM contents increase with soil water content and decrease with temperature (Post *et al.*, 1982, 1985; Robinson *et al.*, 1995), although rates of decomposition vary widely between different soil carbon pools (van Veen and Paul, 1981; Parton *et al.*, 1987; Jenkinson, 1990). Changes in SOM contents depend on the balance between carbon inputs from vegetation and carbon losses through decomposition (Lloyd and Taylor, 1994); most SOM is respired by soil organisms within a few years. Net primary productivity (NPP) usually increases with increasing temperature and elevated atmospheric CO₂, leading to greater returns of carbon to soils (Loiseau *et al.*, 1994). However,

increasing temperature strongly stimulates decomposition (Berg *et al.*, 1993; Lloyd and Taylor, 1994; Kirschbaum, 1995) at rates that are likely to outstrip NPP and lead to reduced SOM contents (Kirshbaum *et al.*, 1996). This effect will be strongest in cooler regions of Europe, where decomposition rates currently are slow (Jenny, 1980; Post *et al.*, 1982; Kirschbaum, 1995). Conversely, excess soil water resulting from increased precipitation will reduce decomposition rates (Kirschbaum, 1995) and thus increase SOM contents.

Plant growth and soil water use are strongly influenced by the availability of nutrients. Where climatic conditions are favorable for plant growth, the shortage of soil nutrients will have a more pronounced effect (Shaver *et al.*, 1992). Increased plant growth in a CO₂-enriched atmosphere may rapidly deplete soil nutrients; consequently, the positive effects of CO₂ increase may not persist as soil fertility decreases (Bhattacharya and Geyer, 1993). Increased SOM turnover rates over the long term are likely to cause a decline in soil organic nitrogen in temperate European arable systems (Bradbury and Powelson, 1994), although, in the short term, increased returns of carbon to soils would maintain soil organic nitrogen contents (Pregitzer and Atkinson, 1993; Bradbury and Powelson, 1994). Greater mineralization may cause an increase in nitrogen losses from the soil profile (e.g., Kolb and Rehfuss, 1997; Lukewille and Wright, 1997), although there is evidence to suggest that temperature-driven, increased nitrogen uptake by vegetation may reduce these losses (Ineson *et al.*, 1998).

There is great uncertainty surrounding the response of soil community function to global change and the potential effects of these responses at the ecosystem level (Smith *et al.*, 1998). Most soil biota have relatively large temperature optima and therefore are unlikely to be adversely affected by climate change (Tinker and Ineson, 1990), although some evidence exists to support changes in the balance between soil functional types (Swift *et al.*, 1998). Soil organisms will be affected by elevated atmospheric CO₂ concentrations where this changes litter supply to and fine roots in soils, as well as by changes in the soil moisture regime (Rounsevell *et al.*, 1996b). Furthermore, the distribution of individual species of soil biota will be affected by climate change where species are associated with specific vegetation and are unable to adapt at the rate of land-cover change (Kirschbaum *et al.*, 1996).

13.2.1.3. Coastal Zones

Coastal zones in Europe contain large human populations and significant socioeconomic activity. They also support diverse ecosystems that provide significant habitats and sources of food. Significant inhabited coastal areas in countries such as The Netherlands, England, Denmark, Germany, Italy, and Poland already are below normal high-tide levels, and more extensive areas are vulnerable to flooding from storm surges. Hard defenses to prevent such flooding, combined with the loss of the seaward edge of coastal habitats as a result of existing rates of sea-level rise, already are causing significant coastal

squeeze in many locations (e.g., Pye and French, 1993; Rigg *et al.*, 1997; Lee, 1998). Deltaic areas often are particularly threatened because they naturally subside and may have been sediment-starved by dam construction (e.g., Sanchez-Arcilla *et al.*, 1998). Other nonclimate change factors such as pollution may condition the impacts of climate change. Information further to the summary given below appears in the chapter on coasts in the European ACACIA report (Nicholls, 2000).

Climate change could cause important impacts on coastal zones, particularly via sea-level rise and changes in the frequency and/or intensity of extreme events such as storms and associated surges. Under the SRES climate change scenarios, global sea level is expected to rise by 13–68 cm by the 2050s. Regional and local sea-level rise in Europe generally will differ from the global average because of vertical land movements (glacial isostatic rebound, tectonic activity, and subsidence). Deviations from the global mean sea level also will occur as a result of oceanic effects such as changes in oceanic circulation, water density, or wind and pressure patterns. Mediterranean sea levels have fallen by as much as 20 mm relative to the Atlantic since 1960, probably as a result of declining freshwater input and consequent seawater density increase (Tsimplis and Baker, 2000). Looking to the future, the net effect of these processes is likely to be as much as 10% of global mean change to the 2080s (Gregory and Lowe, 2000).

Sea-level rise can cause several direct impacts, including inundation and displacement of wetlands and lowlands, coastal erosion, increased storm flooding and damage, increased salinity in estuaries and coastal aquifers, and rising coastal water tables and impeded drainage (Bijlsma *et al.*, 1996). Potential indirect impacts are numerous; they include changes in the distribution of bottom sediments, changes in the functions of coastal ecosystems, and a wide range of socioeconomic impacts on human activities.

Other climate change factors also may be important. For example, rising air and sea temperatures may cause significant shifts in the timing and location of tourism (Perry, 1999) and recreational and commercial fisheries and decrease the incidence of sea ice during winter. These changes also may influence water quality through the occurrence of algal blooms, which

would have adverse effects on tourism and human health (Kovats and Martens, 2000). Changes in the frequency and track of extratropical storms are less certain. It is worth noting that an analysis of the HadCM2 climate change simulations found a decrease in the number of northern hemisphere storms, but with a tendency for deeper low centers (Carnell and Senior, 1998). This would have important implications for coastal areas, including an additional increase in flood risk. Several studies suggest that storm surges in northwest Europe might change as a result of climate change (von Storch and Reichardt, 1997; Flather and Smith, 1998; Lowe and Gregory, 1998), but further investigation is required to produce definitive results. Storm occurrence has displayed significant interannual and interdecadal variability over the past 100 years (WASA, 1998); this could produce important and costly impacts without other changes (e.g., Peerbolte *et al.*, 1991) and might interact adversely with sea-level rise.

The impacts of sea-level rise would vary from place to place and would depend on the magnitude of relative sea-level rise, coastal morphology/topography, and human modifications. The most threatened coastal environments within Europe are deltas, low-lying coastal plains, islands and barrier islands, beaches, coastal wetlands, and estuaries (Beniston *et al.*, 1998). Tidal range is a key factor: In general, the smaller the tidal range, the greater the susceptibility to a given rise in sea level. The Mediterranean and Baltic coasts have a low tidal range (<1 m), which suggests that they will be more vulnerable to sea-level rise than the Atlantic Ocean and North Sea coasts (Nicholls and Mimura, 1998).

A regional/global model of flood and coastal wetland losses described by Nicholls *et al.* (1999) considers the interacting effects of sea-level rise, population growth, and improvements in protection standards. All other climate factors are assumed to be constant. This model allows the impacts of the SRES scenarios on Europe [excluding the former Soviet Union (FSU)] to be explored. Because increases in population and protection standards in Europe are minor, the major changes are caused by sea-level rise. In 1990, about 25 million people were estimated to live beneath the 1-in-1,000 year storm surge, with the largest exposure along the Atlantic/North Sea seaboard. However, these people generally are well protected from flooding now. The

Table 13-3: Estimates of flood exposure and incidence for Europe's coasts in 1990 and the 2080s (new runs using model described by Nicholls *et al.*, 1999). Estimates of flood incidence are highly sensitive to assumed protection standard and should be interpreted in indicative terms only. Former Soviet Union is excluded.

Region	1990 Exposed Population (millions)	Flood Incidence		
		1990		2080s
		Average Number of People Experiencing Flooding (thousands yr ⁻¹)	Increase due to Sea-Level Rise, Assuming No Adaptation (%)	
Atlantic coast	19.0	19	50 to 9,000	
Baltic coast	1.4	1	0 to 3,000	
Mediterranean coast	4.1	3	260 to 120,000	

Table 13-4: Estimated coastal wetland losses by region in Europe by the 2080s (new runs using model described by Nicholls *et al.*, 1999). Range of losses reflects range of SRES sea-level rise scenarios and uncertainty about wetland response to sea-level rise. Losses from other causes, such as direct human destruction, are likely. Former Soviet Union is excluded.

Region	Minimum Wetland Stock in 1990 (km ²)			Range of Losses by the 2080s (%)
	Saltmarsh	Unvegetated Intertidal Areas	Total	
Atlantic coast	2,306	6,272	8,578	0 to 17
Baltic coast	226	271	497	84 to 98
Mediterranean coast	347	136	483	31 to 100

changes in flooding, shown in Table 13-3, indicate a significant increase in the incidence of coastal flooding by the 2080s, assuming no adaptation, particularly around the Mediterranean.

Europe (excluding the FSU) is estimated to have at least 2,860 km² of saltmarshes and 6,690 km² of other unvegetated intertidal habitat, mainly composed of sites recognized in the Ramsar treaty. Based on coastal morphological type and the presence or absence of coastal flood defenses, Table 13-4 shows wetland losses resulting from sea-level rise. Wetland losses are most significant around the Mediterranean and Baltic. Under the A2-high scenario, wetlands in these regions could be eliminated. Any surviving wetlands may be substantially altered. Such losses could have serious consequences for biodiversity in Europe, particularly for wintering shorebird and marine fish populations.

Available national results emphasize the large human and ecological values that could be affected by sea-level rise. Table 13-5 shows results of national assessments in The Netherlands (Baarse *et al.*, 1994; Bijlsma *et al.*, 1996), Poland (Zeidler, 1997), and Germany (Stern and Simmering, 1996; Ebenhöh *et al.*, 1997) for existing development and all costs adjusted to 1990 US\$. In Table 13-5, adaptation assumes protection except in areas with low population density. People at risk are the numbers of people flooded by storm surge in an average year. Adaptation/protection costs for Poland include capital and annual running costs; % GNP assumes that costs are all incurred in 1 year. Subnational and local studies from East Anglia, UK (Turner *et al.*, 1995); South Coast, UK (Ball *et al.*, 1991); Rochefort sur Mer, France (Auger, 1994); Estonia (Kont *et al.*, 1997); and Ukraine (Lenhart *et al.*, 1996), as well as regional reviews (Tooley and Jelgersma, 1992; Nicholls and Hoozemans, 1996) also support this conclusion. Many of Europe's largest cities—such as London, Hamburg, St. Petersburg, and Thessaloniki—are built on estuaries and lagoons (Frassetto, 1991). Such locations already are exposed to storm surges, and climate change is an important factor to consider for long-term planning and development.

Other values that may be affected include archaeological and cultural resources at the coast; these resources sometimes are being recognized only now (Fulford *et al.*, 1997; Pye and Allen, 2000). In Venice, a 30-cm relative rise in sea level in the 20th century has greatly increased the frequency of flooding and damage to this unique medieval city; solutions to this problem are the subject of a continuing debate and need to consider climate

change (Consorzio Venezia Nuova, 1997; Penning-Rowsell *et al.*, 1998).

13.2.1.4. Mountains and Subarctic Environments

Mountain regions are characterized by sensitive ecosystems, enhanced occurrences of extreme weather events, and natural catastrophes. Often regarded as hostile and economically nonviable regions, mountains have attracted major economic investments for tourism, hydropower, and communication routes. The projected amplitude and rate of climatic change in coming decades is likely to lead to significant perturbations of natural systems as well as the social and economic structure of mountain societies, particularly where these are marginal. Because in many instances mountains and uplands are regions of conflicting interests between economic development and environmental conservation, shifts in climatic patterns probably will exacerbate the potential for conflict (Beniston, 2000).

Nested GCM-regional climate model (RCM) techniques for a 2xCO₂ scenario have shown that the European Alps are likely to experience slightly milder winters, with more precipitation, than recently. Summer climate, however, may be much warmer and drier than today, as a result of northward shift of the Mediterranean climatic zones (Beniston *et al.*, 1995). These conditions are likely to have adverse effects on the alpine cryosphere and ecosystems.

Impacts of climatic change on physical systems will affect water, snow, and ice, and shifts in extremes will lead to changes in the frequency and intensity of natural hazards. Water availability in some regions may decline because of a reduction in precipitation amounts and because of reduced snow-pack and shorter snow season. Changes in snow amount will lead to significant shifts in the timing and amount of runoff in European river basins, most of which originate in mountains and uplands; this will have numerous consequences for the more populated lowland regions. Floods and droughts are likely to become more frequent. Indirect impacts include changes in erosion and sedimentation patterns, perhaps disrupting hydropower plants (Beniston *et al.*, 1996).

In most temperate mountain regions, the snowpack is close to its melting point, so it is very sensitive to changes in temperature. As warming progresses in the future, current regions of snow

Table 13-5: Impacts of sea-level rise in selected European countries, assuming no adaptation, plus adaptation costs (from Nicholls and de la Vega-Leinert, 2000).

Country	Sea-Level Rise Scenario (m)	Coastal Floodplain Population		Population Flooded per Year		Capital Value Loss		Land Loss		Wetland Loss (km ²)	Adaptation Costs	
		# 10 ³	% total	# 10 ³	% total	US\$ 10 ⁹	% GNP	km ²	% total		US\$ 10 ⁹	% GNP
Netherlands	1.0	10,000	67	3,600	24	186	69	2,165	6.7	642	12.3	5.5

Turkey	1.0	2450	3.7	560	0.8	12	6	n.a.	n.a.	n.a.	20	10

precipitation increasingly will experience precipitation in the form of rain. For every 1°C increase in temperature, the snowline rises by about 150 m; as a result, less snow will accumulate at low elevations than today, although there could be greater snow accumulation above the freezing level because of increased precipitation in some regions. A warmer climate will lead to the upward shift of mountain glaciers, which will undergo further reductions. It is likely that in the 21st century, 30–50% of alpine glaciers will disappear (Haeberli, 1995). Permafrost also could be significantly perturbed by warming, leading to a reduction of slope stability and a consequent increase in the frequency and severity of rock and mudslides. These in turn would have adverse economic consequences for mountain communities.

According to Sætersdal and Birks (1997), mountain plants with narrow July and January temperature tolerances (typically centric species) are most vulnerable to climate warming. These species are characterized by small ranges and population sizes. Holten (1998) documents that these less common centric species have narrow altitudinal ranges—most between 400–600 m in southern Scandes (the Fennoscandian mountain range)—compared with widely distributed mountain plants that have vertical ranges of 800–1,800 m.

Temperature enhancement experiments in the northern Scandes (Henry and Molau, 1997; Molau and Alatalo, 1998) have shown disintegration of present plant communities; “arctic specialists,” such as *Cassiope tetragona* and *Diapensia lapponica*, are least responsive to warming, but soon will suffer competitive exclusion from more competitive evergreen and deciduous dwarfshrubs such as *Empetrum hermaphroditum*, *Vaccinium vitis-idaea*, *Betula nana*, and *Salix* spp. The latter species are most favored by climatic amelioration (see also Jonasson *et al.*, 1996; Graglia *et al.*, 1997). The following

vegetation types are regarded as most sensitive to climate change in the Scandes:

- *High-alpine fell-field vegetation:* Present plant cover is discontinuous. With available soil resources in combination with extensive seed rain (Molau and Larsson, 2000), rapid colonization by mid-alpine vegetation is expected.
- *Mid-alpine vegetation:* Because of a longer thaw season, spatial cover of snowbed communities—including species with high sensitivity to frost and drought—is anticipated to decrease rapidly.
- *Vegetation on cryosols:* As a result of anticipated accelerated degradation of patchy permafrost, the discontinuous vegetation of wet cryosols (patterned ground and tussock tundra) may be replaced rapidly by low-alpine heath scrub.

As a result of a longer growing season and higher temperatures, European alpine areas will shrink because of upward migration of tree species. After several centuries of invasion of forest into the alpine Scandes, the current alpine area might be reduced by as much as 40–60% (Holten, 1990; Holten and Carey, 1992). The speed and extent of upward migration will depend on species as well as physiographic conditions and climatic regimes. Fairly quick response is expected from pioneer species such as mountain birch (*Betula pubescens* ssp. *tortuosa*). However, there seem to be competing explanations for the response time of migration of the timberline in European mountain ranges and how far timberlines will shift under specific climate scenarios (Woodward, 1992). Under optimal topographic/edaphic conditions, the mountain birch, Scots pine, and Norway spruce treelines might be elevated by as much as 300 m in the continental Scandes and less on the coastal slopes. This will probably take several hundreds of

years, at least for the more slowly responding Scots pine and Norway spruce (Aas and Faarlund, 1995; Kullman, 1995). The interaction between climate change, acidification, and nitrogen deposition in alpine ecosystems in the Scandes certainly is very important; to date, however, it has been more or less overlooked (Keller *et al.*, 2000).

The predicted future climate suggests that the ranges of many species will extend to higher altitudes. In the topmost zone of the Middle Mountains and the lower external Alps, competition from closed-canopy forest of Norway spruce might restrict the area of small islands of arctic-alpine tundra, destroy patterned grounds and subarctic mires, and kill relict and endemic populations of arctic-alpine organisms (Jenik, 1997). Mountain ecosystems that are particularly vulnerable to climate change in Italy include, for example, shrub vegetation with *Pinus mugo* of the Apennines (Vaccinio-Piceetalia). This grows 1,500–2,300 m above sea level on glacial residue and is closely dependent on cold continental climate with long-lasting snow cover (Second National Communication on Climate, 1997).

Evidence from past climate changes indicates that species respond by migrating rather than by adapting genetically (Huntley, 1991). According to Scharfetter (1938), the warmest interglacial periods enabled forests to climb higher toward the summits of low mountains (1,800–2,300 m), thereby reducing high-elevation orophyte populations. This is relevant for many isolated endemics and orophytes that presently are living in refugia, such as tops of low mountains in the Alps. In such habitats, they will have no possibility to migrate upward, either because they cannot move rapidly enough or because the nival zone already is absent (Gottfried *et al.*, 1994; Grabherr *et al.*, 1994, 1995).

There is broad agreement that past climatic changes have had a strong impact on the distribution ranges of species, and the same can be expected in the future (Peters and Darling, 1985; Ozenda and Borel, 1991, 1995). However, some of these biotic changes are subject to considerable inertia, especially with long-lived plants such as trees. For treelines to expand upslope, a significantly warmer climate is required for at least 100 years (Holtmeier, 1994). Based principally on palynological and macrofossil investigations, the forest limit did not extend upward more than 100–300 m during the warmest periods of the Boreal and Atlantic periods in the Holocene (e.g., Bortenschlager, 1993; Lang, 1993; Wick and Tinner, 1997). An increase in mean annual temperature of 1–2°C may not shift the present forest limit upward by much more than 100–200 m in the Alps.

An increase of 1–2°C is still likely to be in the range of tolerance of most alpine and nival species (Körner, 1995; Theurillat, 1995), whereas a greater increase (3–4°C) may not be (Theurillat, 1995; Lischke *et al.*, 1998; Theurillat *et al.*, 1998). This is particularly relevant for endemics and orophytes with widespread distributions throughout the Alps. Where ranges of species already are fragmented they may become even more fragmented, with regional disappearances if they cannot persist, adapt, or migrate. Some categories of vulnerable plants—for

instance, isolated arctic, stenoicous, relict species that are pioneers in wet habitats—may disappear. Specialists in distinct relief situations can suffer from habitat loss through lack of suitable escape routes, as observed from modeling studies (Pauli *et al.*, 1999; Gottfried *et al.*, 2000). Such effects can be pronounced—for instance, in the northeastern Alps, where high numbers of endemics occur in narrow altitudinal ranges (Grabherr *et al.*, 1995).

Biogeographically, the Pyrenees are on the edge between the alpine, central European, and Mediterranean regions. In the eastern Pyrenees around Puigmal (2,910 m), some oro-Mediterranean communities occur, as well as some pasture types with the rude *Festuca supina* (Baudiere and Serve, 1974). On windier and drier areas, an ecological substitution is taking place: Alpine dense pastures are turning to discontinuous oro-Mediterranean communities. There is ongoing degradation of formerly stable soils and communities as a result of periglacial phenomena, including increased cryoturbation (Baudiere and Gauquelin, 1998). With regard to timberlines in the Pyrenees, Montserrat (1992) demonstrates that they have been moving upward in the postglacial period up to the present. Over 1940–1985, an increase in mean annual temperatures is suggested by changes in animal behavior. In Estangento Lake (eastern Pyrenees, 2,035 m), this happens especially in winter months, when the minimum temperatures reach 3°C. This phenomenon affects the hibernation time of a common bat (*Miniopterus shreibersi*), so that populations enter the caves 1.5 months later than they did 20 years ago. Caves are regarded as stable environments that reflect only general climatic trends (White and Martinez Rica, 1996).

13.2.2. Semi-Natural Ecosystems and Forests

13.2.2.1. Forests

European forests belong to an important economic sector that is potentially affected by climate change and changes in atmospheric CO₂ concentrations. Forests also have important interactions with global change processes as a result of their sink potential.

Primarily, temperature and the availability of soil moisture limit the natural range of European tree species. Some forests (particularly in the north) also are nutrient-limited. The structure and composition of many forests is further influenced by the natural disturbance regime (e.g., fire, insects, windthrow). Most European forests are managed for one or several purposes, such as timber production, water resources, or recreation. This management has reduced forest area or strongly modified forest structure in most of Europe, and presently existing forests often consist of species that are different from those that would occur naturally.

In northern Europe, boreal forests are dominated by *Picea abies* and *Pinus sylvestris*, and these species grow well across most of their current distribution ranges. Under warmer conditions, these species are likely to invade tundra regions (Sykes and

Prentice, 1996). In the southern boreal forests, these species are expected to decline because of a concurrent increase of deciduous tree species (Kellomäki and Kolström, 1993). Most climate change scenarios suggest a possible overall displacement of the climatic zone that is suitable for boreal forests by 150–550 km over the next century (Kirschbaum *et al.*, 1996). This shift in climatic conditions would occur more rapidly than most species have ever migrated in the past (20–200 km per century—see Davis, 1981; Birks, 1989). Also questionable is whether soil structural development would be able to follow. Turnover of current tree populations may be enhanced, however, by changes in management practices and changing disturbance regimes, such as increased fire frequency or increased strong winds in late autumn and early spring (Solantie, 1986; Peltola *et al.*, 1999).

Under most recent climate change scenarios, winters are likely to be still cold enough to fulfill the chilling requirements of the main boreal tree species (Myking and Heide, 1995; Leinonen, 1996; Häkkinen *et al.*, 1998), but earlier budburst can be expected. If summer and winter precipitation increase (as indicated by some scenarios), boreal forests would become less susceptible to fire damages, which currently affect about 0.05% of forests yr⁻¹ (Zackrisson and Östlund, 1991).

At present, cold winters in boreal and some temperate regions protect forests from many insects and fungi that are common further south (Straw, 1995). High summer temperatures and associated drought increase the growth of existing insect populations through enhanced physiological activity and turnover of insect populations. Throughout Europe, forests seem to be quite well buffered against new species coming from outside Europe, but the risk exists. A good example of new organisms with large potential to damage trees is *Bursaphelenchus xylophilus*, which originates in North America. This pine nematode is easily transported in fresh timber, but its success is related to temperature. Low summer temperatures and short growing seasons have effectively limited the success of this species in northern Europe (Tommisen and Nuorteva, 1987), although it frequently has occurred in imported timber. Reductions in these limitations may result in increased damage to trees.

In western and central Europe, the current forest structure and, in part, tree species composition are determined mainly by past land use and management rather than by natural factors (Ellenberg, 1986). Site-specific assessments of the future composition of near-natural forests suggests that conifers (e.g., *Picea abies*) may be replaced by deciduous species (e.g., *Fagus sylvatica*) at some sites (e.g., Kräuchi, 1995). Until recently, our capability to assess long-term forest dynamics at the regional scale was quite limited. Lindner *et al.* (1997) provided the first assessment of regional-scale patterns of forest composition under current and future climates. Their study suggests that future near-natural forests in the state of Brandenburg (east Germany) would be much more uniform, with little of the differentiation across different site types that shape today's landscape. A temperature increase of 1–3°C would

advance budburst of many tree species by several weeks (Murray *et al.*, 1989). Introduction of phenologically suitable ecotypes or new species has been among the main tools to increase forest growth (Lines, 1987). Minimum winter temperatures seem to be critical for the survival of exotic species with insufficient winter frost hardiness—for example, *Nothofagus procera* in Britain (Cannell, 1985). Therefore, higher winter temperatures could broaden the potential distribution range of such species in Europe.

In southern Europe, most forests consist of sclerophyllous and some deciduous species that are adapted to summer soil water deficit. Climate scenarios indicate reduced water availability in the summer months and associated responses in forests (e.g., Gavilán and Fernández-González, 1997), although the interactions of this effect with enhanced CO₂ concentrations is uncertain. Temperature changes may allow expansion of some thermophilous tree species (e.g., *Quercus pyrenaica*) when water availability is sufficient. In the Pyrenees, a northward and upward movement of Mediterranean ecotypes is likely to occur with warming accompanied by drier conditions.

13.2.2.1.1. Growth trends

Forest growth has increased during the past several decades in northern forests (Lakida *et al.*, 1997; Lelyakin *et al.*, 1997; Myneni *et al.*, 1997) and elsewhere in Europe (Specker *et al.*, 1996). Climate warming, increasing CO₂, increased nitrogen deposition, and changes in management practices are factors that are assumed to be behind the increase. The impacts of temperature and CO₂ have been shown in experiments and are extrapolated by model calculations. For example, under an assumed increase of CO₂ by 3.5 μmol mol⁻¹ yr⁻¹ and temperature by 0.04°C yr⁻¹ over 100 years, productivity of *Pinus sylvestris* increased by 5–15% as a result of the temperature elevation, 10–15% as a result of the increased CO₂, and 20–30% as a result of combined temperature and CO₂ (Kellomäki and Väistönen, 1997). In northern Europe, the effects of precipitation changes are likely to be much less important than the effects of temperature changes (Kellomäki and Väistönen, 1996; Talkkari and Hypén, 1996). Based on model computations that assume a seasonally uniform temperature increase, Proe *et al.* (1996) have suggested that growth of *Picea sitchensis* in Scotland could increase by 2.8 m³ ha⁻¹ yr⁻¹ for each 1°C rise in temperature.

In Russian boreal forests, some studies predict large shifts in distribution (up to 19% area reduction) and productivity (e.g., Kondrashova and Kobak, 1996; Krainina *et al.*, 1997; Izrael, 1997; Rapsun, 1997). It could be concluded that climate change and CO₂ increase would be favorable for northern forests (e.g., as a result of increased regeneration capacity). Indeed, some studies suggest a significant increase in productivity of forests in higher latitudes. The largest changes are expected for forest tundra and the northern taiga, reaching 12–15% additional growth per 1°C warming (e.g., Karaban *et al.*, 1993; Shvidenko *et al.*, 1996; Lelyakin *et al.*, 1997). The same studies estimate the

impact in more southern forest zones (southern taiga, mixed and deciduous forests) to be less: 3–8% per 1°C.

In central and southern Europe, limited moisture resulting from increasing temperature and (possibly) reduced summer rainfall may generate productivity declines regionally, but this cannot be predicted because of uncertain rainfall scenarios. In addition, CO₂ enrichment is likely to increase water-use efficiency (WUE), which makes growth less drought-sensitive. Forest growth conditions in the southern parts of eastern Europe (Russia, Ukraine, Moldova) are likely to decline as a result of increased drought, specifically in the steppe. Secondary problems could arise in the protective shelterbelts in the south of the forest-steppe zone that now covers about 3 Mha.

13.2.2.1.2. Disturbance regimes

In the Mediterranean region, elevation of summer temperature and reduction of precipitation may further increase fire risk. Colacino and Conte (1993a,b) examined the pattern of forest fires in the Mediterranean region in connection with the number of heat waves. An increase of 70% in the number of heat waves was recorded in the period 1980–1985 with respect to the period 1970–1975, and a similar increase was recorded in the extent of forest burned. In temperate eastern Europe, forest fire increase is less likely, but very dry and warm years could occur more frequently and promote pest and pathogen development. Large areas of pine forests in Ukraine, Belarus, and central regions of Russia might face some increased risk.

Increased forest fire risk is a crucial factor in the survival of boreal forests in Russia. Most dangerous are large forest fires, which occur during extremely dry and warm years. Such climatic conditions occur periodically (every 15–20 years) in parts of the Russian boreal zone. Currently these large fires account for about 1–2% of the total number of forest fires, but burned areas reach 70–80% and losses are as much as 90% of the total values. Most climate scenarios indicate that the probability of large fires will increase.

Estimates of the possible influence of climate change on insect infestation are uncertain because of complex interactions between forests, insects, and climate. The probability of outbreaks of pests such as *Dendrolimus sibirica* or *Limantria dispar* is expected to increase, especially in monocultures. Short-period warming also could promote infestation with new pest species that presently do not occur in the boreal zone. Increases of climate aridity would promote occurrence of some diseases (e.g., root and stem fungi decays).

13.2.2.2. Grasslands and Rangelands

Permanent grassland and heathland occupy a large proportion of the European agricultural area. The type of grassland varies greatly, from grass and shrub steppes in the Mediterranean region to moist heathland in western Europe. The annual cycle

of many temperate grasses is limited by low temperature during the winter and spring and by water stress during the summer. Climate change can affect the productivity and composition of grasslands in two ways: directly through the effects of CO₂, or indirectly through changes in temperature and rainfall. Different species will differ in their responses to CO₂ and climate change, resulting in alterations in community structure (Jones and Jongen, 1996). Legumes, which are frequent in these communities, may benefit more from a CO₂ increase than nonfixing species (Schenk *et al.*, 1995).

Intensively managed and nutrient-rich grasslands will respond positively to the increase in CO₂ concentration and to rising temperature, as long as water resources are sufficient (Thornley and Cannell, 1997). The direct effect of doubling CO₂ concentration by itself may cause a 20–30% increase in productivity in nutrient-rich grasslands (Jones *et al.*, 1996; Cannell and Thornley, 1998). The importance of water management (including drainage) may be even more important, however, under changed climatic conditions in northern Europe (Armstrong and Castle, 1992). This positive effect of increased CO₂ on biomass production and WUE can be offset by climate change, depending on local climate and soil conditions (Topp and Doyle, 1996a; Riedo *et al.*, 1999). These effects also will determine the spatial distribution of agricultural grassland. An analysis by Rounsevell *et al.* (1996a) showed that grassland production in England and Wales is resilient to small perturbations in temperature and precipitation, but larger temperature increases may cause drought stress and reduced suitability for grassland production.

There is a greater controversy regarding the response of nitrogen-poor and species-rich grassland communities. Experimental studies in such grasslands have shown little response or even a reduction in production with CO₂ enrichment (Körner, 1996). On the other hand, simulation studies have shown that this could be just a transient response and that the long-term response of nitrogen-poor grassland ecosystems may be relatively larger than that of nitrogen-rich systems (Cannell and Thornley, 1998). This effect is caused by a reduction in nutrient losses and an increase in nitrogen fixation at elevated CO₂.

Because of its impacts on primary productivity and community structure, the long-term effect of elevated CO₂ on grasslands is an additional carbon sink. By contrast, increasing temperatures alone are likely to turn grasslands into a carbon source because soil respiration would be accelerated more than NPP. The net effect of current scenarios for CO₂ and temperature is likely to be a small carbon sink in European grasslands (Thornley and Cannell, 1997).

Arid and semi-arid environments (e.g., certain steppe-like habitats), which are well represented in the Mediterranean area, are crucial for the preservation of rich species diversity in this region. These regions seem to be the only places within Europe that certain insect species, such as *Lepidoptera*, can inhabit because of the abundant availability of their foodplants. Furthermore, the lack of winter climatic stress makes arid lands

quite suitable as wintering grounds for birds. Overgrazing, fire, urbanization, and changes in land use can be considered the main threats to these regions. The potential distribution of these semi-arid environments may increase under drier and warmer climatic conditions, leading to landscape fragmentation at the local scale and consequent local extinctions (del Barrio and Moreno, 2000).

13.2.2.3. Freshwater Ecosystems: Inland Wetlands, Lakes, and Streams

European freshwater ecosystems encompass a varied assemblage of systems: lakes of various sizes and depth; streams with different hydrological characteristics; and wetlands, which by definition occupy a spatial continuum between aquatic and terrestrial environments. Wetlands are heterogeneous systems ranging from open-water surfaces to densely vegetated areas. Some wetlands are forested; shrubs, grasses, or mosses dominate others. European freshwater systems have been heavily subjected to and modified by damming, channeling, drainage, and other hydrological alterations; they also are influenced by humans through land and water use, pollution, erosion, and other factors.

The fundamental requirement for the existence of freshwater ecosystems is the spatial and temporal distribution of water in the landscape. The impacts of climate change on the future distribution and extent of these systems are analogous to those discussed in Section 13.2.1.1. However, apart from these impacts, changes in climatic parameters also will impact a range of chemical and biological functions, which combine with physical parameters to create the integrated ecological characteristics of future freshwater ecosystems in Europe. During the past 150 years, the winter ice cover of streams and lakes has declined, and in the northern hemisphere there has been a steady trend toward later freeze and earlier ice breakup (Magnuson *et al.*, 2000). Climate warming is likely to exaggerate this trend, and the timing and duration of freeze and breakup of ice in freshwater systems greatly affect inherent biological and ecological processes.

In the arctic and subarctic, freshwater systems are particularly sensitive to climate change—and most climate change scenarios indicate that the highest and most rapid temperature increases will occur in these regions. Increases in temperature may lead to changes in permafrost distribution (Anisimov and Nelson, 1996, 1997), with concomitant impacts on hydrology. In many wetland areas, permafrost acts as a drainage seal and promotes wetland development. However, Camill and Clark (1998) suggest that high-latitude systems might show lagged and complex dynamics in response to global warming, and local factors may exert more direct control over permafrost than regional ones. The estimated effect of climate change on average runoff in tundra regions is highly uncertain, but if water levels decrease, connections between tundra lakes could be severed. This would result in changes in community structure and possibly elimination of seasonal migrants to shallow, ice-covered winterkill lakes. Climate change impacts on ice breakup timing

and intensity also will influence limnological characteristics by regulating the supply and flux of nutrients (Lesack *et al.*, 1991). Furthermore, such changes impact the influx of sunlight, which is a key factor in controlling primary productivity but also can have far-reaching effects on higher trophic levels. The populations of arctic char (and presumably other extreme coldwater fish species) are expected to decrease, especially in low-altitude, shallow lakes (Lehtonen, 1998).

In the boreal areas, scenarios typically display warmer winters (e.g., a shorter season of sub-zero temperatures). This would affect snow-cover conditions and lead to changes in the timing and intensity of snowmelt events and runoff characteristics, which would affect the ecological functions of freshwater systems. Wetland development might benefit if larger fractions of precipitation fell as rain, but the impact would depend on how temperature-induced higher evapotranspiration rates would counteract this effect, as well as topographical characteristics of the landscape. In response to higher temperatures, northern boreal populations of cyprinid and percid fish species are expected to increase at the expense of coldwater, salmonid species (Lehtonen, 1996). Shallow lakes would be most susceptible to these changes because of their lack of thermal stratification. Total freshwater fish production is expected to increase, but with the projected changes in the composition of fish fauna, the recreational and commercial value of catches will decrease (Lehtonen, 1996). A reduction in the spatial and temporal extent of lake and stream ice cover as a result of warmer winters can decrease light attenuation, which is a major limiting factor for production in boreal aquatic systems. Such a change could be expected to cause shifts in the biota of lakes and streams. It also can reduce winter anoxia that typically occurs in shallow lakes. Haapalea and Leppäranta (1997) modeled future ice-cover distribution in the Baltic Sea (which contains freshwater communities in the north). Simulations with a warming of 3.6°C to 2050 reduced the extent of ice cover from 38 to 10%, and a 6.6°C warming to 2100 resulted in no ice cover. The projected increase in biomass productivity in terrestrial systems also would affect lakes and streams because of alterations in the amount and quality of water and solid material inputs. Organic matter inputs are expected to increase when plant productivity increases and would be beneficial for heterotrophic organisms. Increases in organic matter concentrations also result in effects such as reduced light penetration (including damaging UV-B radiation—Schindler and Curtis, 1997) and changes in the vertical distribution of solar heating (Schindler *et al.*, 1996). In lakes, increased summer temperatures could lead to more pronounced thermal stratification, resulting in reduced secondary productivity as well as anoxic conditions in the hypolimnion. Warmer surface water can reduce the nutritional value of edible phytoplankton, but it also may shift primary production toward green algae and cyanobacteria, which are less favored by secondary consumers.

The dominating wetland types in the boreal regions are peatlands. Typically, the vegetation pattern and composition of boreal peatlands are governed by moisture regime rather than temperature and show high spatial variability in plant communities caused

by variation in topography. It follows that a change in water balance could affect the function of boreal wetlands, including their carbon sequestering and carbon storage functions. A study in Finland suggests that very nutrient-poor peatlands can increase their long-term soil carbon accumulation after drainage (Minkkinen and Laine, 1998). In more nutrient-rich peatlands, however, soil carbon sequestering rates decrease and could shift to potential sources of atmospheric CO₂. Cao *et al.* (1998) have suggested that a temperature increase of less than 2°C could enhance methane (CH₄) emission rates from boreal wetlands, but greater warming might lead to reduction of fluxes because of decreasing soil moisture. Furthermore, field manipulation and laboratory experiments in Finland have shown that enhanced CO₂ concentrations (560 ppm) can lead to a 10–20% increase in CH₄ efflux from oligotrophic mire lawn communities (Saarnio and Silvola, 1999; Saarnio *et al.*, 2000). It is likely that boreal peatlands will expand further north into subarctic/arctic areas where the topography after permafrost disintegration still supports wetland formation.

In temperate Europe, the potential for precipitation decreases that result in lower flow rates could have major implications for lakes and streams. This could lead to changes in habitat and breeding locations of aquatic flora and fauna. These hydrological changes have the potential to be more significant for freshwater organisms than a temperature increase. The effect of warmer winters that lead to less extensive ice cover of lakes is expected to affect Europe's temperate lakes and streams as discussed above. Wetlands in the temperate regions of CEE are regarded as vulnerable to climate change (in combination with other anthropogenic threats—Best *et al.*, 1993; Hartig *et al.*, 1997). In the past, wetlands have been extensive in this area—for example, in the basins of the Pechora, Severnaya Dvina, and Upper Dnieper Rivers and in Karelia they have occupied 10–30% of the area. Now, many of them have been converted to agriculture, are affected by agricultural drainage, or are used in other ways, such as growing reed for thatch and livestock feed or collecting peat as a fuel for heating and cooking.

In the Mediterranean, the risk of acute water shortage in response to global warming would have severe impacts on freshwater ecosystems in the region. Hydrologically isolated systems, such as wetlands in topographical depressions, would be the most vulnerable, whereas those situated along larger rivers and lake shores might be less sensitive (Mortsch, 1998), although the extent of the latter may decrease as a result of lower flow rates. Increased competition for diminishing water resources also poses a potential threat to freshwater ecosystems. Although precipitation may increase during the winter—which is the main season for the seasonal wetlands in this area—this probably will be accompanied by comparably large increases in temperature, thus affecting net water availability. Summers are predicted to become warmer and drier, which would lead to deterioration of freshwater ecosystems (Haslam, 1997). Seasonal systems that presently can cope with occasional or periodic drought will experience additional stress that some species might not be able to survive (Brock and van Vierssen, 1992). The fact that wetlands in many parts of southern and

central Europe are scattered in their location may prevent species migration to suitable climate conditions. In general, wetland plants with short life cycles are better adapted for geographical migration, indicating that this response is likely to occur faster in nonforested wetlands than in forested ones.

The risk of increased fire disturbance of terrestrial biota also will have consequences for lakes and streams in southern Europe. Freshwater systems adjacent to burned areas will receive an initial increase in solute input after fire; if the fire generates canopy gaps, the water bodies will be more influenced by wind mixing, inducing changes in thermal and chemical stratification characteristics.

13.2.2.4. Biodiversity and Nature Conservation

Europe is predominantly a region of fragmented natural or semi-natural habitats in a highly urbanized, agricultural landscape. A significant proportion of surviving semi-natural habitats of high conservation value is enclosed within protected sites, which are especially important as refuges for threatened species (Plowman, 1995). Nature reserves form a similarly important conservation investment across the whole of Europe. However, species distributions are projected to change in response to climate change (Huntley and Webb, 1989), and valued communities within reserves may disassociate, leaving species with nowhere to go (Peters and Darling, 1985; Peters and Lovejoy, 1992).

The impact of climate change on a particular reserve will depend on its location in relation to the climatic requirements of the species it accommodates. Sites that lie near the current maximum temperature limits of particular species could expect that if climate warms beyond those limits, species would become extinct at that site. Conversely, sites that lie close to the minimum temperature limits of species may assume greater importance for such species as the climate warms (Huntley, 1999). In Europe, nature reserves tend to form habitat “islands” for species in landscapes that are dominated by other land uses. The possibility of species colonizing other habitat islands could be limited. As a result of climate change, reserve communities may lose species at a faster rate than potential new species can colonize, leading to a long period of impoverishment for many reserves.

The requirements of a future conservation strategy in the advent of climate change have been considered by Huntley *et al.* (1997). They suggest that for Europe, where large-scale range changes are projected, a network of habitats and habitat corridors will be required to facilitate migration.

Questions that urgently must be asked are as follows: To what extent do rare and vulnerable species in Europe rely on protected areas for their survival in the present day? Do current policy measures being implemented throughout Europe under the Biodiversity Convention take into account the potential impacts of climate change? It will become increasingly important for

conservation strategies to be developed on a pan-European scale to protect species in parts of their ranges that are least likely to be negatively impacted by climate change. Reevaluation of conservation priorities and the role of reserves is required for individual sites and in relation to national and international conservation strategies (Hendry and Grime, 1990; Parsons, 1991).

13.2.2.5. Migratory Animals

Insects: Parmesan *et al.* (1999) analyzed data for 35 nonmigratory butterflies with northern range limits in Great Britain, Sweden, Finland, or Estonia and southern boundaries in southeastern France, Catalonia (Spain), Algeria, Tunisia, or Morocco. More than 60% were found to have shifted north by 35–240 km in the 20th century, consistent with the 120-km northward shift of climatic isotherms reported in the SAR. This finding is contrary to the trend that might have been expected as a result of land-use change: Habitat loss has been greater in northern European countries over this period than southern ones. Scientific knowledge of butterfly biology supports the inference that this shift is in response to increased temperatures. Population eruptions of several species of forest lepidoptera in central Europe in the early 1990s, including the gypsy moth *Lymantria dispar*, have been linked to increased temperatures (Wulf and Graser, 1996), as have northward range expansions of several species of *Odonata* and *Orthoptera* (Kleukers *et al.*, 1996).

Insect pests: Most studies concur that insect pests are likely to become more abundant in Europe as temperature rises, as a result of increased rates of population development, growth, migration, and overwintering (Cannon, 1998). There has been little or no reported research at the level of pest population dynamics, however, about potential responses of insect pests to increased CO₂ (Cannon, 1998). Although changes in rainfall also could have a substantial effect (Lawton, 1995), this is difficult to quantify, particularly given uncertainties with regional precipitation scenarios. Migratory species may be able to extend their ranges as crop distributions change. For example, a 3°C rise in temperature would advance the limit for grain maize across much of Europe, which could be followed by a northward range expansion by the European corn borer *Ostrinia nubilalis* of as much as 1,220 km (Parry *et al.*, 1990; Porter *et al.*, 1991; Porter, 1995).

Birds: Climate change in Europe already has been demonstrated to be affecting migratory wild bird populations. In the UK, 20 of 65 species, including long-distance migrants, significantly advanced their egg-laying dates by 8 days, on average, between 1971 and 1995 (Crick *et al.*, 1997; Crick and Sparks, 1999). In general, species show advancement in average arrival and laying dates of about 3–5 days per 1°C. It is quite likely that birds will be able to adapt faster than most taxa to such changes, given their mobility and genetic variability (e.g., Berthold and Helbig, 1992). However, increased aridity in the Mediterranean region may be detrimental to the trans-Saharan migrants that use the area for foraging en route. Potentially great problems face the internationally important populations

of waterfowl that use a relatively limited number of sites for wintering or while on passage in Europe. Where sea-level rise causes coastal squeeze on the availability of intertidal feeding areas (because sea defenses prohibit encroachment onto currently dry land), feeding resources available to wintering waterbirds may become limited and lead to population declines (Norris and Buisson, 1994). Arctic-breeding shorebirds are predicted to benefit in the short term as warmer temperatures increase the numbers of their insect food supplies, but in the long term they may suffer from the disappearance of their habitat as vegetation zones move northward toward the limit of any land (Lindström and Agrell, 1999).

13.2.3. Agriculture and Fisheries

13.2.3.1. Agriculture

Agriculture accounts for only a small part of GDP in Europe. Therefore, the vulnerability of the overall economy to changes that affect agriculture is low (Reilly, 1996). Locally, however, effects on society may be large. Europe as a whole is noted for its substantial output of arable crops and animal products (FAOSTAT, 1998).

Trends in European agriculture are dominated by the EU's Common Agricultural Policy (CAP). This occurs because EU member states account for a large proportion of agricultural production in Europe and because several countries currently are seeking membership in the EU and in this process are adjusting their policy to match the CAP. The EU seeks to integrate concerns for environmental protection and countryside livelihood into the CAP.

Many studies have assessed the effects of climate change on agricultural productivity (e.g., Ryszkowski and Kedziora, 1993; Harrison *et al.*, 1995b; Semenov and Porter, 1995; Alexandrov, 1999; Cuculeanu *et al.*, 1999; Harrison *et al.*, 1999). Relatively little work, however, has been done to link these results across sectors to identify vulnerable regions and farming systems. Such assessments are needed to identify appropriate policy responses to climate change. More extensive information than the summary presented in this section appears in the agriculture chapter of the European ACACIA report (Bindi and Olesen, 2000).

Cereals of different species and varieties are grown throughout Europe. Climatic warming will expand the area of cereals cultivation (e.g., wheat and maize) northward (Kenny *et al.*, 1993; Harrison and Butterfield, 1996; Carter *et al.*, 1996a). For wheat, a temperature rise will lead to a small yield reduction, whereas an increase in CO₂ will cause a large yield increase; the net effect of both for a moderate climate change is a large yield increase (Nonhebel, 1996; Harrison and Butterfield, 1999). Drier conditions and increasing temperatures in the Mediterranean region and parts of eastern Europe may lead to lower yields and the need for new varieties and cultivation methods. Yield reductions have been estimated for eastern

Europe, and yield variability may increase, especially in the steppe regions (Alexandrov, 1997; Sirotenko *et al.*, 1997). Figure 13-6a shows the response of wheat yields to change of climate and CO₂ concentration for a GCM scenario for 2050 that resembles the A1 scenario. The largest increases in yield occur in southern Europe—particularly northern Spain, southern France, Italy, and Greece. Relatively large yield increases (3–4 t ha⁻¹) also occur in Fennoscandia. In the rest of Europe, yields are 1–3 t ha⁻¹ greater than at present. There are small areas where yields are predicted to decrease by as much as 3 t ha⁻¹, such as in southern Portugal, southern Spain, and Ukraine. For maize, future climate scenario analyses carried out for selected sites in Europe suggest mainly increases in yield for northern areas and decreases in southern areas (Wolf and van Diepen, 1995). This is a result of a small effect of increased CO₂ concentration on growth (maize is a C₄ plant that responds less positively to CO₂ increases than C₃ plants such as wheat and barley) and a negative effect of temperature on the duration of growing season. The latter effect, however, can be largely prevented by growing other maize varieties (Wolf and van Diepen, 1995).

Seed crops generally are determinate species, and the duration to maturity depends on temperature and day length. A temperature increase therefore will shorten the length of the growing period and possibly reduce yields (Peiris *et al.*, 1996). At the same time, the cropping areas of cooler season seed crops (e.g., pea, faba bean, and oilseed rape) probably will expand northward into Fennoscandia, leading to increased productivity of seed crops there. There also will be northward expansion of warmer season seed crops (e.g., soybean and sunflower). Harrison

and Butterfield (1996) estimate this northward expansion for sunflower; they also found a general decrease in water-limited yield of sunflower in many regions, particularly in western Europe. Analysis of the effect of climatic change on soybean yield for selected sites in western Europe suggests mainly increases in yield (Wolf, 2000a). This is a result of a positive effect of CO₂ concentration on growth and only a small effect of temperature on crop duration.

Vegetables cover a wide range of species with a large variation in type of yield components, including leaves, stalks, inflorescence, bulbs, roots, and tubers. Most vegetables are high-value crops that are grown under ample water and nutrient supply. Their response to changes in temperature and CO₂ varies among species, mainly depending on the type of yield component and the response of phenological development to temperature change. For determinate crops such as onions, warming will reduce the duration of crop growth and hence yield (Harrison *et al.*, 1995b), whereas warming stimulates growth and yield in indeterminate crops such as carrots (Wheeler *et al.*, 1996). Onion yields are sensitive to the degree of warming (Harrison *et al.*, 1995b), with a yield decrease for warmer scenarios and a yield increase for cooler scenarios. There also is a spatial gradient, with yield increases in northwest Europe to decreases in southeast Europe. For lettuce, temperature has been found to have little influence on yield, whereas yield is stimulated by increasing CO₂ (Pearson *et al.*, 1997). For cool-season vegetable crops such as cauliflower, large temperature increases may decrease production during the summer period in southern Europe because of decreased yield quality (Olesen and Grevsen, 1993).

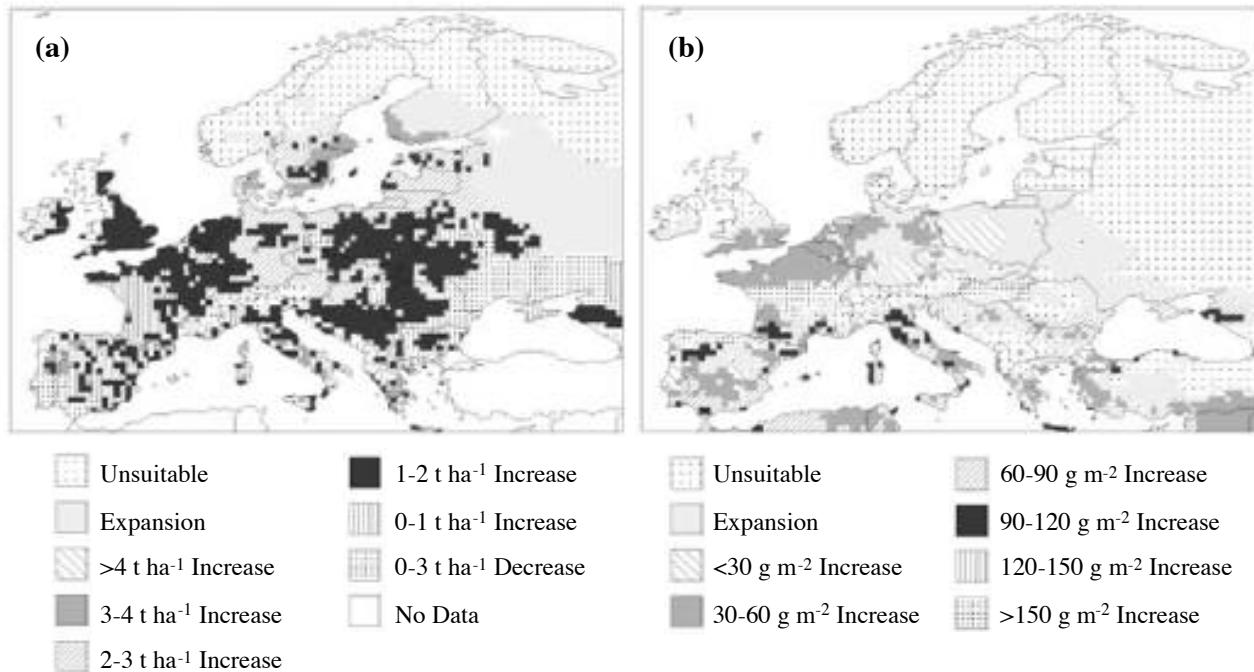

Figure 13-6: Change in water-limited yield for wheat (a) and potential yield for grapevine (b), using HadCM2 scenario for 2050 (Harrison and Butterfield, 1999).

Root and tuber crops are expected to show a large response to rising atmospheric CO₂ because of their large underground sinks for carbon and apoplastic mechanisms of phloem loading (Farrar, 1996; Komor *et al.*, 1996). On the other hand, warming may reduce the growing season and enhance water requirements, with consequences for yield. Climate change scenario studies performed with crop models show increases in potato yields in northern Europe and decreases or no change in the rest of Europe (Wolf, 2000b). Simulation results show an increase in potato yield variability for the whole of Europe, which enhances the risk for this crop. However, crop management strategies (e.g., advanced planting and cultivation of earlier varieties) seem to be effective in overcoming these changes (Wolf, 2000b). Indeterminate root crops such as sugar beet may be expected to benefit from warming and the increase in CO₂ concentrations. A study performed by Davies *et al.* (1996) for England and Wales indicates that the area of suitability for the growth of the crop moves westward.

Forage crops, including maize and whole crop cereals for silage, as well as root crops such as sugar beet and some Brassica species, also are described under cereals and root crops. When these crops are grown as forage crops, yield components and quality may change. Thus, there is a larger emphasis on total biomass yield and on digestability of biomass. The effects on production and quality of wheat whole crop silage will depend on the relative magnitudes of changes in CO₂ and temperature (Sinclair and Seligman, 1995). Yields of the different forage crop types will be affected differentially. Yields of indeterminate crops such as sugar beet and silage maize can be expected to show a larger increase than the yields of whole crop cereals, especially in northern Europe. This probably will lead to changes in the types of forage crops grown. Studies indicate an increase in suitability of the north and west UK to forage maize (Cooper and McGeechan, 1996; Davies *et al.*, 1996).

Perennial crops (e.g., grapevine, olive, and energy crops) have been relatively less studied in the context of climate change impacts. A study on the potential cultivation of grapevine in Europe under future climate scenarios has shown that there is potential for expansion of the wine-growing area in Europe and an increase in yield (see Figure 13-6b). Yet detailed predictions made for the main EU viticultural areas have shown an increase in yield variability (fruit production and quality). The quality of wine in good years is not guaranteed, and the demand for wine in poor years is not met, implying a higher economic risk for growers (Bindi *et al.*, 1996; Bindi and Fibbi, 2000). For olive, it was shown that in a 2xCO₂ case, the suitable area for olive cultivation could be enlarged in France, Italy, Croatia, and Greece as a result of changes in temperature and precipitation patterns (Bindi *et al.*, 1992). For indeterminate energy crops that are favored by the longer growing season and by increased WUE resulting from higher CO₂ levels, higher temperatures and CO₂ concentrations generally would be favorable. A study of willow production in the UK found that warming generally would be beneficial for production, with increases in yield of as much as 40% for a temperature increase of 3°K (Evans *et al.*, 1995).

Livestock systems may be influenced by climate change directly by means of its effects on animal health, growth, and reproduction and indirectly through its impacts on productivity of pastures and forage crops. Heat stress has several negative effects on animal production, including reduced reproduction and milk production in dairy cows and reduced fertility in pigs (Furquay, 1989). This may negatively affect livestock production in summer in currently warm regions of Europe. Warming during the cold period for cooler regions is likely to be beneficial as a result of reduced feed requirements, increased survival, and lower energy costs. Impacts probably will be minor for intensive livestock systems where climate is controlled. Climate change may affect requirements for insulation and air-conditioning, however, and thus change housing expenses (Cooper *et al.*, 1998). The impact of climate change on grasslands will affect livestock living on these pastures. In Scotland, studies of the effect on grass-based milk production indicate that these effects vary by locality. For herds grazed on grass-clover swards, milk output may increase regardless of site, as a result of the CO₂ effect on nitrogen fixation (Topp and Doyle, 1996b).

Pest-disease-weed-host relationship can be affected by climate change in different ways. Pests, diseases, and weeds that currently are of minor significance may become key species, thereby causing serious losses. The distribution and intensity of current key pest, diseases, and weeds may be affected, leading to changed effects on yield and on control measures such as pesticides and integrated pest management. Competitive abilities in weed-plant interactions may be affected through changes in ecophysiology (i.e., CO₂ fertilization effects on C₃ and C₄ species). Pests and diseases generally will migrate as crops migrate (e.g., Lipa, 1997, 1999).

13.2.3.2. Fisheries

Detailed analyses of fish physiological response to water temperature have shown that the potential impact of climate change on freshwater and marine fish is large (Wood and McDonald, 1997). Unfortunately, current knowledge appears to be limited mostly to single key species, abstracted from the wider ecosystem context that supports fisheries production. It is likely that extrapolation from biological first principles will provide only limited foresight at a fisheries level in that context. However, it is likely that in the short term, fish will move to new habitats to find conditions to which they have adapted.

Two first-order effects—changes in biodiversity and changes in fisheries and aquaculture productivity—are examined. For each of these, key impacts in the European region are discussed with respect to temperature rise and other factors that are linked to climate change. For marine systems, these key factors are sea-level rise and changes in ice cover, salinity, and ocean currents; for inland waters, factors such as hydrological changes (e.g., dams, water abstraction), hydrochemical changes (including anoxia, water acidity, pollution and toxicity events), and eutrophication are key.

13.2.3.2.1. Freshwater and marine biodiversity

It has been possible, for the better-known species, to obtain a rough first picture of likely faunal movements and range shifts that would result from the temperature rise currently forecast for the European region.

This has been done, for example, for wild Atlantic salmon (*Salmo salar*), which sustains important recreational and commercial fisheries over most of northern Europe and has a high conservation indicator value over its entire range. Atlantic salmon spends its early and juvenile life in freshwater slowly moving away from the headwater spawning grounds in rivers out to sea, to grow and mature. Looking at the direct and indirect influence of temperature on protein synthesis on all life-cycle stages, McCarthy and Houlihan (1997) suggest that there will be a northward shift in the geographic distribution of Atlantic salmon in Europe, with likely local extinction at the southern edge of the current range and new habitats colonized in the north. The influence of temperature on overwintering survival of 1- and 2-year-old salmon and the distribution of post-smolts in the North Sea area already is apparent (Friedland *et al.*, 1998).

High sensitivity to water temperature of fish larval and juvenile stages, combined with the higher susceptibility of headwaters and smaller rivers to air temperature rise, implies important effects of climate change on cold and temperate anadromous species such as the sea trout, alewife (*Alosa alosa* Atlantic and Mediterranean), and sturgeon (Atlantic, Black Sea, Caspian Sea). Similar impacts are likely for all salmonid species in Europe, including those that do not migrate to sea. Fish species are likely to extend their range northward (e.g., Brander, 1997). To identify impacts on recreational fisheries and conservation efforts that can be attributed to climate change, changes in local species presence will need to be assessed at a pan-European level, beyond watershed and national levels.

Global environmental change and introduction of species make it difficult to identify impacts of climate change in freshwater systems. Direct evidence of species shift and long-range movement often is physically limited between watersheds; introductions of alien species and genotypes—either voluntary or accidentally—have been very extensive. The influence of global warming on marine fish species and migratory species that reproduce and spend their early life history in marine waters (catadromous fish—e.g., eel) is more complex to foresee because of the various spatial and long temporal scales involved, as well as the feedback loop between air and ocean temperatures.

Some insight may be gained by reviewing historical shifts in the geographical distribution of European fish species to gain a better estimation of how fast and how far species may change their distributions. For example, the period of warming between 1920 and 1940 resulted in widespread changes in the distribution of terrestrial and marine species from Greenland to the Barents Sea.

13.2.3.2.2. Fisheries and aquaculture productivity

Future impacts on aquatic systems productivity from climate change are mostly uncertain because of other, related or independent, pressures. Resource overexploitation appears to be the single most important factor directly threatening the sustainability of many commercial fisheries in Organisation for Economic Cooperation and Development (OECD) countries (OECD, 1997). Overexploitation increases the vulnerability of fisheries to climate variability because so few fish are left in the stock to grow and multiply in a year of poor recruitment. The North Sea cod fishing industry, for example, now relies on only 1- or 2-year classes (Cook *et al.*, 1997) and therefore is vulnerable to a year or two of poor recruitment caused by adverse climatic conditions.

Productivity of some fish stocks may benefit from warming trends. For example, recruitment of cod in the Barents Sea is higher in warm years. This probably comes about as a result of indirect effects (on capelin and zooplankton) as much as through direct effects.

Cod in the North Sea are at the warm end of their thermal range, and their recruitment therefore seems to benefit during cold periods, such as the 1960s and 1970s (Dippner, 1997; Brander, 2000). The temperature and wind regime of the North Sea are strongly influenced by the NAO, records of which go back more than a century. Some of the variability in catches of North Sea cod may be explained by trends in the NAO, but changes in exploitation are a major factor.

Other factors are likely to combine with changes in temperature and decrease fish and shellfish productivity. Chronic levels of pollution are known to reduce marine and freshwater fish fecundity (Kime, 1995), decrease freshwater supply (which exacerbates low dissolved-oxygen concentrations), increase solid transport from erosion, and increase habitat fragmentation in inland waters. Development of marine aquaculture may be slowed by a decreasing availability of sites with cool enough surface water temperature and by increased susceptibility to disease.

The consequences of fisheries collapse are complex. For example, the North Sea herring fishery collapsed in 1977 and was closed for 5 years. Although the rapid recovery of the resource surprised fisheries biologists, the most dramatic effect on the industry resulted from a permanent change of consumer preferences (Bailey and Steele, 1992) away from kippers and fresh and pickled herring. The fishery recovered, but the market did not.

Finally, the dramatic effect of climate change on fisheries production is well documented (Durand, 1998) for the world's four main upwelling systems: the California current, the Peru current, the Canary current (off northwest Africa and southern Spain and Portugal), and the Benguela current (off the Atlantic coast of southern Africa). Although these currents are mostly outside European waters, the effects on Europe's distant water

fishing fleet, fishing sector investments, and import prices for human consumption and aquaculture feed cannot be ignored.

13.2.4. Other Impact Areas

13.2.4.1. Energy

Increasing temperatures will have a direct impact on energy use, especially in the domestic sector, as Palutikof *et al.* (1997) note for the unusually warm year of 1995 in the UK. The main effects of climate variability are on markets for space-heating fuels and on the amount of electricity used for air conditioning and refrigeration. Air conditioning has become universal in new office buildings, and there is a strong likelihood that it may spread to new markets such as houses and flats in future years. The relationship between climate change and the “take up” of new air conditioning installations is largely unknown, especially in areas where the practice currently is not widely used.

Requirements for heating and cooling can be estimated from the change in the number of heating and cooling degree days per year. In general, we can expect increased temperatures in Europe to lead to an increase in space cooling and a decrease in space heating requirements (Climate Change Impacts Review Group, 1991, 1996). Very mild winters in the EU, such as those experienced between 1988 and 1990, resulted in a 2% drop of energy demand. Milbank (1989) estimates that for northern Europe, a 4.5°C temperature rise would more than double summer electricity consumption by air conditioning and refrigeration systems.

13.2.4.2. Insurance

The insurance industry in Europe has an annual turnover of 600 billion EUR, with assets of 4,000 billion EUR. The common view is that the sectors that are most germane to climate change impacts and adaptation are property insurance and reinsurance. There will be lesser effects on other branches, such as casualty, life, and pensions, and the industry also could be affected in its investment activities by shifts in the economics of other industries that are impacted by mitigation policies (Dlugolecki and Berz, 2000). Essentially, the insurance industry “recycles” other sectors’ monetary risks, thereby focusing information on such impacts. However, there is a wide variety of insurance systems in place in Europe, so international comparisons or extrapolations are difficult. In addition, many economic risks are not handled through insurance currently—for example, standing crops, flood damage, and “pure” economic losses where no physical damage has occurred. Weather affects insurers through the medium of property damage caused by a variety of extreme events; storm, flood, freeze, drought, and hail are the prime ones (Dlugolecki and Berz, 2000).

In early 1990, a series of storms in northwest Europe resulted in insured damage of 10 billion EUR. Despite the use of reinsurance, much of this risk remains within the European

insurance industry. The risk will continue to rise because of pressure from economic growth and economic wealth. The industry’s assets are sufficiently large to cope with purely European climate change impacts. The industry’s main vulnerability is likely to arise outside Europe, from events such as hurricanes, earthquakes, or a global stock-market collapse. Human health impacts will be minimal for insurers as employers or suppliers.

This analysis assumes that there will be no major change in the scope of insurance services to include impacts that currently are not insured, such as standing crops, flood (in many countries), and pure economic losses. Establishment of the common market will help to reduce national differences in insurance services, but only slowly.

13.2.4.3. Industry and Transport

An sophisticated transport system has evolved in Europe to move people and goods. Efficient, rapid, reliable, and dependable transport is an essential part of the continent’s infrastructure, and disruptions and dislocations to transport systems have a rapid impact on most industrial and commercial activities. Air transport probably is the most sensitive sector to weather and climate change and rail transport the most tolerant. In manufacturing and retailing, “just-in-time” distribution systems are quickly disrupted by adverse weather conditions. Changes in consumer demand for many products, which influence indices of retail sales (Agnew and Thornes, 1995), are likely to accompany climate change.

Significant changes in the frequency of short-term climatic extremes such as windstorms impact transportation (Perry and Symons, 1994). The impact of wind and windstorms includes the effect on land-based terminals such as seaports and airports, as well as in-transit delays and damage to the means of transport itself. Instances of wind shear associated with summer thunderstorms, which pose a hazard to aircraft during takeoff and landing, could become more common in Europe. Increases in rainfall and increasing frequency of temperature oscillating around the freezing point can be expected to lead to higher levels of corrosion of transport infrastructures. Flooding in rivers and low water levels lead to interruptions of river navigation.

Coastal transport infrastructure can be damaged by a combination of sea-level rise and increased storminess. In many countries, a significant percentage of manufacturing industry is located along coastlines and estuaries and may require expensive coastal protection schemes. Transport infrastructure in river valleys also may be damaged or destroyed during floods. There are management implications for winter maintenance activities on roads and railways. Savings may be possible, especially in western Europe as winter temperatures rise, but more freeze-thaw activity is expected in CEE as winter minimum temperatures oscillate around the freezing point. Analysis of the levels of saving that can be expected in different areas are required, together with cost-benefit studies to examine whether further

investment in comprehensive ice-detection systems can be justified.

Comprehensive studies of the likely impacts of climate change on transport are in their infancy in many countries. Broad-scale assessments are needed of likely climate-induced demands for transport as lifestyles and residential and migration patterns change. The evidence that currently is available (summarized in the Europe ACACIA report), suggests that fewer severe winters would be beneficial to the manufacturing industry, reducing disruption at all stages from the supply of raw materials through processing to marketing of finished goods. However, an increase in the frequency of hot summers could disrupt some industrial processes that use large quantities of water. There may be some absolute limiting factors in some countries, such as lack of water for power stations, that can be overcome only through massive capital investment or new technology (Perry, 2000).

13.2.4.4. Tourism

The tourist industry in Europe is expected to continue to grow, in part as a result of higher incomes and more leisure time. Predominant tourist flows presently are from north to south; at present these flows help to transfer capital. Changes in recreational habits and preferences will lead to opportunities for tourist investment in new areas, but existing major tourist flows to the Mediterranean might be weakened if summer heat waves increase in frequency or if prolonged droughts result in water supply problems and forest fires. Giles and Perry (1998) have shown that summers as good as that of 1995 in northern Europe can lead to a drop in the numbers of outbound tourists from countries such as the UK to traditional Mediterranean sun destinations.

Changing demographic patterns—particularly an aging, wealthy population—may lead to an increase in winter and shoulder season tourism to Mediterranean resorts and expansion of retirement to attractive areas, particularly coasts. “Health tourism” to spas and mountains is likely to increase in Europe. In northern Europe, short breaks are likely to be taken over a longer season as temperatures rise.

The coastal zone is the primary tourist resource of Europe, and associated tourist infrastructure is at risk from sea-level rise, including unique tourist attractions such as the city of Venice (Perry, 1999). Beaches, wetlands, and estuaries also are tourist resources that are at risk. Already, many tourist amenities, such as coastal golf courses and hotels, require protection. The need to maintain coastal amenity values, as well as protect infrastructure, is an important factor that is encouraging a shift from hard, rigid defenses to softer approaches, including sediment management and nourishment (Penning-Rowsell *et al.*, 1992; Hamm *et al.*, 1998).

Heat stress and poor urban air quality may render cities undesirable locations in summer, with more tourist traffic to

the country and the coast. Outdoor recreational spending is likely to increase.

Mountainous zones are used extensively for recreation and are the main sites of the European winter sports industry, which is based on snow resources that are vulnerable to climate change. Mohnl (1996) has shown that there is a statistically significant trend in snow-cover reduction in the Alps over recent years. Abegg and Froesch (1994) have suggested that assuming a 3°C rise in mean temperatures, the snow line in winter will rise by 300 m in the central Alps, the first snowfall of the season will be delayed, and below an altitude of 1,200 m there will not be continuous winter snow cover. As the season contracts, there will be a need to bolster winter tourism with increased use of artificial snow and more alternatives to outdoor skiing. In Scotland, the skiing industry is likely to experience more frequent snow-deficient winters, with adverse impacts on the financial viability of the industry.

Jaagus (1997) analyzed the impact of climate change on the snow-cover pattern in Estonia, where snow cover is important for winter sports and tourism. Indications are that a considerable drop in snow-cover duration will take place on islands and in the coastal region of west Estonia.

13.2.4.5. Migrations

Migration caused by soil degradation is a very important issue in the Mediterranean region, the southern part of which is mostly arid and vulnerable to climate change. With perhaps 24% of total drylands in Africa in the process of desertification and 0.3% of the African population permanently displaced largely as a result of environmental degradation (LeHouerou, 1992), consequent in-migration pressures on neighboring regions such as southern Europe can be substantial (Goria, 1999).

13.2.5. Human Health

Climate change will influence human health in several ways. Impacts will reflect the conditions of the ecological and social environments in which humans live. The impacts of projected changes in climate will depend on current and future public health defenses. Difficult economic conditions during the past decade have had serious implications for the delivery of health care and the public health infrastructure in some countries in CEE. These countries are most at risk from potential health impacts of climate change.

13.2.5.1. Thermal Stress and Air Pollution

One can expect an increase in the frequency of heat waves, as well as warmer summers and milder winters. Analyses in European cities show that total mortality rises as summer temperatures increase (Katsouyanni *et al.*, 1993; Kunst *et al.*, 1993; Jendritzky *et al.*, 1997). Episodes of extreme high temperatures

(heat waves) also have significant impacts on health. Heat waves in July 1976 and July–August 1995 were associated with a 15% increase in mortality in greater London (McMichael and Kovats, 1998; Rooney *et al.*, 1998). A major heat wave in July 1987 in Athens was associated with 2,000 excess deaths (Katsouyanni *et al.*, 1988, 1993). Much of the excess mortality attributable to heat waves is from cardiovascular, cerebrovascular, and respiratory disease, and the elderly are particularly vulnerable to heat-related illness and death (Faunt *et al.*, 1995; Sartor *et al.*, 1995).

In cold and temperate locations, daily deaths increase as daily wintertime temperature decreases (Khaw, 1995; Laake and Sverre, 1996). Based on current evidence, climate change (increase in mean winter temperatures) is likely to result in a reduction in wintertime deaths, at least in temperate countries. Langford and Bentham (1995) estimate that 9,000 wintertime deaths yr⁻¹ could be avoided by the year 2025 in England and Wales under a 2.5°C increase in average winter temperature. A meta-analysis by Martens (1997) estimates that an increase in global temperature could result in a reduction in winter cardiovascular mortality in Europe, leading to a decrease in mortality rates in regions with cold/temperate climates. At this time, the literature does not enable quantitative comparison between changes in summer and winter mortality.

Climate change also is likely to affect air quality in urban areas. Formation (and destruction) of secondary air pollutants, such as ozone, increases at higher temperatures and increased levels of sunlight. Studies in the United States indicate that climate change would entail an increase in average ambient concentrations of ozone and an increase in the frequency of ozone pollution “episodes” (USEPA, 1989). Experiments with the Hadley Centre climate model indicate significant increases in baseline ozone concentrations in Europe. Ozone and other air pollutants have significant impacts on health; these pollutants are considered to be one of the most important environmental health problems in Europe. Finally, climate change is likely to change the seasonality of pollen-related disorders such as allergic rhinitis (hay fever) (Emberlin, 1994).

13.2.5.2. Vector-Borne Diseases

Climate plays a dominant role in determining the distribution and abundance of insects and tick species—directly, through its effects on vector and parasite development, and indirectly through its effects on host plants and animals and land-use changes (McMichael *et al.*, 1996). Therefore, it is anticipated that climate change will have an effect on the geographical range and seasonal activity of vector species and, potentially, disease transmission (Bradley, 1993; Martens *et al.*, 1997; Martens, 1998).

As a result of deterioration of health systems, the recent resurgence of malaria in eastern Europe is now a growing cause for concern. Climate change could exacerbate this increased risk. In regions of southern Europe, climate change would increase the current very small risk of local (autochthonous) transmission. A few such cases are reported in the Mediterranean area under

current climate conditions (e.g., in Italy—Balderi *et al.*, 1998). Concomitant with increases in the volume of international travel, all countries in Europe have seen a steady increase in the number of imported cases of malaria, which provide the source of the pathogen (WHO, 1997). In the UK, however, local vectors are physiologically unable to transmit the most lethal form of malaria (*falciparum*) (Marchant *et al.*, 1998). Although localized outbreaks are more likely to occur under climate change, in northern and western Europe existing public health resources and a lack of breeding habitats necessary to maintain high densities of mosquitoes make re-emergent malaria unlikely.

Dengue currently is not present in Europe, although it has been present in the past (Gratz and Knudsen, 1996). However, one of the vectors (*Ae. albopictus*) currently is extending its range in Europe, and climate change could facilitate this expansion (Knudsen *et al.*, 1996). This vector has been reported in Italy since 1990 and in Albania since 1979.

In all countries bordering the Mediterranean, cutaneous and visceral leishmaniasis are transmitted to humans and dogs by phlebotomine sandflies (Dedet *et al.*, 1995). Higher temperatures are likely to change the geographical distribution of the important sandfly vector species and accelerate maturation of the protozoal parasite, thereby increasing the risk of infection (Rioux *et al.*, 1985). Increased incidences of visceral leishmaniasis, unrelated to immune suppression, have been reported from regions of Italy and coastal Croatia (Gabutti *et al.*, 1998; Punda-Polic *et al.*, 1998). Several imported cases of canine leishmaniasis are reported in Germany, Switzerland, and Austria every year (Gothe *et al.*, 1997). Thus, imported canine cases are a potential source of the pathogen, if the vectors expand further north with climate change.

Ixodid ticks (e.g., *Ixodes ricinus* and *I. persulcatus*) are widely distributed in temperate regions and transmit tick-borne diseases in Europe, of which Lyme disease (Berglund *et al.*, 1995) and tick-borne encephalitis (TBE) are the most important (Tälleklint and Jaenson, 1998). In Sweden, TBE incidence has increased after milder winters, in combination with extended spring and autumn seasons during 2 successive years (Lindgren, 1998). There also is some evidence that the northern limit of the distribution of ticks in Sweden has moved northward between 1980 and 1994 as a result of the increased frequency of milder winters (Tälleklint and Jaenson, 1998; Lindgren *et al.*, 2000). Climate change may extend the length of the transmission season of tick-borne diseases and facilitate spread to higher latitude and altitudes in northern Europe. However, a model-based study indicates that overall the region suitable for TBE transmission may contract significantly (Randolph and Rogers, 2001).

13.2.5.3. Water-Related Diseases

Climate change could have a major impact on water resources and sanitation in situations where water supply is effectively reduced. Some populations in eastern Europe with restricted

access to water in the home would be vulnerable to any climate-related decreases in freshwater availability. Decreased water availability also could lower the efficiency of local sewage systems and may necessitate use of poorer quality sources of freshwater, such as rivers. All of these factors could result in an increased incidence of water-borne diseases.

The most significant water-borne disease associated with the public water supply in western Europe is cryptosporidiosis. Increases in the frequency or intensity of extreme precipitation events can increase the risk of outbreaks of this disease. Cases of cercarial dermatitis (water-based parasitic disease) may increase if the climate becomes more favorable for the host—a water snail (de Gentile *et al.*, 1995).

13.2.5.4. Food-Borne Diseases

Warmer climate in combination with inappropriate food behavior may contribute to increased incidences of food-borne diseases. A study of food-borne illness in the UK found a strong relationship between incidence and temperature in the month preceding the illness (Bentham and Langford, 1995). The distribution and activity of flies, cockroaches, and rodents could change in response to climatic changes. These species are carriers of food-borne pathogens and are considered to be major hygienic pests in the domestic environment.

13.2.5.5. Health Implications of Floods

The risk of flooding (coastal and riverine) is likely to increase in Europe under climate change. With this risk comes additional risk to people's health as a consequence of flooding (Menne *et al.*, 1999). Some floods in Europe have been associated with an increased risk of leptospirosis—for example, outbreaks were

reported following floods in Ukraine and the Czech Republic in 1997 (Kriz, 1998; Kriz *et al.*, 1998) and in Portugal in 1967 (Simoes, 1969). Many cases of post-flood food poisoning were noted during and after the Odra flood in 1997.

Some of the effects of flooding on mortality and ill health in developed countries is attributable to the distress and psychological effects of the event (Bennett, 1970). This was demonstrated in the Easter 1998 flooding in parts of England (the worst since 1947); the majority of flood victims interviewed cited stress associated with the event and post-flood recovery as the worst aspect of their experience (Tapsell and Tunstall, 2000). Cases of post-traumatic stress disorder, including 50 flood-linked suicides, were reported in the 2 months following the major floods in Poland in 1997 (IFRC, 1998). The health effects of flooding are complex and can result from a combination of factors. The impact of flooding on mental health therefore may be significant.

13.3. Adaptation Potential

In this section, our analysis is restricted to adaptation in the major primary sectors (water, soils, ecosystems, agriculture) and in coastal regions. These are the main sectors where adaptation will be needed.

13.3.1. Water

There are, broadly, two different approaches to adaptation in the water sector: "supply side" (change the water supply) and "demand side" (alter exposure to stress). Table 13-6 summarizes some supply-side and demand-side techniques that are available to cope with adverse impacts in the water sector and may be appropriate in the face of climate change.

Table 13-6: Adaptive techniques in the water sector: some examples.

Impact	Supply Side	Demand Side
Reduced water-supply potential	<ul style="list-style-type: none"> – Change operating rules – Increased interconnections between sources – New sources – Improved seasonal forecasting 	<ul style="list-style-type: none"> – Reduce demand (through pricing, publicity, statutory requirements, etc.)
Increased stress on irrigation water	<ul style="list-style-type: none"> – New sources (e.g., on-farm ponds storing winter runoff) 	<ul style="list-style-type: none"> – Increase irrigation efficiency – Change cropping patterns
Increased flood risk	<ul style="list-style-type: none"> – Increase flood protection 	<ul style="list-style-type: none"> – Accept higher risk of loss – Reduce exposure by relocation
Reduced navigation opportunities	<ul style="list-style-type: none"> – Enhance water-level management – Increase dredging 	<ul style="list-style-type: none"> – Smaller ships
Reduced power generation opportunities	<ul style="list-style-type: none"> – Install/increase water storage 	<ul style="list-style-type: none"> – Increase cooling water-use efficiency

“Supply-side” techniques to address water resources and risks are most widely known and used at present. In terms of water supply, these strategies include building new supply and distribution infrastructure and managing existing sources more efficiently. There is an increasing tendency toward conjunctive use of different sources within a region. Supply-side techniques in flood management are termed structural adjustments; they involve actions to lessen flood peaks and keep floodwaters away from at-risk property. Demand-side techniques historically have been less well used but are the focus of increasing attention. In terms of water supply, the most obvious demand-side approach is to reduce the demand (or slow the increase in demand) for the water resource through a range of measures, including differential pricing, public awareness campaigns, or statutory requirements for WUE (e.g., for domestic appliances).

Attention to date has been concentrated on supply-side options; demand-side techniques are less well-known and the subject of considerable technological advance. Although there is a good deal of awareness of broad options, there has been less research into applying these options in an uncertain future: How, for example, can a water distribution network be designed so that it can be incrementally updated as more information on climate change appears, rather than built to a single fixed standard?

An adaptation in one aspect of the water environment or in one area might have a severe effect on another aspect or area. For example, increased use of a river to maintain supplies may impact the instream environment. Increased storage of water in a reservoir over the winter might reduce its ability to prevent flooding. Finally, the time scales over which adaptation can occur vary. Some adaptive strategies can be implemented with little warning and can be easily amended. Others take longer to implement and, once completed, are harder to change. For example, it typically takes decades for a reservoir to move from the planning stage to completion. Urban storm drainage has a relatively short lead time but a very long design life. An ideal adaptive strategy is one that can be altered as more information becomes available. However, the adaptive response by a water management agency to climate change will depend on procedures for considering strategies, as well as adaptive capacity.

13.3.2. Soils

The use of land management techniques in adaptation to climate change will seek to maintain soil functions. A summary of appropriate techniques and their relationships to the soil functions and properties discussed earlier in this chapter is given in Table 13-7.

13.3.3. Ecosystems

Tundra areas have practically no adaptive options available. The only possible response is to better protect areas with particular value (e.g., for bird life) from other stresses such as land exploitation and tourism.

In boreal regions, many effects of climate change and CO₂ increase, as noted above, are positive in terms of productivity. Areas that are under threat (e.g., low-productivity mountain forests) have no adaptive options available. If changing water tables present a significant problem, boreal wetlands could receive technical measures for controlling water level, but such measures are unlikely to be technically and economically feasible in many areas. Other approaches to adaptation can include establishment of buffer areas around wetlands, promotion of sustainable uses of wetlands to minimize additional stresses brought on by climate change, and restoration of already destroyed wetland habitats (Hartig *et al.*, 1997).

Water shortage in parts of the temperate zone may be compensated to some extent by additional irrigation or river management. To achieve any large-scale effect, however, such measures would have to be applied in economically infeasible dimensions. Most other areas will have positive effects and therefore no adaptive problems.

In the Mediterranean, many landscapes face an acute management problem already without climate change because bush encroachment in earlier agricultural areas is affecting many ecosystems with respect to species richness and susceptibility to fire. Climate change may aggravate these developments in some areas. It is not likely that there are direct ways to adapt to these trends.

With regard to forests, the central problem is that any potential adaptation requires long-term planning. Essentially, adaptation to climate would require planting trees today that will be suitable for such a future climate. However, given our uncertainties in the prediction of future climate and the formulation of models that are used to assess its ecological impacts, it is unlikely that adaptation measures will be put into practice in a timely manner.

13.3.4. Agriculture

To avoid or at least reduce negative effects and exploit possible positive effects, several economic and agronomic adaptation strategies for agriculture have been suggested. Economic strategies are intended to render the agricultural costs of climate change small by comparison with overall expansion of agricultural products. Agronomic strategies intend to offset the loss of productivity caused by climate change, either partially or completely. Agronomic strategies include short-term adjustments and long-term adaptations.

13.3.4.1. Short-Term Adjustments

Short-term adjustments to climate change are efforts to optimize production with major system changes. They are autonomous in the sense that no other sectors (e.g., policy, research) are needed for their development and implementation. Thus, short-term adjustment can be considered the first defense tool against

Table 13-7: Land management options to mitigate impact of climate change on soils.

Function	Impact	Management/Adaptation Options
Land production	<ul style="list-style-type: none"> – Salinization – Peat wastage – Acidification – Erosion – Compaction – Soil biodiversity 	<ul style="list-style-type: none"> – Improved technology for application, better water quality, better water scheduling – No drainage of lowland peat soils – Soil pH management – Soil conservation techniques (expand) – Better timing of field operation, use of new tillage equipment – ???
Land regulation	<ul style="list-style-type: none"> – Soil water – Soil organic matter – Soil nutrients – Polluting chemicals – Soil temperature – Soil material resources 	<ul style="list-style-type: none"> – Irrigation (with improved technology and scheduling) – Use of manures, reduced tillage, improved farming system methods, crop rotation management – Sustainable use of fertilizers/manures, crop rotation management – Limits on use of polluting chemicals, clean-up of contaminated land – Mulching – No adaptation possible
Land carrier	<ul style="list-style-type: none"> – Water movement and soil structure – Nitrate leaching – Volatilization – Carbon dioxide fluxes – Methane fluxes – Nitrous oxide fluxes 	<ul style="list-style-type: none"> – Management of vertisols(?), timing of manure and sewage sludge applications – Change in fertilizer application rates, precision farming, crop selection (i.e., with different N requirements), breeding nitrogen-fixing crops, breeding crops to improve N-use efficiency (e.g., lower requirements, more efficient uptake), irrigation management, soil pH management, nitrification inhibitors, release rates (e.g., slow or timed release, coatings to limit or retard water solubility), improved fertilizer placement and timing (e.g., band placement, foliar applications), application placement (e.g., slurry injection), application timing, application amounts (e.g., controlled rate systems) – See management options appropriate to reduce nitrate leaching – Land-use change for carbon sequestration – Increased sink through fertilizer management – See management options appropriate to reduce nitrate leaching
Land information	<ul style="list-style-type: none"> – Historical record 	<ul style="list-style-type: none"> – Conserve intact soil profiles and representative reference sites
Land consumption	<ul style="list-style-type: none"> – Shrink/swell damage 	<ul style="list-style-type: none"> – Underpinning of building foundations, insure differently (e.g., location restrictions)

climate change. A large range of such adjustments have been reported, including:

- *Changes in planting dates and cultivars:* For spring crops, climate warming will allow earlier planting or sowing than at present. Crops that are planted earlier are more likely to have already matured when extreme high temperatures, such as in the middle of summer, can cause injury. Earlier planting in spring increases the length of the growing season; thus, earlier planting and use of long-season cultivars will increase yield potential, provided moisture is adequate and the risk of heat damage is low. Otherwise, earlier planting combined with a short-season cultivar would give the best assurance of avoiding heat and water stresses. Deeper planting of seeds also will contribute to making seed germination more likely. For winter crops (i.e., cereals), this approach may cause problems because

their cycle length often is linked with cold temperature requirements (vernalization) that may not be completely fulfilled during warmer winters. Late cultivars also may not be able to escape heat and drought risks in the summer. Winter cereals must have a specific growth stage before the onset of winter to ensure winter survival, and they often are sown when temperatures approach the time when vernalization is most effective (Harrison and Butterfield, 1996). This may mean later sowings in northern Europe under climatic warming.

- *Changes in external inputs:* External inputs are used to optimize production of crops in terms of productivity and profitability. The use of fertilizers generally is adjusted to fit the removal of nutrients by the crop and any losses of nutrients that may occur during or between growing seasons. A change in yield level therefore, all other things being equal, will imply a corresponding change in fertilizer inputs. Projected

increases in atmospheric CO₂ concentration will cause a large nitrogen uptake by the crop and thus larger fertilizer applications. On the other hand, climatic constraints on yields may lead to less demand for fertilizers. Changes in climate also may cause larger (or smaller) losses of nitrogen through leaching or gaseous losses. This also may lead to changes in the demand for fertilizer. Global warming will lead to a higher incidence of weeds, pests, and diseases in many areas and thus to potentially increased use of chemical control measures (e.g., pesticides). These inputs can be kept low through adoption of integrated pest management systems, which adjust control measures to the observed problem and also take a range of influencing factors (including weather) into account. Current fertilizer and pesticide practices are based partly on models and partly on empirical functions obtained in field experiments. These models and functions are updated regularly with new experimental evidence. This process probably will capture the response of changes in the environment through CO₂ and climate. It is important, however, that agricultural researchers and advisors are aware of the possible impact of global change on the use of external inputs, so that older empirical data are used with proper caution.

- *Practices to conserve moisture:* Several water-conserving practices are commonly used to combat drought. These also may be used to reduce climate change impacts (Easterling, 1996). Such practices include conservation tillage and irrigation management. Conservation tillage (the practice of leaving some of the previous season's crop residues on the soil surface) may protect the soil from wind and water erosion and retain moisture by reducing evaporation and increasing infiltration of precipitation into the soil. Irrigation management can be used to improve considerably the utilization of applied water through proper timing of the amount of water distributed. For example, with irrigation scheduling practices, water is applied only when the crop needs it. This tunes the proper timing and amount of water to actual field conditions, allowing a reduction in water use as well as the cost of production.

13.3.4.2. Long-Term Adaptations

Long-term adaptations refer to major structural changes to overcome adversity caused by climate change. These may include:

- *Changes in land use* result from the differential response of crops to climate change. Studies reported by Parry *et al.* (1988) for central Europe show an "optimal land use" in which the area cultivated with winter wheat, maize, and vegetables increases while the allocation to spring wheat, barley, and potato, decreases. Changes in land allocation also may be used to stabilize production. In this case, crops with high interannual variability in production (e.g., wheat)

may be replaced by crops with lower productivity but more stable yields (e.g., pasture).

- *Biotechnology* offers another possibility to adapt to stresses (heat, water, pests and disease, etc.) that are enhanced by climate change by allowing development of "designer cultivars" (Goodman *et al.*, 1987)—considering strictly the principles of biosafety to avoid possible negative impacts of this technique. Species that have not been used previously for agricultural purposes may be identified and others already identified may be more quickly brought into use.
- *Crop substitution* also may be useful for conservation of soil moisture. Some crops use a low amount of water and are more water- and heat-resistant, so they tolerate dry weather better than others do. For example, sorghum is more tolerant of hot and dry conditions than maize.
- *Microclimate modification* may be used to improve WUE in agriculture. Windbreaks, for example, reduce evaporative demand from the plants they shelter. Sheltered plants remain better hydrated and thus are better able to carry out photosynthesis (Rosenberg, 1979). A wide array of intercropping, multi-cropping, relay cropping, and other techniques provide greater production per unit area occupied and can be useful to improve WUE. Irrigation efficiency can be improved considerably with new land-field techniques (laser-leveling of fields, minimum tillage, chiseling compacted soils, stubble mulching, etc.) or new management strategies (irrigation scheduling, monitoring soil moisture status, etc.) (Kromm and White, 1990).
- *Changes in farming systems* may be necessary in some areas for farming to remain viable and competitive. Specialized arable farms with production of vegetables, cereals, seed crops, fruits, and other crops often have only a few species on the farm, depending on soil and climate conditions. These specialized farms, especially dairying and arable, may be more affected by climate change than mixed farms. Mixed farms with both livestock and arable production have more options for change and thus larger resilience to change in the environment.

Studies on adapting farming systems to climate change need to consider all of the agronomic decisions made at the farm level (Kaiser *et al.*, 1993). Economic considerations are very important in this context (Antle, 1996). Results of farm-level analyses on the impacts of climate change generally have shown a large reduction in adverse impacts when adaptation is fully implemented. However, this will result in land-use changes (Parry *et al.*, 1999).

13.3.5. Coastal Regions

Three broad response strategies are distinguished (Klein *et al.*, 2000):

- Reduce the risk of the event by decreasing its probability of occurrence

- Reduce the risk of the event by limiting its potential effects
- Increase society's ability to cope with the effects of the event.

These strategies have been termed "protect," "retreat," and "accommodate," respectively. Protection usually is associated with coastal squeeze and hence a decline in natural functions and values, although soft protection approaches may not raise this problem.

The actual strategy chosen will depend on local and national circumstances, including the economic and ecological importance of the coastline, technical and financial capabilities, and the legislative and political structure of the countries concerned. Although optimum response strategies have yet to be developed, it is likely that a range of responses will be the norm within any country (Bijlsma *et al.*, 1996). Turner *et al.* (1995) analyzed protection in East Anglia, England. At the aggregated scale of East Anglia, protection can be justified for the entire coast given a 50-cm rise in sea level by 2050. However, this is not the scale at which coastal management decisions are made. When the 113 individual flood compartments are evaluated independently, 20% optimally would be abandoned even for present rates of relative sea-level rise (10-cm rise in sea level by 2050). This analysis assumes that there is no interaction between flood compartments—which may not always be the case. However, it reinforces the conclusion that a range of responses will be appropriate.

Some national estimates of protection costs are given in Table 13-5, primarily for a 1-m rise in sea level. In terms of relative costs, Poland appears to be more vulnerable than Germany and The Netherlands. The absolute costs for Germany are larger than for The Netherlands, reflecting the much longer German coastline.

Adapting successfully to climate change requires more than a list of options. Klein *et al.* (1999) argue that successful adaptation must consider several issues, including recognizing the need for adaptation, planning, implementation, and evaluation. Although there is increasing recognition of the need for adaptation in some countries, this is not uniform across Europe (e.g., Nicholls and Hoozemans, 1996). It also is clear that coastal adaptation to climate change must happen in the broader context of coastal management.

Response options may be hindered by resource constraints. In Cyprus, the coast is no longer receiving new supplies of sand as a result of catchment regulation and management (Nicholls and Hoozemans, 1996). Erosion is expected in response to sea-level rise, but there are no ready sources of sand available for beach nourishment. Yet maintaining the beach is critical to the tourist industry. Although this problem has not been analyzed in detail, external (and hence costly) sources of sand may be required for beach nourishment. Many other Mediterranean islands appear to have similar problems, including those in Greece, Italy, France, and Spain.

Some adaptation that anticipates climate change already is being implemented, and this seems to be raising important questions about long-term coastal management (Klein *et al.*, 1999). The Netherlands is highly threatened by sea-level rise (see Table 13-5): About 60% of the country (23,600 km²) is in the potential impact zone (Baarse *et al.*, 1994). A new national law "outlaws" erosion and mandates maintenance of the present shoreline position via ongoing beach nourishment (Koster and Hillen, 1995). However, a debate about the optimum response continues; some people advocate a more dynamic response, including a mixture of holding the line, allowing some retreat, and coastal advancement in areas where more land is required (de Ruig, 1998; Klein *et al.*, 1998). The debate includes explicit consideration of maintaining and enhancing coastal resilience.

In Britain, coastal cells have become the basis of shoreline management; about 40 shoreline management plans that cover the entire coastline of England and Wales are finished or nearing completion (UK Ministry of Agriculture, Fisheries, and Food, 1995; Leafe *et al.*, 1998). Managed realignment of sea defenses in estuaries also is attracting increasing attention, including some trial experiments (Klein *et al.*, 1999). Low-grade agricultural land is given up to the sea as flood defenses are abandoned or relocated inland. If managed realignment is practiced at a large scale, it will help to maintain natural values as well as the flood protection benefits of coastal wetlands under a rising sea level. However, there will be a corresponding net loss of freshwater ecosystems in the protected areas (Lee, 1998). About 100 ha yr⁻¹ of land would need to be released just to counter present rates of salt marsh loss resulting from sea-level rise. Although the economic analysis of Turner *et al.* (1995) would suggest that there are many suitable sites available, this requires strategic planning to be put in place as part of shoreline management planning (UK Ministry of Agriculture, Fisheries, and Food, 1995; Leafe *et al.*, 1998). Political acceptance of managed retreat remains to be assessed.

Around the Mediterranean, models of deltaic response to sea-level rise and frameworks to analyze vulnerability and sustainability are being developed (e.g., Sanchez-Arcilla *et al.*, 1998). This raises the prospect of a dynamic management approach that harnesses natural inputs and processes within deltas to counter global and local (as a result of subsidence) sea-level rise, rather than a move to hard defenses.

One pertinent issue is cross-border transport of sediment, which has costs within the country of origin but reduces the vulnerability of the receiving country to sea-level rise. For instance, coastal erosion on the east coast of England provides mud that helps to sustain the Wadden Sea in The Netherlands and Germany under rising sea level (Dyer and Moffat, 1998; Nicholls and Mimura, 1998). This suggests a need for a regional perspective on the coastal impacts of sea-level rise.

In conclusion, a common problem across Europe is developing strategic management approaches that allow both continued human utilization of the coastal zone and preservation of coastal

ecosystems, given sea-level rise (Nicholls, 2000). Slow but steady degradation of the coastal fringe in much of Europe has gone largely unnoticed until recently, and this will continue and accelerate with sea-level rise. Developing methods to balance protection of people and the economy against the costs of degradation of the coastal environment will require multidisciplinary research.

13.4. Synthesis

13.4.1. Key Impacts

Two important messages emerge from this review:

- Potential impacts on key resources (land, ecosystems, and particularly water) are significant.
- Even in prosperous Europe, adverse climate change impacts may aggravate equity issues.

Climate change in Europe will involve losses and gains to the natural resource base; in some cases, these changes have begun. These impacts will vary substantially from region to region (they will be particularly adverse in the south) and within regions, from sector to sector as well as within sectors. The significance of these effects, however, will depend to a considerable extent on nonclimatic drivers of environmental change, socioeconomic development, and policy evolution within Europe. The most significant impacts (and opportunities) that will require greatest attention with respect to policies of response may be summarized in general terms as follows (a fuller precis appears in the Executive Summary at the beginning of this chapter). Climate changes as characterized by the scenarios described in Chapter 3 of this report, if not adequately responded to through effective adaptation and policy development, would lead in Europe to:

- Increased pressures on water resources, particularly in the south

- Aggravated flood hazard
- Deterioration in soil quality
- Altered natural ecosystems, with loss of some habitats and potential loss of species
- Increased productivity of northern commercial forests but reductions in the south
- Increased forest fire risk
- Positive effects on agriculture in the north but broadly negative effects in the south
- Altered fisheries potential
- Increased property damage
- Relatively minor effects on the transport, energy, and manufacturing sectors, some of which may be positive (though substantial effects may derive from policies of mitigation that are necessary to reduce impacts elsewhere)
- Changing tourist potential
- A range of human health implications
- Increased risk of flooding, erosion, wetland loss, and degradation in coastal zones
- Upward shift of biotic zones and snowlines in mountain regions.

In general, more adverse effects may be expected to occur in regions of Europe that are economically less developed because adaptive capacity will be less developed there. These areas would include more marginal areas of the EU and regions outside the EU such as the Balkans.

13.4.2. Uncertainty

The ability to adapt to adverse impacts and exploit opportunities as they emerge is significant. However, present uncertainties with regard to the magnitude and even the sign of the impacts, which characterize almost all of the conclusions reported in this chapter, often will hinder such efforts. These uncertainties stem from uncertainties concerning how climate may change in the future (a subject considered in Chapter 3) and how the

Table 13-8: Minimum, maximum, and median estimates of changes in water-limited wheat yield ($t ha^{-1}$) from baseline climate derived from running 24 climate change scenarios for 2050 through EuroWheat model. Estimates are summaries for selected regions in Europe (Harrison and Butterfield, 1999). Result for HadCM2 scenario also is shown.

Region	Summary of 24 Scenarios			HadCM2
	Minimum	Maximum	Median	
Nordic countries	0.7	3.5	2.1	2.8
British Isles	0.9	2.6	1.7	1.8
Germany + Benelux	0.7	2.5	1.7	2.1
Alpine countries	1.5	3.2	2.1	2.8
France	-1.5	3.0	1.3	1.5
Portugal + Spain	-0.9	4.5	1.4	1.2
Italy + Greece	0.7	3.6	1.7	1.8
Poland	-0.5	2.2	1.3	1.7
Central Europe	-1.7	2.6	1.7	1.7
Bulgaria + Romania	-2.9	2.3	1.0	0.8

natural resource base may respond to such changes. In some cases, the combination of these uncertainties may mean that we are unsure about whether the total effect is broadly positive or negative. To illustrate, Table 13-8 shows the estimated effect of a wide range of possible climate futures on wheat yields in different regions of Europe. In half of the regions, yield responses range from negative to positive.

Low-probability/high-consequence events (sometimes termed “surprises”) such as collapse of the thermohaline circulation of the North Atlantic (Hulme and Carter, 2000) also need to be considered (see Chapters 3 and 19). Therefore, caution must be exercised in interpreting currently available information, and there must be recognition that much more research is needed. This might include identifying flexible actions that are robust to a range of possible futures.

13.4.3. Research Needs

Further investigation is needed to understand how European climate is likely to change under various emission trends, as well as what the implications of these changes would be for Europe’s human and ecological systems. There is a need to analyze outputs from climate models that relate to extreme events. The biophysical impacts of climate change on European water, soil, and land resources have been quite thoroughly researched, but we know less about their socioeconomic consequences (e.g., in agriculture, fisheries, nature conservation, transport systems, and tourism). Improved knowledge of European coastal systems is required for their sustainable management. A key research challenge is to evaluate the feasibility, costs, and benefits of potential adaptation options, measures, and technologies. In general, research programs could benefit from more integration between basic studies of the Earth system, climate change modeling, impact and adaptation assessments, and mitigation/policy analysis. Key research challenges include:

- Transboundary regional impact assessment of various natural and socioeconomic systems
- Transboundary monitoring of impacts on sensitive ecosystems
- Better understanding of likely changes in extreme weather events
- Quantification of natural and technological hazards resulting from climate change (especially flooding)
- Guidelines for water management decisions for different regions under climatic uncertainty
- Changes in European legislation for adaptation to and/or mitigation of climate change impacts.

13.4.4. Regional Issues

13.4.4.1. Extreme Events

One of the most important continent-wide issues is the effect of climate change on future water resources, particularly on extreme

events—whether abundance or scarcity of water will increase in severity. A tendency toward increases in the frequency of extreme events is likely but largely unquantified. The implications of changes in the characteristics of extreme hydrological events extend beyond the water sector into agriculture, industry, settlements, coastal zones, transport, tourism, health, and insurance. Climate change is likely to lead to increased winter flows in much of Europe. In Mediterranean Europe, it is likely to increase variability in flow through the year, with summer flows reduced. In coastal areas, the risk of flooding and erosion will increase substantially. Instability of thermohaline circulation is a process whose probability of occurrence in the 21st century is low (see Chapters 3 and 19), yet potential consequences of this on the changing heat budget in Europe are very great.

13.4.4.2. Subregional Impacts

Climatic observations and the scenarios presented here suggest that southern Europe will be more adversely affected than northern Europe. A shift in climate-related resources from south to north may occur in sectors such as tourism, agriculture, and forestry. In particular, the Mediterranean region appears likely to be adversely affected. Among likely adverse effects are increased variability of river flow; increased flood risk; decreased summer runoff and recharge of aquifers; and reduced reliability of public water supply, power generation, and irrigation. Increased fire hazards affecting populated regions and forests and heat stress to humans, crops, and livestock may occur. Even a change of tourist destinations is possible if the present optimal summertime climate shifts northward, and heat waves and water shortages may jeopardize the attractiveness of the present southern summer destinations.

13.4.4.3. Sustainability and Equity

Sustainable development (understood as relaying natural capital to future generations in a nondepleted state) has been in jeopardy in Europe from several existing pressures, mostly nonclimatic (e.g., land-use change, environmental pollution, atmospheric deposition). Yet climate change adds an important element to the threat to the environment. Sea-level rise threatens coastal habitats with a squeeze between hard defenses and rising water levels. Most (50–90%) of the alpine glaciers could disappear by the end of the 21st century, and there may be local extinctions of species that require cold habitats for their survival (e.g., subarctic and montane species). Many ecosystems will respond to climate change via migration and change; a policy challenge is how to manage these changes.

Finally, climate change impacts will be differently distributed among different regions, generations, age classes, income groups, occupations, and genders. This has important equity implications, although these implications have not been investigated in detail. For example, elderly and sick people suffer more in heat waves. There is greater vulnerability, in general, in southern than in northern Europe. Mediterranean

and mountain farmers are likely to be worse off in a warmer world. This presents a challenge to existing regional policies within the EU that are aimed at leveling up less-developed areas (peripheral Europe versus core Europe). In general, the more marginal and less wealthy areas will be less able to adapt, so climate change without appropriate policies of response may lead to greater inequity.

Possible climate change impacts on key resources are sufficient to warrant early consideration by European policymakers to ensure sustainable development. In general, the adaptation potential of socioeconomic systems in much of Europe is high because of economic conditions, a stable population with the capacity to move within the region, and well-developed political, institutional, and technological support systems.

EXECUTIVE SUMMARY

The Latin America region is remarkably heterogeneous in terms of climate, ecosystems, human population distribution, and cultural traditions. Land-use changes have become a major force driving ecosystem changes. Complex climatic patterns, which result in part from interactions of atmospheric flow with topography, intermingled with land-use and land-cover change, make it difficult to identify common patterns of vulnerability to climate change in the region. Water resources, ecosystems, agriculture and plantation forestry, sea-level rise, and human health may be considered the most important among the various sectors that may be impacted by climate change.

Climate, Extreme Events, and Water Resources

In most of Latin America, there are no clear long-term tendencies in mean surface temperature. Some changes in regional atmospheric circulation have been detected. For instance, the south Atlantic anticyclone has intensified, and the subtropical jet stream in South America has shifted south. These phenomena may be a sign of changes associated with climate change as they already are impacted by the El Niño-Southern Oscillation (ENSO) phenomena and extreme events.

The cryosphere in Latin America, which is composed of glaciers in the high Andes and three major ice areas in southern South America, may be severely affected by global warming. It has been well established that glaciers in Latin America, particularly along the tropical Andes, have receded in recent decades. Glaciers contribute to streamflow in rivers of semi-arid and arid areas of South America. Streamflows in Andean rivers—for example, in northwest Peru—exhibit tendencies that may be related to glacial extent changes before and after the mid-1970s. However, there also is evidence that rainfall and river flows in other regions of Latin America correspond only to interdecadal variability in the hydrological cycle. For instance, rainfall and streamflow in Amazonia and northeast Brazil exhibit interdecadal variability linked to Pacific and Atlantic Ocean influences. Warming in high mountains also could affect mountain sports and tourist activities, which represent an important source of income in the economies of some countries in the region.

At a subregional level, precipitation trends in Latin America vary. Precipitation trends depend on the location and the length of the time series under study. For instance, negative trends in some parts of Central America (e.g., Nicaragua) contrast with positive trends in northeastern Argentina, southern Brazil, and northwestern Mexico. Other regions, such as central-western

Argentina, do not show well-defined trends. This suggests, for instance, an increase in precipitation in some regions of the mid-latitude Americas.

The Amazon River—by far the world's largest river in terms of streamflow—plays an important role in the water cycle and water balance of much of South America. Several model studies and field experiments show that about 50% of the rainfall in the region originates as water recycled in the forest. In the Amazon region, even small changes in evapotranspiration affect water vapor fluxes. Therefore, deforestation is likely to reduce precipitation because of a decrease in evapotranspiration, leading to important runoff losses in areas within and beyond this basin. Any reductions in rainfall would affect not only Amazonia but also Brazil's central-south region, where most of the country's agriculture and silviculture are located. However, with the current rate of deforestation of no more than 10% in Amazonia as a whole, discharge observations across the basin do not exhibit, to date, any significant trends.

Although it is expected that tropical storms (e.g., tropical cyclones) will increase their peak intensity under global warming (see Table 3-10), only some hints of such intensification in the tropical cyclones affecting the Americas have been detected. Some studies based on model experiments suggest that under climate change the hydrological cycle will be more intense, with changes in the distribution of extreme heavy rainfall, wet spells, and dry spells. Frequent severe droughts in Mexico during the past decade coincide with some of these model findings. Even though it is uncertain how global warming may affect the frequency and intensity of some extreme events, the infrequent overlapping of hydrological and weather/climate events historically have given rise to disasters, whose frequency may be enhanced by such warming.

El Niño

It also has been suggested that under climate change, more El Niño-like mean conditions will be experienced. El Niño differentially influences precipitation and temperature in different parts of the region; for example, it is related to dry conditions in northern northeast Brazil, northern Amazonia, and the Peruvian-Bolivian Altiplano. Southern Brazil and northwest Peru exhibit anomalously wet conditions during these periods. In Mexico and the Caribbean coast of Central America, there is compelling evidence of more winter precipitation and less summer precipitation during El Niño. Some of the most severe droughts in Mexico in recent decades have occurred during

El Niño years. During the 1997–1998 El Niño event, droughts occurred in Amazonia, Mexico, and Central America, favoring forest fires. Under climate change conditions, the number of forest fires may increase.

Natural Ecosystems

Latin America contains a large percentage of the world's biodiversity, and climate change could accelerate losses in biodiversity that already are occurring. Some adverse impacts on species that can be related to regional changes in climate have been observed. Studies show that climatic changes already are affecting frogs and small mammals in Central America. The tropical forests play an important role in the hydrological cycle of much of South America. Several model studies and field experiments show that a large part of the rainfall in the region originates as water recycled in the forest. Large-scale deforestation is likely to result in increased surface temperatures, decreased evapotranspiration, and reduced precipitation. Forest fragmentation and degradation has led to increased vulnerability of forests to fire. Global warming and regional climate change resulting from land-cover change may be acting synergistically to exacerbate stress over the region's tropical ecosystems.

Mountain ranges and plateaus play an important role in determining not only the Latin America climate and its hydrological cycle but also its large biodiversity. Mountains constitute source regions of major rivers such as the Amazon, the Parana, and the Orinoco. These river basins represent important habitats of biological diversity and endemism and are highly vulnerable to extreme climate conditions.

On decadal to centennial time scales, changes in precipitation and runoff may have significant impacts on mangrove forest communities. Sea-level rise would eliminate mangrove habitat at an approximate rate of $1\% \text{ yr}^{-1}$. The rate is much faster in the Caribbean mainland (approximately $1.7\% \text{ yr}^{-1}$). This problem is causing a decline in some of the region's fisheries at a similar rate because most commercial shellfish use mangroves as nurseries or refuges. Coastal inundation stemming from sea-level rise or flatland flooding resulting from climate change therefore may seriously affect mangrove ecology and associated human economy.

Agriculture

Agricultural lands (excluding pastures) represent approximately 19% of the total area of Latin America. For the past 40 years, the contribution of agriculture to the gross domestic product (GDP) of Latin American countries has been on the order of 10%. Therefore, this economic sector remains a key element of the regional economy. An important aspect of this sector is that a large percentage (30–40%) of the economically active population works in this sector. Agriculture also is an important element for the food security of the poorest sectors of the

population. Under climate change conditions, subsistence farming could be severely threatened in some parts of Latin America, such as northeastern Brazil.

Studies in Argentina, Brazil, Chile, Mexico, and Uruguay based on general circulation models (GCMs) and crop models project decreased yields in several crops (e.g., maize, wheat, barley, grapes), even when the direct effect of carbon dioxide (CO_2) fertilization and the implementation of moderate adaptation measures at the farm level are considered. It is likely that increases in temperature will reduce crop yields in the region by shortening the crop cycle. However, the lack of consistency in the various GCM precipitation scenarios makes it difficult to have a precise scenario for crop production under climate change, even when the relationships between precipitation and crop yields are well known. Increased temperature, ultraviolet radiation, sea-level rise, and changes in pest ecology may threaten food production as well (e.g., in Argentina). Climate change may reduce silvicultural yields as a result of changes in water availability during the dry season.

Human Health

The magnitude of the impacts of climate change on health in Latin America primarily depends on the size, density, location, and wealth of the population. It has been established that exposure to heat or cold waves has an influence on mortality rates in risk groups in the region. The projected increase in temperature in polluted cities, such as Mexico City or Santiago, may have an influence on human health. There is evidence that the geographical distributions of vector-borne diseases (e.g., malaria, dengue) in Brazil, Colombia, Argentina, and Honduras and infectious diseases (e.g., cholera, meningitis) in Peru and Cuba change when temperature and precipitation increase. The exact distribution of these diseases, however, is not clear.

It is likely that extreme weather events will increase death and morbidity rates (injuries, infectious diseases, social problems, and damage to sanitary infrastructure), as during the heavy rains in Mexico in 1999 or in Venezuela in 1999. On longer time scales, El Niño and La Niña cause changes in disease vector populations and the incidence of water-borne diseases in Brazil, Peru, Bolivia, Argentina, and Venezuela. Extreme climate events appear to affect the incidence of allergies in Mexico. Some economic and health problems could be exacerbated in critical areas, fostering migrations from rural and small urban settlements into major cities and giving rise to additional stress at the national level and, at times, adversely affecting international relations between neighboring countries. Therefore, under climate change conditions the risks for human health in Latin America may increase.

Adaptation Potential and Vulnerability

The economy of Latin American countries can be severely affected by extremes of natural climate variability. There were

more than 700 natural disasters in the region between 1980 and 1998. For instance, Hurricane Mitch in 1998 resulted in economic losses of approximately 40 and 70% of the gross national product (GNP) in Nicaragua and Honduras, respectively. Poverty and unequal distribution of wealth may increase as a result of the negative effects of climate change.

Trade agreements are becoming increasingly important for Latin American economies. In principle, they have been designed mainly to speed up socioeconomic development. However, various elements that relate to environmental issues gradually are being introduced into these agreements, including

provisions related to climate change. Environmental issues are beginning to be reflected in the environmental legislation in the region. For instance, environmental impact assessments are now required in most project developments.

Although climate change may bring benefits for certain regions of Latin America, increasing environmental deterioration, combined with changes in water availability and agricultural lands, may reduce these benefits to a negligible level. The adaptive capacity of socioeconomic systems in Latin America is very low, particularly with respect to extreme climate events, and vulnerability is high.

14.1. The Latin America Region

14.1.1. What is Unique about the Latin America Region?

The Latin American population will increase to 838 million by the year 2050. Annual population growth rates will decrease from 1.68%, in the period 1995–2000, to an estimated 0.51% in the period 2040–2050, according to the medium prospect of the United Nations (Nawata, 1999). This signifies that the population explosion will continue, even if a decrease in population growth rates were possible. One of the critical difficulties caused by growing population is the problem of nutrition and availability of food. Global food supply is expected to meet the overall needs of the growing world population, but significant regional variation in crop yields as a result of climate change (Rosenzweig *et al.*, 1993) could lead to an increased risk of hunger for an additional 50 million people by the year 2050. Because most Latin American countries' economies depend on agricultural productivity, the issue of regional variation in crop yields is very relevant for the region.

The area of the Latin American region is approximately 19.93 million km²—double that of Europe, but smaller than that of North America, Asia, or Africa. Latin America includes all of the continental countries of the Americas, from Mexico to Chile and Argentina, as well as adjacent seas (Canziani *et al.*, 1998). Even though the region has a predominantly southern location, Latin America also has a presence in the northern hemisphere, including Mexico, Central America, the Guyanas, Suriname, Venezuela, and parts of Colombia, Ecuador, and Brazil.

Latin America's orographical systems present a predominant north-south orientation, extending from the ranges of Mexico and Central America to the southern Andes. These features divide the region into two contrasting but interdependent ecosystems, influencing the climatic and hydrological patterns and making primary productivity a direct dependent variable of the aforementioned environmental factors (Lieth, 1976).

These conditions initially led to a prevalence of agricultural activities near coastlines. From the end of the 19th century and the arrival of European migrations, these activities were extended to inner valleys and plateaus. Pre-Colombian cultures, however, had developed many of their community farming activities in the high plateaus, where the largest proportion of Latin America indigenous communities still are settled.

Mountain ranges and high plateaus play an important role in determining local climates that are conditioned by altitude and orientation, which in turn enhance biological diversity. Agricultural diversification also is coupled to habitat heterogeneity through varying crop species and agricultural time schedules. Morello (1976) has reported the way in which hunting, fishing, cattle and sheep grazing, and cropping activities are correlated to discontinued habitats along the altitudinal gradients in the humid tropical Andes in Colombia. Similar patterns have been reported for the Andes of Ecuador (Cornik and Kirby, 1981). Mountain ranges in Latin America also should be considered

genetic/germplasm banks for a wide variety of plants cultivated since the pre-Hispanic period, as well as for domesticated animals (llama, alpaca) and their wild relatives. The success of agriculture in the Andes is based on the genetic variability of plant populations and on the people themselves who have acquired the proper technology after centuries of agricultural practices. This genetic variability has resulted not only in a high number of cultivated species but also in a striking diversity of cultivars and genotypes adapted to the environmental heterogeneity of the mountain ecosystems (Blanco Galdós, 1981).

Each valley or mountain range has its own characteristics, especially in the tropical Andes, making the area one of the most diverse physical and biological mosaics in the world. At the same time, local populations in the Andes have developed appropriate technologies that are applicable in highlands agriculture; these technological reservoirs are comparable only to those existing in the high plateaus of Asia (Morello, 1984).

Earthquakes, volcanoes, and tectonic movements are common all over Latin America. Some of these events may be catastrophic because urban and rural settlements are likely to be devastated, but some may have positive effects. For example, floods in Argentina, which originate in the high Andean watersheds, have devastating effects on cultivated valleys. However, aquifers previously exhausted through alfalfa irrigation become recharged, and salinized soils are washed. Furthermore, volcanic eruption generates soil enrichment, which nourishes a wide range of crops, including coffee in Central America and Colombia.

Latin America contains a large variety of climates as a result of its geographical configuration. The climatic spectrum ranges from cold, icy high elevations, with some of the few glaciers still found in the tropics, to temperate and tropical climate. The region also has large arid and semi-arid areas. One of the most important characteristics of Latin America from the climatic point of view is its large sensitivity and vulnerability to ENSO events. From northern Mexico to Tierra del Fuego, every country in the continent exhibits anomalous conditions associated with ENSO.

The region also hosts the largest pluvial forest in the world: 7.5 million km² constitute Amazonia, of which 6.12 million km² are within the Amazon basin. The average rainfall in the Amazon basin is about 2,300 mm yr⁻¹, with real evaporation estimated at 1,146–1,260 mm yr⁻¹. The Amazon is undoubtedly the world's largest river in terms of its outflow, with an average annual flow rate of 209,000 m³ sec⁻¹. The Amazon, the Paraná-Plata, and the Orinoco carry into the Atlantic Ocean more than 30% of the freshwater of the world. However, these water resources are poorly distributed, and extensive zones have extremely limited water resources.

Latin America hosts one of the largest terrestrial and marine biological diversities in the world. South America has the largest fish catch on the eastern Pacific. There is an important flow of krill and other plankton species as a result of cold sea

currents on both sides of the southern tip of South America. A combination of the prevailing atmospheric and oceanic circulation defines the climate and the land and sea productivity of the region. This explains the actual distribution of human settlements and the availability of basic services (e.g., water supply).

Overall, the health profile of the Latin American population can be classified as undergoing a slow epidemiological transition. At one extreme of the spectrum there is a high incidence of (and mortality from) chronic noninfectious diseases such as cardiovascular problems and cancer, which predominate in large metropolitan areas. On the other hand, infectious diseases still impose a heavy burden on the poverty-stricken parts of the population. The reasons for this dichotomy are two-fold: uneven socioeconomic development within countries and the extreme diversity of regional environments.

Latin America (and the Caribbean) has the greatest disparity in income distribution in the world. A mere 5% of the population receives 25% of all national income, and the top 10% receive 40%. Such proportions are comparable only to those found in some African countries (IDB, 1999).

Many problems that have affected Latin America adversely are now showing a wood-saw type of change, with some temporary improvements and downfalls. However, in some countries of the region, improvement in the macroeconomy is being observed, in spite of the negative impact from recent developments in Asia and some countries of the region (Mexico and Brazil). Improvement currently observed in the economies of Mexico, Brazil, Chile, and Argentina does not reflect the meso- and microeconomies net deterioration in the living standards of rural and peri-rural urban areas. The middle class, which had become a sign of progress in several countries, also is adversely affected. This situation, added to the effect of extreme events, has exacerbated migration toward richer cities and countries with relatively better economies. Shantytowns have grown steadily around big cities, and poverty belts have even tripled. Their location in flood-prone valleys and unstable hills results in a lack of potable water and sanitation services, which is posing a serious threat to these cities.

Cultural (language, traditions, religion), economic (degree of development, economic systems, wealth distribution), and social (demographic growth, political systems and practices, educational systems) similarities in Latin American countries indicate that they could address climate change with common (shared) methods.

14.1.2. Climate Variability and Change

There is ample evidence of climate variability at a wide range of time scales all over Latin America, from intraseasonal to long term. In many subregions of Latin America, this variability in climate normally is associated with phenomena that already produce impacts with important socioeconomic and environmental consequences that could be exacerbated by global warming

and associated climate change. Signals that can be related to variability and/or change in climate conditions for Latin America have been identified in some of the analyses performed by researchers in the region, particularly for streamflow, precipitation, temperature, glacier oscillations, general circulation, and extreme events. Estimations of potential future climate conditions are based on climate change scenarios studies developed for some subregions of Latin America.

14.1.2.1. Past to Present

14.1.2.1.1. Glaciers, precipitation, and streamflow

Glaciers in Latin America have receded dramatically in the past decades, and many of them have disappeared completely (Williams and Ferrigno, 1998). In 18 glaciers in the Peruvian Andes, mass balances since 1968 and satellite images show a reduction of more than 20% of the glacial surface, corresponding to 11,300 million m³ of ice (Morales-Arnao, 1969a,b; INAGGA-CONAM, 1999). Significant reductions also have occurred in southern Chile and Argentina (e.g., glacier Sarmiento) (Basso, 1997). Deglaciation may have contributed to observed negative trends in streamflows in that region (Morales-Arnao, 1999). For rivers in arid lands in northwest Peru and northeast and southeastern Brazil, significant negative trends also have been detected, but these variations seem to be related to human water management for irrigation purposes and increases in agricultural areas, rather than climate-induced changes (INRENA, 1994; Marengo, 1995; Marengo *et al.*, 1998).

Between 20°S and 40°S, precipitation around the Andes occurs mainly during the winter. Snow accumulates in the high parts of the cordillera and melts during the summer, becoming the main source of water for rivers in the region. Agricultural activities in central Chile and the Argentinean central western plains are maintained through irrigation. Therefore, it may be said with high confidence that fluctuations in winter precipitation have a strong socioeconomic impact in the region.

The precipitation record for Santiago, Chile, is highly correlated with snow depth in the cordillera. Recorded precipitation exhibited a decreasing trend from the late 19th century through the mid-1970s but has reverted since then. A similar trend has been detected in streamflow in the region (Minetti and Sierra, 1989; Carril *et al.*, 1997; Compagnucci and Vargas, 1998; Compagnucci *et al.*, 2000; Waylen *et al.*, 2000). In southern Chile and the Argentinean cordillera, a negative trend in precipitation and streamflow has been detected (Quintela *et al.*, 1993; Nuñez *et al.*, 1999).

In northwestern Mexico, there is a tendency for more winter precipitation, which has resulted in positive trends in river water levels. However, along with more intense winter precipitation, interannual climate variability has increased (Magaña and Conde, 2000). On the other hand, some parts of southern Mexico and Central America exhibit positive or negative rainfall trends, depending on the orientation of the catchment

(Aparicio, 1993; IPCC, 1996; Jáuregui, 1997; TAR WGI Chapter 3).

For Nicaragua, rainfall analysis for 1961–1995 showed negative trends in the north and northwest parts of the country. A systematic increment was detected on the Caribbean coast, and almost no variation was found along the central and the Pacific coastal regions (MARENA, 2000).

In Colombia, weak rainfall trends have been observed for the period 1955–1995, with no preferred sign at a regional level. For central Colombia, rainy seasons have been occurring earlier in recent years than 25 years ago (Mesa *et al.*, 1997). Trends in Colombian river streamflow are mixed, but the main river catchments such as the Cauca and Magdalena Rivers exhibit decreasing trends. Deforestation could account for such decreasing trends in river discharges (Poveda and Mesa, 1997).

For the Amazon region, Marengo *et al.* (2000) have identified multidecadal variations in rainfall in northern and southern portions of the basin, with opposite tendencies. Perhaps the most important finding is the presence of periods with relatively wetter or drier conditions that are more relevant than any unidirectional trends themselves. For instance, the period 1950–1976 was regionally wet in northern Amazonia, but since 1977 the region has been drier. This dryness does not seem to be related to regional deforestation (see Marengo *et al.*, 1998; Marengo and Nobre, 2000; TAR WGI Chapter 3). Similarly, streamflow series in Amazonian rivers also exhibit multidecadal variations; they do not display significant unidirectional trends (Richey *et al.*, 1989; Marengo, 1995).

In northeast Brazil, multidecadal variations in atmospheric circulation over the tropical Atlantic have been linked to similar time-scale variations in rainfall over the region (Hastenrath and Greischar, 1993; Nobre and Shukla, 1996; Wagner, 1996). On longer time scales, rainfall in northern northeast Brazil exhibits weak positive trends that are consistent with changes in decadal changes in circulation described in Wagner (1996).

Streamflow in the River Plate basin—particularly in the Negro, Paraguay, Paraná, and Uruguay Rivers—exhibits a negative trend from 1901 to 1970, which reverses after this period. Multidecadal variability also is observed in discharges (García and Vargas, 1998; Genta *et al.*, 1998; Robertson and Mechoso, 1998). Moreover, there are written reports of alternating floods and droughts periods during the 16th–18th centuries, indicating high natural variability (Prieto and Herrera, 1992).

In subtropical Argentina, Paraguay, and Brazil, precipitation exhibits a long-term change, with a sharp increase in the period 1956–1990 after a dry period along 1921–1955 (Castañeda and Barros, 1996). In the Pampa region, there is a positive trend in precipitation during the period 1890–1984. This increase in annual rainfalls was accompanied by a relative increase in precipitation during the spring and summer (Penalba and Vargas, 1996; Hoffman *et al.*, 1997; Krepper and Sequeira, 1998).

At high elevations in northwest Argentina, paleoclimatic records suggest an increase in precipitation in the past 200 years (Villalba *et al.*, 1997). In the same region, as well as in Bolivia and southeast Peru, records show that the 17th-century climate was wetter and less variable (fewer floods and droughts), whereas the 18th century was highly unstable, with a large amplitude in the annual cycle and recurrent wet and dry periods (Prieto and Herrera, 1992).

Variations in precipitation in Latin America have a strong effect on runoff and streamflow, which also are affected by melting of glaciers and snow. Based on available information, there is evidence that these variations and their sign depend on the geographical subregion under consideration.

14.1.2.1.2. Temperature

Temperature in Latin America varies depending on the different subregions. For tropical Latin America, temperature depends on cloud cover and altitude; for other subregions, altitude, advection, and, at the southern cone, sea-surface temperature (SST) play more predominant roles. The following description is based on observed records; where possible, paleoclimatic information has been included to present a wider view.

Central America shows different signs for temperature trends, according to the specific area under analysis. For example, in Costa Rica, Alfaro (1993) identifies a positive trend in daily maximum temperature. Gómez and Fernández (1996) and OCCH (1999) have identified negative trends for large areas of Costa Rica and Honduras. MARENA's (2000) analyses of time series for Nicaragua find only a small increase in mean temperature for Managua, which might be associated with growth in urbanization.

For northwestern South America, monthly mean air temperature records show a warming of 0.5–0.8°C for the last decade of the 20th century (Pabón, 1995a; Pabón *et al.*, 1999; Quintana-Gomez, 1999). Colombia also presents increasing trends in the time series for the daily series of daily mean and minimum temperature for the past 30–40 years. Similar patterns have been observed in average monthly dew point and relative humidity (Mesa *et al.*, 1997; Pérez *et al.*, 1998). Coastal cities from northern Peru presented increases in air temperature since 1940, where 16 El Niño events were reported (Jaimes, 1997; SENAMHI, 1999).

In several cities in southern and southeastern Brazil, studies on long-term tendencies for air temperature, from the beginning of the 20th century, have indicated warming tendencies (Sansigolo *et al.*, 1992). This could be attributable to urbanization effects or to systematic warming observed in the south Atlantic since the beginning of the 1950s (Venegas *et al.*, 1996, 1998). In the Amazon region, Victoria *et al.* (1998) have detected a significant warming trend of +0.63°C per 100 years.

Data since the beginning of the 20th century do not show a clear tendency in mean temperature in the southern cone, but

there is a decrease in the thermal range. Moreover, south of 50°S there are indications of a positive tendency (Hoffman *et al.*, 1997). However, when a shorter record is used for the analysis, Argentina and Chile show a large warming rate of 1.2–3.0°C per 100 years (Rosenblüth *et al.*, 1997).

In south tropical Argentina, warming is observed only during the austral autumn season (Bejarán and Barros, 1998). The Argentina humid pampa, represented by Buenos Aires, presents a warming as a result of urban effects (Camilioni and Barros, 1997). Intensity and persistence of heat and cold waves present tendencies in which the sign depends on the region (Rusticucci and Vargas, 1998).

In extra-tropical west South America (Chile), surface air temperature has varied differently during the 20th century. South of approximately 45°S, temperatures have been increasing in stepwise fashion (Aceituno *et al.*, 1993). In the area spanning about 35°S to 45°S, the most significant feature is a well-defined cooling of 1–2°C from the 1950s to the mid-1970s.

At decadal scales, multiple climate records throughout Latin America consistently exhibit a shift in the mean during the mid-1970s. This could be a climatic consequence of sudden changes in the climatology of the Pacific Ocean (Trenberth, 1990).

Using tree-ring and glacial evidence, summer temperatures in northern Patagonia show distinct periods of higher and lower temperatures during the past 1,000 years (Villalba, 1994; Villalba *et al.*, 1997). For instance, there was a cold interval from AD 900 to 1070, followed by a warm period from AD 1080 to 1250 (coincident with the Medieval warm period). Warm climatic episodes similar to that observed during the 1980s may have occurred in the recent past under preindustrial CO₂ levels in northern Patagonia (Chile and Argentina) (Villalba *et al.*, 1997).

Latin America, in general, shows important variations in temperature, some of which might be connected to change in climate. At the same time, these variations might depend on the origin and quality of the data as well as the record periods used for the studies.

14.1.2.1.3. Large-scale atmospheric circulation

Latin America's climate is influenced mainly by the northern Atlantic anticyclone and the migration of the inter-tropical convergence zone, which also affects large areas of tropical South America. The southern part of the continent is more affected by Atlantic and Pacific anticyclones, the thermic low pressure of northwestern Argentina, and mid-latitudes westerlies. All of these circulation features interact strongly with the complex topography of Latin America.

Analysis of ice cores in west Antarctica indicate that meridional atmospheric circulation intensity between middle and high

latitudes has experienced substantial strength variability, increasing in the Little Ice Age (Kreutz *et al.*, 1997; Leckenbush and Speth, 1999). At paleoclimatic time scales, analyses of fossilized pollen and lake sediments have shown more intense and frequent incursion of polar air from the Antarctic region 12,000–8,000 years before the present (BP) (Ledru *et al.*, 1994).

In southern Brazil, there has been a tendency over the past 20 years for fewer wintertime cold fronts and polar outbreaks (Marengo and Rogers, 2000), which is somewhat consistent with reported interdecadal variations in the mean position and intensity of the south Atlantic anticyclone (Venegas *et al.*, 1998).

For mid-latitude South America, important changes in zonal circulation have been observed between 1899 and 1986, with wintertime circulation weaker for the period 1939–1949 and strong during 1967–1977—suggesting interdecadal changes. Over Paraguay, southern Brazil, Uruguay, and northeast Argentina, northeasterly circulation associated with the subtropical Atlantic anticyclone increases after 1954 (Hoffman *et al.*, 1987; Minetti and Sierra, 1989; Cantañeda and Barros, 1993; Barros *et al.*, 1999).

Instrumental records, sounding information, and satellite data show changes, fluctuations, and “sudden jumps” in some features of atmospheric circulation over Latin America and its adjacent oceans, in connection with detected changes in the global climate system.

14.1.2.1.4. Variability and impacts from El Niño and the Southern Oscillation

The extremes of the Southern Oscillation are partly responsible for large portions of climate variability at interannual scales in Latin America. Therefore, some of the variations in the foregoing elements could be associated with manifestations of climate variability, such as the El Niño phenomenon, which represents the low phase of the Southern Oscillation; the positive phase is referred to as La Niña. Atmospheric circulation patterns are more perturbed during El Niño than during La Niña years (Salles and Compagnucci, 1995, 1997).

In Mexico and parts of the Caribbean, the ENSO signal corresponds to more winter precipitation and less summer precipitation (Magaña and Quintanar, 1997). Some of the most severe droughts in Mexico in recent decades have occurred during ENSO summers (Magaña *et al.*, 1998). The signal of La Niña is almost opposite to the ENSO signal. In Central America, orographic effects play an important role in understanding regional ENSO effects in precipitation. During El Niño years, the Pacific side of Central America suffers an important reduction in precipitation, whereas some parts of the Caribbean side experience more rain than usual.

Over Colombia, ENSO events are associated with reductions in precipitation, river streamflows, and soil moisture, whereas

La Niña is associated with heavier precipitation and floods (Poveda and Mesa, 1997). There also is a very high positive correlation between the Southern Oscillation Index (SOI) and river discharge in Colombia. This relationship is stronger during the December–January period and weaker during April–May. The influence of ENSO is stronger at river stations located in western Colombia and weaker for stations located in eastern Colombia. Over the eastern part of the Andes, Ecuador, and northern Peru, large positive anomalies in precipitation typically are observed during the warm episode.

Dry anomalous conditions affect the Amazon region of Brazil northward to the Caribbean through the latter half of the year (Ropelewski and Halpert, 1987, 1989, 1996; Díaz and Kiladis, 1992). In northern Amazonia and northeast Brazil, deficient rainy seasons have been observed during ENSO years (Aceituno, 1988; Marengo, 1992; Uvo, 1998). Droughts that led to forest fires were detected during the very strong ENSO events of 1911–1912, 1925–1926, 1982–1983, and 1997–1998. Extreme droughts also occurred during these years in northeast Brazil. In contrast, the ENSO signal in southern Brazil is opposite to that in northeast Brazil and northern Amazonia, with positive and sometimes extremely large anomalies of rainfall during the rainy season of ENSO years, whereas drought can occur during the positive Southern Oscillation phase (Ropelewski and Halpert, 1989; Grimm *et al.*, 1996, 2000).

Through northern and central Chile and at high altitudes of the Andes in Argentina, between 30°S and 40°S, most precipitation is recorded during the winter, with positive anomalies registered during early stages of the warm phase of ENSO. Because of the semi-arid conditions of this area, their economy is strongly affected (Quinn and Neal, 1982; Compagnucci, 1991; Rutland and Fuenzalida, 1991; Canziani *et al.*, 1997; Compagnucci and Vargas, 1998). At the same time, strong rainfall events occur in low altitudes of Chile, triggering debris flows during the winter such as those in Santiago and its surrounding areas in 1991–1993 (Garreaud and Rutland, 1996) and 1997.

At high altitudes of the Andes, large amounts of snow are recorded consistently. Melting of this accumulated snow is the main cause of river runoff during the summer. In Chile and central-western Argentina, north of 40°S, streamflows were normal or above normal during El Niño years (Waylen and Caviedes, 1990; Compagnucci and Vargas, 1998; Compagnucci, 2000). On the other hand, during cold events (La Niña), negative anomalies of rainfall and snowfall are present—with opposite consequences, including below-normal summer streamflow. For this region, the likelihood of dry conditions during La Niña is higher than that of wet conditions during El Niño (Compagnucci and Vargas, 1998).

14.1.2.1.5. Extreme events

Cold and warm fronts, tropical cyclones, and severe convergence are some of the most frequent phenomena that produce floods, droughts, mud and snow slides, heat waves, frosts, and

climate-related fires throughout Latin America. These extreme events produce direct and indirect impacts on productivity and affect the quality of life for Latin Americans. A hazard (extreme climate phenomenon) becomes a disaster when it outstrips the ability of a country or region to cope.

There are subregions of Latin America where the occurrence of extreme events is very frequent. Central America and southern Mexico often experience the effect of tropical cyclones and associated heavy rain, flooding, and slides. For northwestern South America and northeastern Brazil, many of the extremes that occur are highly related to El Niño.

Sometimes these extreme events could be magnified to such a level (extreme of extremes) that the impact becomes a disaster. In Latin America, interaction with other complex phenomena, such as interannual or interdecadal oscillations, can contribute to create the appropriate conditions to produce a disastrous impact. Examples of these extraordinary extreme events include Hurricane Mitch in Central America, heavy rains in Venezuela, some of the most severe droughts in northeastern Brazil, and variations in ocean currents during El Niño for Peru and Ecuador.

Emanuel (1987, 1991) has suggested that warmer surface conditions and colder lower stratospheric temperatures would result in stronger hurricanes. Data for the eastern Pacific region indicate that the number of strong hurricanes in the region has been increasing since 1973 (Whitney and Hobgood, 1997). Such changes may represent a major environmental threat for countries such as Mexico (Jáuregui, 1995) and the Central American isthmus.

Some of the relatively weak cold surges may exhibit unusual intensity, causing frosts and low temperatures in coffee-growing areas of southeastern Brazil, resulting in heavy damage and losses in coffee production (Marengo *et al.*, 1997). In the Mexican Altiplano, dry atmospheric conditions result in radiative cooling and frosts even during the summer (Morales and Magaña, 1998).

Even though it is still uncertain how global warming may affect the frequency and intensity of extreme events, extraordinary combinations of hydrological and climatic conditions historically have produced disasters in Latin America. Thus, in assessing vulnerability and adaptation mechanisms, it is necessary to consider the potential influence that global warming might have on extreme events.

14.1.2.2. Future: Climate Scenarios

Climate modeling has proven to be extremely useful in building projections for climate change and scenarios of future climate under different forcings. General circulation models have demonstrated their ability to simulate realistically the large-scale features of observed climate; hence, they are widely used to assess the impact that increased loading of the atmosphere

with greenhouse and other gases might have on the climate system. Although there are differences among models with regard to the way they represent the climate system processes, all of them yield comparable results on a global basis. However, they have difficulty in reproducing regional climate patterns, and large discrepancies exist among models. In several regions of the world, distributions of surface variables such as temperature and rainfall often are influenced by the local effects of topography and other thermal contrasts, and the coarse spatial resolution of GCMs cannot resolve these effects. Consequently, large-scale GCM scenarios should not be used directly for impact studies, especially at the regional and local levels (von Storch, 1994); downscaling techniques are required (see TAR WGI Chapters 10 and 13).

At the large scale, rates of mean annual temperature changes in the Latin American region for the next century are projected to be 0.2–2°C (Carter and Hulme, 2000) under the low-emissions scenario (B1) produced as part of the IPCC *Special Report on Emission Scenarios* (SRES). The warming rate could range between 2 and 6°C for the higher emissions case (A2). Most GCMs produce similar projections for temperature changes on a global basis; projected changes in precipitation remain highly uncertain.

For impact studies, it is crucial to have a projection of concurrent changes of temperature and precipitation at the regional scale. Various scenarios of climate change for Latin America have been put forward on the basis of GCM projections under the IS92a scenario. Most of these regional scenarios are based on GCM experiments that are downscaled through statistical techniques. Derived climate change scenarios for Mexico suggest that climate in Mexico will be drier and warmer (Perez, 1997). Several hydrological regions in Mexico are highly vulnerable to decreased precipitation and higher temperatures (Mendoza *et al.*, 1997). A regional climate change scenario for central

Argentina in response to CO₂ doubling under the IS92 scenario for the year 2050, also obtained through a statistical downscaling approach, shows a smaller increase in minimum temperature as compared to the maximum and larger increases for summer than for winter months, which generates enhanced temperature amplitudes (Solman and Nuñez, 1999). In addition, a decrease in precipitation is projected over the region, which is larger for summer (12%) than for winter months (5%). This result highlights an important consequence in the rainfall regime over the region: A large decrease in rainfall projected for the rainy season will seriously affect soil moisture, hence agricultural production in the region.

Several climate change scenarios for other parts of Latin America rely on linear interpolation of GCM output to estimate increases in surface temperature and precipitation (Mata, 1996; Carril *et al.*, 1997; Hofstatter and Bidegain, 1997, Paz Rada *et al.*, 1997; Centella *et al.*, 1998; MARENA, 2000). In the case of Costa Rica (MINAE-IMN, 2000), under the IS92a scenario for the year 2100, the results show a small increase in precipitation for the southeastern Caribbean region and an important decrease—close to 25%—in the northwestern Pacific region. This latter region already experiences water problems as a result of El Niño and an increasing demand from infrastructure for tourism and irrigation. Under the same climate scenario, mean temperature in Costa Rica is expected to rise by more than 3°C by 2100, and tendencies in actual climate series (1957–1997) show already an increase of 0.4°C every 10 years for the more continental Central Valley areas. This last estimation may reflect signals other than the one related to climate change.

Results from climate scenarios for Nicaragua imply an additional pressure on productivity sectors and human activities. Under the IS92a emissions scenario, mean temperature for the Pacific watershed would be expected to rise, ranging from 0.9 for the year 2010 to 3.7°C for the year 2100, and precipitation would

Table 14-1: Estimated changes projected under IS92 scenario for some countries within Latin America region.

Region	Temperature	Precipitation
Mexico	increase	decrease
Costa Rica		
– Pacific sector	+3°C	-25%
– Southeast Caribbean sector		small increase
Nicaragua		
– Pacific sector	+3.7°C	-36.6%
– Caribbean sector	+3.3°C	-35.7%
Brazil		
– Central and south central sector	+4°C	+10 to +15% for autumn reductions for summer
Central Argentina	summer: +1.57°C (+1.08–2.21°C) winter: +1.33°C (+1.12–1.57°C)	summer: -12% winter: -5%

decrease by 8.4% for the year 2010 and 36.6% for the year 2100. For the Caribbean watershed, mean temperature would increase, ranging from 0.8°C for the year 2010 to 3.3°C for the year 2100, and precipitation would decrease in a range between 8.2% for the year 2010 and 35.7% for the year 2100 (MARENA, 2000).

Potential effects of climate change in Brazil suggest changes of 4–4.5°C in surface temperature as a result of increased CO₂ concentrations (de Siqueira *et al.*, 1994, 1999). Central and south-central Brazil may experience increases of 10–15% in autumn rainfall; reductions could appear during December, with high risk of drought during summer, affecting crops (see Table 14-1).

Analysis of climate variations during the instrumental period and evidence suggested by paleoclimatic and other proxy climate information suggests that climate variations and change have been found in several regions in Latin America. Most climate records cover the past century; at this time scale, there have been indications of multidecadal and interannual variability, some linked to extremes of the Southern Oscillation. The lack of continuous and long-term records from the past does not allow one to identify climate patterns with a high degree of confidence to determine whether these climates were similar to or much different from that of present times—particularly with respect to the frequency and intensity of extreme events such as drought, floods, freezes, heat waves, and especially hurricanes and tropical storms. However, multidecadal variations have been identified in rainfall and streamflow records in the region, although no clear unidirectional trend indicators of climate change have been identified.

14.1.3. Socioeconomic and Trade Agreements Issues

14.1.3.1. Socioeconomic Issues

Latin America has one of the greatest disparities in income distribution in the world. From the social and environmental point of view, the region clearly is vulnerable to the effects of natural disasters. Inappropriate land use, for agriculture and human settlements, in watersheds causes serious damages during the occurrence of extraordinary climate extreme events, such as Hurricanes George and Mitch in Central America and intense rain events in Venezuela and Argentina. CEPAL (1999a,b,c,d,e) estimated losses from Hurricane Mitch (see Table 14-2). Losses in Honduras and Nicaragua were 70 and 45% of GNP, respectively, affecting the development and economic growth of both countries. There is strong evidence that the effects of natural disasters contribute to rising poverty and inequality in many regions of Latin America.

The year 1998 was one of the most problematic periods in recent times for Latin America and the Caribbean. The side effects of the international financial crisis that originated in Asia in the middle of 1997 limited the possibilities for the region to obtain external aid. In addition, many adverse climatic events

Table 14-2: Estimated losses from Hurricane Mitch.

Country	Losses (US\$ million)	Percentage of GNP
Costa Rica	92	1.0
El Salvador	388	6.1
Guatemala	748	1.5
Honduras	4,000	70.0
Nicaragua	988	45.0

worsened the socioeconomic conditions. The Latin American region hosts a myriad of socioeconomic conditions. Countries with a high level of development coexist with least-developed countries. Macro-economic figures indicate a moderately constant degree of growth in the region, even though more than 200 million people in Latin America are poor (CEPAL, 1998).

The Human Development Report for 1998 (UNDP, 1998), in its section on consumption patterns, notes that the overwhelming majority of people who die each year from pollution are poor people in developing countries. Large cities in Latin America such as Mexico City already have a serious problem with air pollution. The report also identifies several issues that affect most of Latin America which may be increased by global warming, including desertification, floods and storms, and harvest. Poor people are less resilient to these problems.

The World Bank (1997) analyzed the 1982–1983 El Niño event and, with a great degree of certainty, considered it to be the most intense in the 20th century. Losses from droughts, floods, and hurricanes were estimated at US\$14 billion. Of these, US\$2 billion were lost in the western coast of South America, half in Peru—mainly losses from fishing revenue and destruction of infrastructure. Social losses also were very high. Reconstruction and development of related activities in Peru depleted resources and resulted in losses of 6% in GNP. Damages in Peru in 1997–1998 were on the order of US\$1 billion (of which 55% was transportation infrastructure, 15% agriculture, 14% energy, and 9% education), and more than 400 relief projects had to be implemented, requiring emergency attention in 14 of the 24 departments of Peru. Some positive effects resulted, such as increases in pastures (200,000 ha) and reforestation of 100,000 ha.

One sector that might be affected by climate change, based on previous experiences during the ENSO period, is fisheries. Fish capture was reduced by 53% during the 1998 ENSO event (IMARPE, 1998). However, adaptation measures such as changing the species captured and price increases reduced the losses to 40%. Some adaptation options, such as switching from anchovy to tuna, can significantly reduce losses from seawater warming (Arntz and Fahrbach, 1996; IMARPE, 1998). Adaptation to flooding conditions may reduce damage from extreme floods. One way to address water-shortage areas is to store excess water; for example, a lake was created in north Peru in 1998 (IMARPE, 1998).

Insurance is an important financial aspect that may be impacted by climate change. A joint World Meteorological Organization/Inter-American Development Bank (WMO/IDB) meeting—with participation by scientists, bankers, and insurers—recognized the importance of climate change in insurance policy and of the need for increased cooperation (WMO, 1994), but few concrete actions materialized, mainly because insurers feel that larger risks should be compensated with higher insurance premiums.

14.1.3.2. Trade Agreements

Several trade agreements exist in the region and have important effects on the economy and, indirectly, on the environment of the region. The most important of these agreements are listed in Table 14-3. Regional intergovernmental agreements could be an important mechanism for adaptation to climate change in Latin America. Agreements such as the one developed for conservation of water, the environment, and natural disaster management in the Central American isthmus (Central American Integration System—SICA) could be interpreted as a way to coordinate sectorial adaptation to different climatic conditions. During the South American presidential meeting in August 2000, leaders attempted to consolidate efforts for the region's political and economic integration, with emphasis on free trade. Because natural disasters cause a decline in productive capacity and increase demand for strong public and private investment in reconstruction, imports are likely to increase and

exports are likely to fall, leading to a trade deficit. Disasters such as floods, droughts, and hurricanes also may lead to a significant increase in food product prices if production and distribution are disrupted (IDB, 2000).

There also have been other agreements on the technological and scientific agenda, such as initiatives to foster research on global and climate change and environmental issues. The Inter-American Institute for Global Change (IAI) supports research initiatives to document climate variability and change characteristics and their societal impacts in the Latin American and Caribbean region.

14.1.4. Environmental Legislation

Ratification of international and regional conventions and agreements brings the responsibilities and commitments associated with them into the text of national legislation. As a consequence, ratification of the recommendations of the United Nations Conference on Environment and Development (UNCED, 1992) by Latin American governments has initiated a path for preventive actions for natural hazards, as well as other recommendations included in Agenda 21 to be incorporated into national legislation. The same is true for the United Nations Framework Convention on Climate Change (UNFCCC), the United Nations Convention on Biodiversity, and the United Nations Convention to Combat Desertification and Drought.

Table 14-3: Important trade agreements in Latin America region.

Agreement	Participating Countries	Notes
Asociación Latinoamericana de Libre Comercio (ALADI)	Spanish speaking countries of the region	Not a particularly active agreement.
Pacto Andino (Andean Pact)	Bolivia, Colombia, Ecuador, Peru, and Venezuela	Tends to eliminate duties in a gradual way. Has incorporated an environment unit and places increasing attention on environmental issues.
Mercosur	Argentina, Brazil, Paraguay, and Uruguay	Bolivia and Chile are associate members. Tends to eliminate duties in a gradual way. Future common currency under consideration.
Central American Common Market	Costa Rica, El Salvador, Guatemala, Honduras and Nicaragua	One of the oldest trade agreements. Plans to convert to a free-trade zone.
North America Free Trade Agreement (NAFTA)	Mexico, plus Canada and USA	Very successful for expanding trade. Strict environmental considerations. Plans call for expansion to all Latin American countries.
Bilateral agreements	Several pairs of countries or groups	Environmental considerations increasingly important, especially in agreements with the European Union.

This also has been the case with the adoption of the Vienna Convention on the Protection of the Stratospheric Ozone Layer and its Montreal Protocol. Similar steps will be needed should the Kyoto Protocol be ratified. The UNFCCC, particularly Articles 2 and 4, calls for action vis-à-vis climate variations, and the Kyoto Protocol opens avenues for mitigation of greenhouse gas (GHG) emissions; through Article 12, on Clean Development Mechanisms, the UNFCCC makes provision for assistance and transfer of technology from Annex I to non-Annex I Parties.

There also are a substantial number of regional agreements and a huge body of laws, rules, and regulations to ensure systematic and coordinated actions for protecting the environment, including flora and fauna and coastal and inland wetlands, as well as to promote sustainable development (PNUMA, 1991; Bertucci *et al.*, 1996; Solano, 1997). Most Latin American governments have a comprehensive environmental legal framework with relevant laws, rules, and procedures for specific resources and activities (e.g., water, forestry and mineral resources, marine resources and coastal areas, hunting and fishing, and tourism, as well as specific products and pesticides and pollution) (Sebastiani *et al.*, 1991, 1996a,b). Latin American governments also have developed national and regional environmental plans and strategies, as well as other sectoral or special programs. Although implementation in some countries is far from satisfactory, it also is very common to find legislation that regulates the use of natural resources and makes provision to punish noncompliance (Solano, 1997). In a large number of countries in the region, recent legal developments on environmental management include mandatory environmental impact assessment (EIA) studies. All Latin American countries are expected to adopt this policy. With regard to the climate component, the main shortcomings highlighted in the report to the IPCC Bureau on Systematic Observations are lack of sufficiently dense terrestrial and marine observing systems; lack of systematic observations on specific biological variables and socioeconomic impacts, as well as GHGs and aerosols; and consolidation of land surface observations (hydrology, ecosystems, and land use) (WMO, 1998). This means that, generally speaking, there are limitations that affect the value and reliability of EIAs in some areas of the region.

In line with United Nations Resolution A/52/629—which calls for cooperation to incorporate sustainable development programs at national, regional and global levels—countries in Latin America are engaged in fulfilling the objectives of such development programs. In this respect, policymakers and decisionmakers should be made aware of the role played by climate variation issues in such development strategies. The large majority of countries follow the recommendations made by the United Nations Commission for Sustainable Development (UNCSD), and the Economic Commission for Latin America and the Caribbean (ECLAC) is assisting them in integrating relevant disciplines and sectors, particularly for incorporating natural hazard response strategies in sustainable development policies. However, more work still is needed, as a result of the aforementioned shortcomings in the operation of observing

and monitoring systems as well as the need for capacity-building on issues related to sustainable development and their well-known linkages with climate issues. Such action becomes relevant to efforts for mitigating environmental hazards and acting in line with the planning of the Pan-American Climate Information and Applications System (PACIS), as suggested by the Summit of the Americas in Santiago, Chile, in 1998.

As environmental concerns become more pressing, they are climbing higher on the international political agenda. Globalization in its many guises poses an enormous challenge for traditional governance structures. While nations—particularly developing nations—are losing ground in globalization, other actors are moving to the forefront, particularly international corporations and nongovernmental organizations (NGOs). Therefore, governments should not only take into account this new spectrum of participants in future environmental legislation but, above all, give them specific and urgently required roles in defense of the environment. New information and communication technologies are facilitating international networking, and activist groups, businesses, and international institutions are forging innovative partnerships.

14.1.5. Summary of Main Findings from the IPCC Special Report on Regional Impacts of Climate Change

Glaciers in the high Andes and three major ice fields in southern South America represent the cryosphere in Latin America. Warming in high mountain regions could lead to disappearance of significant snow and ice surfaces. In addition, changes in atmospheric circulation resulting from the ENSO phenomenon and climate change could modify snowfall rates—with a direct effect on the seasonal renewal of water supply—and surface and underground runoff in piedmont areas. This could affect mountain sports and tourist activities, which represent an important source of income in some economies. Glaciers are melting at an accelerated rate in the Venezuelan (Schubert, 1992; Hastenrath and Ames, 1995) and Peruvian Andes.

In the humid tropics, extreme precipitation events would increase the number of reservoirs silting up well before their design lives have been reached. Other areas affected by the impact of climate change on water resources could be those that rely on freshwater ecosystems (i.e., lakes and inland wetlands and their biota), including commercial and subsistence fisheries.

According to climate change projections, approximately 70% of the current temperate forest in Mexico could be affected by climate change (Villers, 1995). Other vulnerability studies (Gay-García and Ruiz Suarez, 1996)—carried out on the basis of Canadian Climate Centre (CCC)-J1 (Boer *et al.*, 1992; McFarlane *et al.*, 1992; Boer, 1993) and Geophysical Fluid Dynamics Laboratory (GFDL)-A3 (Wetherald and Manabe, 1988) GCMs—suggest that 10% of all vegetation types in northern Mexico's ecosystems—including forests and shrublands of southern Chihuahua, eastern Coahuila, northern Zacatecas, and San Luis Potosí—would be affected by drier and warmer

conditions, resulting in expansion of dry and very dry tropical forests and xerophytic shrublands.

Studies of vulnerability to sea-level rise (Perdomo *et al.*, 1996) have suggested that countries such as Venezuela and Uruguay could suffer adverse impacts, leading to losses of coastal land and biodiversity, saltwater intrusion, and infrastructure damage. Impacts likely would be multiple and complex, with major economic implications. In Central America, impacts associated with sea-level rise would have their greatest effects on infrastructure, agriculture, and natural resources along the coastline, with immediate effects on socioeconomic conditions in the isthmus countries. Sea-level rise would exacerbate the processes of coastal erosion and salinization of aquifers and increase flooding risks and the impacts of severe storms along the coastline (Campos *et al.*, 1997). Flooding associated with sea-level rise is one of the main impacts in lowland areas such as the Amazon, Orinoco, and Parana River deltas and the mouth of other rivers, such as the Magdalena in Colombia. The report also identified the Rio de La Plata estuary as an area where saltwater intrusion could create problems in the freshwater supply.

In Latin America's extremely arid deserts (<100 mm annual precipitation)—the Chihuahuan, Sonoran, Peruvian, Atacama, Monte, and Patagonia—the impacts of climate change are not expected to be severe (Canziani *et al.*, 1998), because these systems already are adapted to wide fluctuations in rainfall. Therefore, hyper-arid lands are not as susceptible as drylands to climate change (Middleton and Thomas, 1997).

Studies developed in Costa Rica and Nicaragua (Halpin *et al.*, 1995) observed that shifts may occur in climatic zones that are associated with particular vegetation types in these countries. Global warming would have its greatest impacts on the cold temperate forest of southern Chile and Argentina, especially those neighboring xerophytic ecosystem types.

Projected changes in climate could increase the impacts of already serious chronic malnutrition and diseases affecting a large sector of the Latin American population. The geographical distribution of vector-borne diseases (e.g., malaria) would spread to higher elevations.

14.2. Key Regional Concerns

Studies developed after the *Special Report on Regional Impacts of Climate Change* (RICC) add new findings on the potential impact of climate change on different sectors in Latin America. Many of these new studies evolved from those mentioned in RICC, indicating that a process is in place in Latin America to reduce uncertainties associated with climate change.

14.2.1. Natural Ecosystems

Climate variations produce a variety of impacts on natural ecosystems (see Sections 5.4 to 5.9). Latin America possesses

a large quantity of ecosystems, ranging from Amazonian tropical rainforest to cold Andean systems (Paramos). It also hosts remarkable rangelands, shrublands, deserts, savannas, grasslands, coastal wetlands (mainly along the Caribbean and Atlantic coastlines), and inland freshwater wetlands such as Pantanal and Iberá. Natural ecosystems in Latin America can be expected to suffer a variety of impacts from climate change. Latin American humid tropical forests represent an important group of ecosystems for which a great deal of information is offered (e.g., Canziani *et al.*, 1998).

14.2.1.1. Humid Tropical Forests

Conversion of large areas of tropical forest to pasture could reduce water cycling and precipitation in the region, in addition to its global role as a contribution to global warming. Pasture has much less leaf area than forest (McWilliam *et al.*, 1993). Because evapotranspiration is proportional to leaf area, water recycled through forest is much greater than that recycled through pasture—especially in the dry season, when pasture is dry but forest remains evergreen (Roberts *et al.*, 1996). This is aggravated by the much higher runoff under pasture, with measured increases of more than 1,000% in small (10 m^2) plots (Fearnside, 1989). Pasture grasses can partially compensate for reduced evapotranspiration by increasing their efficiency of water use when soil moisture is low, whereas forest trees maintain constant efficiency (McWilliam *et al.*, 1993). Soil under pasture quickly becomes highly compacted, inhibiting infiltration of rainwater into the soil (Schubart *et al.*, 1976). Rain falling on compacted soil runs off quickly, becoming unavailable for later release to the atmosphere through transpiration. The shallower root system of pasture, compared to that of forest, prevents pasture from transpiring during periods of drought (Nepstad *et al.*, 1994, 1999). Precipitation decreases therefore are greatest at the time of year when rain is most needed.

If the extent of deforestation were to expand to substantially larger areas, we have high confidence that reduced evapotranspiration will lead to less rainfall during dry periods in Amazonia and medium confidence that rainfall will be reduced in the center-west, center-south, and south regions of Brazil (Lean *et al.*, 1996). Although the annual rainfall total in Amazonia would decrease by only 7% from conversion to pasture, based on simulations with the Hadley Centre model, in August (dry season) the average rainfall would decrease from 2.2 mm day^{-1} with forest to 1.5 mm day^{-1} with pasture—a 32% decrease (Lean *et al.*, 1996). Simulations of conversions of Amazonian forest to pasture, using the Météo-France EMERAUDE GCM, indicate reduced volumetric soil moisture in the “arc of deforestation” where clearing activity is concentrated along the southern boundary of the Amazon forest. Rainfall reduction in southern Brazil is greatest for the January–March period (Manzi and Planton, 1996).

Greater dependence of Amazonian rainfall on water derived from evapotranspiration in the dry season means that conversion to pasture would cause this period to become longer and more

severe—a change that could have harsh repercussions on the forest even if total annual precipitation were to remain unchanged (Fearnside, 1995). In patches of forest isolated by cattle pasture, trees on the edges of forest patches die at a much greater rate than do those in continuous forest (Laurance *et al.*, 1997, 1998; Laurance, 1998). Because many trees die while they are still standing, rather than being toppled by wind, dry conditions (particularly in the air) near reserve edges are a likely explanation for mortality. Soil water may partially counterbalance the effect of drier air; as trees die, soil water in the gaps they leave normally increases because the roots that would have removed water from the soil are gone. Increasing vines and decreasing forest biomass are strongly associated near forest edges, probably as a consequence of a positive feedback relationship between these factors (Laurance *et al.*, 2000). Drier microclimatic conditions have been found at forest edges (Kapos, 1989). Increased water stress—as indicated by altered ^{13}C in plant leaves—extends 60 m into the forest from an edge (Kapos *et al.*, 1993). Tree mortality increases significantly up to 100 m from the forest edge (Laurance *et al.*, 1998). Considering the length of forest edges measured by Skole and Tucker (1993) for the Brazilian Amazon in 1988, a 100-m disturbance buffer to these edges would represent a disturbed area in 1988 of 3.4×10^6 ha, or 15% of the area cleared by that year. Forest edges, which affect an increasingly large portion of the forest with the advance of deforestation, would be especially susceptible to the effects of reduced rainfall.

Greater severity of droughts reinforced by deforestation effects could lead to erosion of the remainder of the forest once a substantial portion of the region had been converted to pasture. The greatest effects are likely to occur during occasional complex phenomena such as El Niño (Tian *et al.*, 1998; Nepstad *et al.*, 1999). Precipitation in Amazonia is characterized by tremendous variability from 1 year to the next, even in the absence of massive deforestation (e.g., Fearnside, 1984; Walker *et al.*, 1995). If the forest's contribution to dry-season rainfall were to decrease, the result would be to increase the probability of droughts that are more severe than those experienced in the centuries or millennia over which the present forest became established. Occasional severe droughts would kill many trees of susceptible species. The result would be replacement of tropical moist forest with more drought-tolerant forms of scrubby, open vegetation resembling the *cerrado* (scrub savanna) of central Brazil (Shukla *et al.*, 1990).

Until recently, burning in Amazonia has been almost entirely restricted to areas where trees have been felled and allowed to dry before being set alight. Fire normally stops burning when it reaches the edge of a clearing rather than continuing into unfelled forest. Archaeological evidence suggests that catastrophic fires have occurred in Amazonia during major El Niño events four times over the past 2,000 years: 1,500, 1,000, 700, and 400 BP (Meggers, 1994). Human action could now turn less intensive El Niño events, which are much more frequent than major ones, into catastrophes. Increased fire initiation foci, together with increased forest flammability from logging, already have resulted in substantial incursions of fires into standing forest in

eastern and southern Amazonia during dry years (Uhl and Buschbacher, 1985; Uhl and Kauffman, 1990; Cochrane and Schulze, 1999; Cochrane *et al.*, 1999; Nepstad *et al.*, 1999). The 1998–1999 fires in Roraima, in the far northern portion of Brazil, reflect the vulnerability of standing forests in Amazonia during El Niño events now that settlement areas in the forest provide permanent opportunities for fire initiation (Barbosa and Fearnside, 1999).

Increases in the amount of biomass burning could affect nutrient cycling in Amazonian forest ecosystems (medium confidence) (Fearnside, 1995). Droughts lead to increases in the area and completeness of burning in clearings in Amazonia, contributing to smoke and dust that function as sources of wind-borne nutrients to the surrounding forest (Talbot *et al.*, 1990). Climatic change also could increase nutrient supply via long-range transport of dust. African dust transported across the Atlantic Ocean by winds may be supplying significant amounts of phosphorus and calcium to Amazonia (Swap *et al.*, 1992). Amazonian soils are very poor in these elements. Soil nutrients are among the factors that limit growth, recruitment, and mortality of trees (Laurance *et al.*, 1998; Sollins, 1998). Smoke and ash particles from burning in savannas, possibly including those in Africa, also contribute nutrients (Talbot *et al.*, 1990). The extent to which these nutrient sources could increase the growth of Amazonian forests is not known. Increases undoubtedly differ by tree species, thereby altering forest composition. Burning is affected by climate, as well as by the size and behavior of the human population. Factors that influence the growth of intact forests in Amazonia are particularly important because of the large amounts of carbon that could be released to or removed from the atmosphere if the balance between forest growth and decay is altered.

CO_2 enrichment is believed to contribute to observed imbalances between CO_2 uptake and release by forest biomass in Amazonia; forest recovery from past disturbances also may contribute to these imbalances. Eddy correlation measurements (studies of gas movements in air flows inside and immediately above the forest) at one site in Rondônia indicated an uptake of $1.0 \pm 0.2 \text{ t C ha}^{-1} \text{ yr}^{-1}$ (Grace *et al.*, 1995). A similar eddy correlation study near Manaus found uptake of $5.9 \text{ t C ha}^{-1} \text{ yr}^{-1}$ (Malhi *et al.*, 1999). An estimate based on reviewing existing measurements of tree growth and mortality in permanent plots found mean uptake of $0.62 \pm 0.37 \text{ t C ha}^{-1} \text{ yr}^{-1}$ (Phillips *et al.*, 1998). On the other hand, at the Biological Dynamics of Forest Fragments site near Manaus (the largest and longest running study included in the forest growth measurement data set), no uptake or loss was found in 36 1-ha control plots located >100 m from a forest edge (Laurance *et al.*, 1997). The Rondônia and Manaus eddy correlation studies and the basin-wide review of tree growth indicate uptakes of 0.63, 3.66, and $0.38 \times 10^9 \text{ t C}$, respectively, when extrapolated on the basis of consistent definitions of forest that indicate a total area of forest in the Amazon Basin of 620.5×10^6 ha (Fearnside, 2000). A process-based model of undisturbed ecosystems in the Amazon Basin, including savannas and forests (not necessarily defined as above), indicates wide interannual variations in net carbon flux

from vegetation and soil, ranging from emissions of 0.2×10^9 t C in El Niño years to a sink of as much as 0.7×10^9 t C in other years; mean annual flux simulated over the 1980–1994 period gives an uptake of 0.2×10^9 t C (Tian *et al.*, 1998). If the frequency of El Niño events increases as a consequence of global warming (Timmermann *et al.*, 1999), these forests may release some of their large carbon stocks to the atmosphere. The future course of accumulation of CO₂ in the atmosphere—and consequently the time when concentrations would reach “dangerous” levels—depends heavily on continued uptake of carbon by the biosphere, including an important contribution from Amazonian forests. Climate effects contribute to making the sink in Amazonian forests unreliable as a brake on atmospheric carbon accumulation.

Although temperature changes from global warming are expected to be modest in the tropics as compared to temperate regions, it is important to realize that each degree of temperature alteration in a tropical environment may be “perceived” by forest species there as a greater change than would be the case for the same temperature shift in a temperate forest (Janzen, 1967). The direct effects of global warming on ecosystems at relatively low latitudes, if not at the equator itself, therefore may be greater than the small predicted temperature alterations at these sites might lead one to believe. In addition, direct effects of global warming through temperature change are likely to be less pronounced than effects that temperature can have through its influence on other climatic parameters, such as rainfall (Fearnside, 1995).

GCMs indicate a range of results for the effect of global warming on precipitation in Amazonia. Drying generally is expected; some models indicating greater drying than others. The Hadley Centre’s HadCM2 model indicates especially dry climate over Amazonia. Process-based ecosystem models that use this simulated climate show large declines in net primary productivity (NPP) and release of carbon as a result of Amazonian forest dieback (Friend *et al.*, 1997). The varied GCM results suggest the need for a range of climate scenarios as inputs to ecosystem simulations (Bolin *et al.*, 2000). It should be noted that available scenarios (e.g., Nakicenovic *et al.*, 2000) represent the change in climate resulting from altered composition of the atmosphere only, not the additional impacts of regional land-use changes such as replacement of Amazonian forest by pasture.

Globally, models show that a doubling of GHGs may lead to a 10–15% expansion of the area that is suitable for tropical forests as equilibrium vegetation types (Solomon *et al.*, 1993). For tropical rainforest, the suitable area would expand 7–40%, depending on the GCM employed in estimating the future distribution of climatic zones. The GCM studies used by Solomon *et al.* (1993) assess the effects of doubled GHGs (i.e., CO₂-equivalence), through the direct effects of temperature and through temperature-driven alteration of precipitation regimes (but not rainfall changes provoked by deforestation). These results are indicators of *potential* for forest expansion and are not intended to reflect expected landscapes in the future; they do not include the influence of human populations in converting

to other uses land that is climatically suitable for tropical forests.

One model that includes climate-induced and human changes to the year 2050 points to decreases in forest areas by about 5% in Latin America (Zuidema *et al.*, 1994). The deforestation estimates used in these calculations are based on the areas needed to satisfy expected demands for agricultural products. In the case of Brazil, deforestation is likely to exceed these forecasts because much of the forest clearing stems from motivations other than consumption of agricultural products (Hecht *et al.*, 1988; Reis and Margulis, 1991; Hecht, 1993; Fearnside, 1997). In any case, the combination of forces driving deforestation makes it unlikely that tropical forests will be permitted to expand to occupy the increased areas that are made climatically suitable for them by global warming. Land-use change interacts with climate through positive feedback processes that accelerate the loss of Brazil’s Amazonian forests.

14.2.1.2. Dry Forests

Seasonally dry tropical forests have wide global distribution and coverage. Nearly 42% of tropical forests around the world are seasonally dry plant communities (Murphy and Lugo, 1986). Ancient Mesoamerican cultures developed in these regions. Domestication of animals and plants (e.g., maize, beans, sweet potato) has occurred mainly in dry forests (Challenger, 1998). Degradation of these seasonal forests is similar to or even greater than that of tropical rain forests, and only a small fraction remains intact (Janzen, 1988; Gentry, 1995; Murphy and Lugo, 1995). Janzen (1988) argues that because only a small proportion of the original distribution of dry forest remains intact in Mesoamerica, neotropical seasonally dry forests should be considered severely threatened. The estimated deforestation rate for Mexico, for the 1973–1989 period, is 1.4% yr⁻¹, which is equivalent to loss of 17.9 km² yr⁻¹ (Trejo and Dirzo, 2000).

Costa Rican and Nicaraguan forests will be more severely affected by changes in precipitation than by changes in the annual mean temperature (see Section 14.1.5). In Venezuela, 40–50 Mha of moist forest will shift to dry or very dry forest under climate change scenarios (Mata, 1996). Between 44 and 51% of the total covered area of the Mexican deciduous tropical forest will be affected (Villers-Ruiz and Trejo-Vázquez, 1997).

Burning in the Cerrado shrubland that borders Amazonian forest to the south has increased in frequency in recent decades. This appears to create an unfavorable nutrient balance for the entire Amazonian ecosystem (Coutinho, 1990).

14.2.1.3. Savannas, Grasslands, and Deserts

Latin American dryland ecosystems are seriously threatened by desertification processes that have negative social, economic, ecological, cultural, and political consequences (Benedetti, 1997;

Table 14-4: Estimated land use, drylands, desertification (modified from Dregne and Chou, 1992).

Country	Irrigated		Rainfed		Rangeland		Hyperland		Total Drylands (10 ³ ha)
	Area (10 ³ ha)	% Desertified	Area (10 ³ ha)	% Desertified	Area (10 ³ ha)	% Desertified	Area (10 ³ ha)		
Argentina	1,680	31	12,068	10	178,878	70	0		192,626
Bolivia	160	19	1,458	31	31,069	85	0		32,687
Brazil	2,300	11	3,904	69	74,558	90	0		80,762
Chile	1,257	8	1,281	47	20,976	80	11,740		35,254
Colombia	324	3	322	40	9,376	85	0		10,022
Cuba	390	1	35	14	10	90	0		435
Ecuador	540	7	400	62	7,986	90	0		8,926
El Salvador	110	5	10	10	15	93	0		135
Guatemala	75	8	88	11	719	89	0		882
Mexico	4,890	36	10,005	54	113,142	90	1,738		149,775
Paraguay	65	8	42	5	16,326	31	0		16,433
Peru	1,210	34	1,027	78	40,121	85	8,097		50,455
Venezuela	324	12	345	29	9,728	70	0		10,397

Anaya, 1998). Desertification is defined as land degradation in arid, semi-arid, and dry subhumid areas resulting from various factors, including climatic variations and human activities (conclusion from Earth Summit of Rio de Janeiro in 1992—UNCED, 1992). Evaluation of desertification around the world is complex because there is no unique measure of aridity. For example, using Thornthwaite's aridity index, 75% of Mexico is considered arid land (Thornthwaite, 1948). However, Garcia (1988) states that the arid region constitutes just more than 50% of Mexico. Large variability in the temporal and spatial distribution of precipitation complicates determination of arid and semi-arid region extension and consequently analysis of land degradation (Balling, 1994; Williams and Balling, 1996; Hernández and García, 1997).

At a global scale, the main desertification processes are degradation of vegetation, water and wind erosion, and salinization and waterlogging (Dregne and Chou, 1992). Major land-use activities in arid regions, such as irrigation and rainfed agriculture and livestock on rangelands, also are common factors in land degradation in various Latin American countries (see Table 14-4). In irrigated lands, salinization and waterlogging mainly cause the desertification. In rainfed cropland, the dominant processes for desertification are water and wind erosion; in this case, the percentage of the affected areas ranges from 10% for Argentina and El Salvador to 78% for Peru. Rangeland desertification is caused by overgrazing that results in vegetation degradation, as well as deforestation of woody species for fodder, fuel, charcoal production, and construction materials. Rangelands correspond to the major surface of drylands, where the percentage of desertified areas reach the highest levels (70–90%) compared to other land uses. On the other hand, according to the Global Assessment of Human-Induced Soil Degradation (GLASOD) survey (Middleton and Thomas, 1997), deforestation and removal of natural vegetation cover is the primary cause of soil degradation in South America, affecting 41.7% of the 79.1 Mha of drylands.

The most affected regions are in northeast Brazil, along the Caribbean coasts of Venezuela and Colombia, and in northern Argentina (semi-arid Chacoan). Secondary causes of soil degradation are overgrazing (26.2%) and agricultural activities (11.6%) (<100 mm annual precipitation).

According Greco *et al.* (1994), precipitation changes projected under various climate change scenarios are unlikely to produce major ecosystem changes in this region. However, normal variations in rainfall patterns that are characteristic of this region may induce cyclic changes in vegetation physiognomy. These variations probably are more important than the total amount of precipitation. Very humid years may affect the vegetation of the region. For example, in San Luis Potosí, Mexico, in 1955, heavy rainfall from a large number of hurricanes caused the “mezquital” (*Prosopis*) shrub to disappear as a consequence of extremely wet soils, and the region became a grassland (Medellín-Leal and Gómez-González, 1979).

In the same way, the presence of El Niño in 1997–1998 in coastal arid zones of northern Peru generated drastic temporal changes in dry forest ecosystems (Torres Guevara, 1992). That area, where the historical average of annual precipitation is only 20–150 mm, received 1,000–3,000 mm of rainfall between December 1997 and May 1998. This precipitation had positive and negative effects in the region: NPP increased in all vegetation communities (Torres Guevara, 1992), reactivating rainfed agriculture activities. However, there was an outbreak of insect pests that reduced NPP.

14.2.1.4. Temperate Forests and Mountain and Polar Ecosystems

Studies carried out in Latin America on the potential impact of climate change in mountain ecosystems report an increase in

mean temperature followed by a gradual reduction of glaciers in the high mountains (Flórez, 1992). As Flórez (1992) has reported, in Colombia there will be an ascent of the altitudinal limits of forest and agriculture, reducing the paramo life zone and possibly causing disappearance of current flora and fauna. The limits of the Andean and sub-Andean life zones also would ascend, as would the upper limit of the lowland tropical forest zone (Pabón, 1995b; van der Hammen, 1997). In the same way, studies in Costa Rica suggest the same effect on the tropical montane cloud forests, where biodiversity is very high. Halpin and Smith (1991) identify three types of changes in the areal arrangement of ecoclimatic zones in Costa Rica from four GCM models (UKMO, GISS, OSU, and GFDL). The first change is a strong trend toward displacement of montane and subalpine zones by warmer pre-montane climate types. The second change indicates potential heat stress in vegetation, and the third is a change in all altitudinal levels toward warmer climate types.

Villers-Ruiz and Trejo-Vázquez (1997) determined the vulnerability of Mexican forest ecosystems and forestry areas to climate change under two climate change scenarios, considering doubled-CO₂ concentrations (CCCM and GFDL-R30 models). They used Holdridge's life zones classification for their analysis. Their results showed that the most affected life zones would be temperate cold and warm forests. They conclude that increases in temperature and decreases in precipitation would reduce the extent of cool temperate and warm temperate life zones but would increase dry and very dry tropical forest zones.

The most affected natural protected areas in Mexico would be those located in the northern and western regions of the country (Villers-Ruiz and Trejo-Vázquez, 1998). Similarly, the most affected forest exploitation areas would be those located in the western part of Mexico. These changes suggest that life zones that sustain temperate desert, warm temperate desert, and cool temperate wet forest would disappear or would be severely reduced (Villers-Ruiz and Trejo-Vázquez, 1998). These changes would put national cellulose and paper production at risk because high and medium forestry production areas are located in the northern and western states of Mexico (Vargas-Pérez and Terrazas-Domínguez, 1991). Cool, temperate moist and wet forests (coniferous and oak forests) currently occupy these zones.

Natural protected areas would be affected by the change of their original vegetation, causing a reduction of animal populations. Sierra de Manantlán and the Monarch Butterfly reserves are examples of climate change impacts on natural protected areas (Villers-Ruiz and Trejo-Vázquez, 1998).

The severe drought during early 1998, associated with an El Niño event, resulted in an unusually large number of forest fires and severe economic losses (Palacio *et al.*, 1999). Cairns *et al.* (2000) estimates fuel consumption and coal emission in tropical Mexico for those events. The land-use/land-cover classes most extensively impacted were evergreen tropical forests and fragmented forests. They point out that similar fire events may be expected more frequently in the future if global

change shifts toward a warmer and drier climate. The atmospheric consequences of those events were continuous emission of smoke to the United States for a large period of time (Wright, 1999). The costs from droughts and forest fires in Mexico and Central America during El Niño were approximately US\$600 million.

The effects of a strong El Niño event on terrestrial ecosystems of Peru and Ecuador are as relevant (with high possibility) as in the ocean and shores (Arntz and Fahrbach, 1996). Increases in precipitation were recorded in Ecuador, Colombia, and northern Peru during the 1982–1983 El Niño event, with a simultaneous decrease in rainfall southward. Increases in precipitation also were recorded during the 1941 El Niño event. However, the increase in rainfall should not be assumed to be homogeneous. Whereas significant increases have been recorded in northern Peru, Ecuador, and even Colombia, severe droughts occurred around the Titicaca region and in northern Chile. In the highlands of the Andes as well, a north-south gradient in rainfall has been observed during El Niño events.

Increases in precipitation during El Niño events result in enhanced vegetation cover (from 5 to 89%) and primary productivity (from 0.005 to 3.5 t yr⁻¹) in coastal desert ecosystems. In northern Peru, strong El Niño events increase not only the ephemeral vegetation but also seed germination and seedling recruitment of woody species. Increases in precipitation from 20 mm (1996) to more than 1,000 mm (December 1997 to May 1998) have been recorded in Belizario in northern Peru. This increase in rainfall was correlated with a significant increase in annual NPP of the herb layer in a dry *Prosopis pallida* woodland, from almost zero in December 1997 to 0.51 g⁻² yr⁻¹ in February 1998. In the same region, the annual NPP of the shrub and tree layers also were significantly higher during the El Niño event, but fruit productivity decreased as a result of the mechanic effect of rain drops on buds, flowers, and immature fruits. Demographic explosions of two land snails were observed (Torres Guevara, 1992) during the increase in vegetation cover and annual NPP in northern Peru during 1998.

Besides the foregoing observations, little information has been reported about the explosive development of plant cover during strong El Niño events. Moreover, no data are available about the way in which this enhanced annual NPP impacts wildlife and range activities. According to Arntz and Fahrbach (1996), however, during this vegetation "explosion," insects, snails, and other invertebrates increase in number and diversity. Consequently, vertebrates such as rodents, birds, and foxes benefit from a diversified and enriched diet. Observational studies confirm a significant increase in the density of rodents (Muridae and Cricetidae), followed by an increase in the activity of foxes (*Dusicyon culpaeus*). The considerable increase in the density of insects and rodent populations has a direct impact on agriculture. Damage associated with the incidence of pests on crops is further aggravated by the occurrence of floods.

Extraordinarily strong precipitation during El Niño events is not restricted to the continent. The Galápagos Islands also were affected by increased rainfall during 1983. As in continental

ecosystems, enhanced annual NPP had direct consequences on the densities of species in higher trophic levels (Taraazona and Valle, 1999).

As a consequence of the unusual combination of climatic and meteorological conditions attributed to the El Niño before and after the winter of 1997–1998, fires had a particularly strong effect on forests in Mexico. The number of fires was twice the average for the period 1992–1997 and 35% higher than the historical high mark recorded in 1988. The area affected was three times larger than the average for the same period (Barkin and García, 1999). Economic losses from those fires were estimated to be about US\$230 million (Delgadillo *et al.*, 1999). Following the increase in rainfall associated with the strong El Niño event in 1982–1983, the next 2 years were exceptionally dry and cold in the Galápagos. Most of the plant biomass produced during the rainy years died back and accumulated as a result of the low decomposition rate. This increase in dry biomass is directly associated with the occurrence of fires affecting large areas. Recovery of plant cover after fires has been different in grasslands and woody vegetation. Whereas species diversity in grasslands has increased, fires had dramatic effects on woody vegetation because many trees and shrubs were severely affected by underground fires (Arntz and Fahrbach, 1996).

Scenarios of climate change for Latin America mountain areas are highly uncertain because available GCMs do not provide sufficiently accurate local predictions. Glacial retreat is underway in various parts of the Andes and in the ice fields at the southern tip of the continent (Canziani *et al.*, 1998). Shifting of ecosystems upslope is expected to result in loss of some vegetation types and increased vulnerability to genetic and environmental pressures.

14.2.1.5. Biodiversity

Latin America is known as home to some of the Earth's greatest concentrations of biodiversity (Heywood and Watson, 1995; Harcourt and Sayer, 1996). Seven of the world's most diverse and threatened areas are in Latin America and the Caribbean (Myers *et al.*, 2000). Of these, three rank among the world's five most critical hotspots. The tropical Andes qualifies as one of the world's two hyper-hot areas for its exceptional numbers of endemic plants and endemic vertebrates—the highest in the world. Maintenance of this diversity depends on the continued existence of representative areas of natural ecosystems (Fearnside and Ferraz, 1995; Fearnside, 1999). Dinerstein *et al.* (1995) have divided Latin America into 191 terrestrial “ecoregions” and collated information on the biodiversity importance and degree of risk of each in a systematic fashion to establish priorities for conservation. Many ecosystems already are at risk, without additional stresses expected from climatic change: 48% of all ecoregions are critical (18%) or endangered (30%); 32% are vulnerable, 16% are relatively stable, and 5% are relatively intact. Ecuador holds the distinction of being wholly covered by ecoregions with top priority at the regional level. The

impacts of climate change can be expected to increase the risk of biodiversity loss in Latin America.

Central America has about 8% of the world's biodiversity concentrated in only 0.4% of the emerged surface of the planet. More than 15,000 species of plants and 1,800 species of vertebrates have been identified in the region. There are high quantities and variety of coastal wetlands in Central America. Central America's unique location between the Pacific Ocean and the Caribbean Sea—along with extreme climatic variations, tidal patterns, and geology—make these coastal wetlands among the most productive in the world (Tabilo-Valdivieso, 1997).

In addition to the loss of genetic resources, loss of productivity, and loss of ecosystem buffering against ecological perturbation, loss of biodiversity also may alter or impair the services that ecosystems provide (Naeem *et al.*, 1994). For a 2xCO₂ scenario, surface relative humidity zones shift upward by hundreds of meters during the winter dry season, when these forests typically rely mostly on moisture from cloud contact (Leo, 1995). At the same time, an increase in the warmth index implies increased evapotranspiration; this combination of reduced cloud contact and increased evapotranspiration could have serious conservation implications, as indicated in studies in anurans (Donnelly and Crump, 1998). The results of Pounds *et al.* (1999) indicate the association in populations of birds, lizards, and anurans with the same climatic patterns, implying a broad response to regional climate change. Other studies inspired by the climate-linked epidemic hypothesis have found that dry weather in 1983 increased the vulnerability of harlequin frogs (*Atelopus varius*) to lethal parasites along one stream (Crump and Pounds, 1985, 1989).

Suárez *et al.* (1999) have found that the coastal biodiversity (flora and fauna) in Cuba will be most affected by sea-level rise. Adaptation options include establishing a national legal system and a national strategy for conserving biodiversity that includes terrestrial, marine, or coastal reserves.

14.2.2. Agriculture and Plantation Forestry

14.2.2.1. Arable Farming and Tree Crops

Agricultural lands (excluding pastures) represent approximately 19% of the land area of Latin America. Over the past 40 years, the contribution of agriculture to the GDP of Latin American countries has been on the order of 10%. Agriculture remains a key sector in the regional economy because it employs an important segment (30–40%) of the economically active population. It also is very important for the food security of the poorest sectors of the population.

Arable farming is based on annual crops of cereals (wheat, maize, barley, rice, oats), oil seeds (soybean, peanuts, sunflower), vegetables/tuberous roots (potatoes, cassava), and a variety of perennial grasses, including specialty crops such as cotton, tobacco, tea, coffee, cacao, sugarcane, and sugar beet. Major tree/shrub

crops include a large variety of fruits, oil palm, and others. This farm production has given rise to associated activities—such as beekeeping and bee products—as well as important agro-industries that produce valuable incomes in countries that already have developed their own markets and exporting lines.

Although the more important commercial agriculture and agro-industry businesses are well developed in a few countries, many Latin American economies rely on small farming system production. In smaller and poorer countries, such as rural communities in Central America and the Andean valleys and plateaus, agriculture is the basis of subsistence lifestyles and the largest user of human capital. For these countries, agriculture is the main producing sector; it undoubtedly is severely affected by climate variations and would be seriously influenced by climate change (Rosenzweig and Hillel, 1998).

Extremes in climate variability (e.g., the Southern Oscillation) already severely affects agriculture in Latin America. In southeastern South America, maize and soybean yields tend to be higher than normal during the warm Southern Oscillation and lower during the cold phase (Berlato and Fontana, 1997; Grondona *et al.*, 1997; Magrin *et al.*, 1998; Baethgen and Romero, 2000). Contributions to variability as a result of global warming and/or reduction in evapotranspiration from forest loss would be added to this background variability, thereby aggravating losses caused by extreme events.

Land-use choices will be affected by climate change. For example, increasing precipitation in marginal areas could contribute to an increase in cropped lands (Viglizzo *et al.*, 1995). On the other hand, more favorable prices for grain crops relative to those for cattle are causing an increase in cultivated lands (Basualdo, 1995). The continued global trend to replace subsistence with market crops also creates an increasing threat to soil sustainability and enhances vulnerability to climate change.

Global warming and CO₂ fertilization effects on agricultural yields vary by region and by crop. Under certain conditions, the positive physiological effects of CO₂ enrichment could be countered by temperature increases—leading to shortening of the growth season and changes in precipitation, with consequent reductions in crop yields. Reduced availability of water is expected to have negative effects on agriculture in Mexico (Mundo and Martínez-Austria, 1993; Conde *et al.*, 1997b). However, increases in temperature would benefit maize yields at high altitudes and lower the risk of frost damage (Morales and Magaña, 1999). Several studies were carried out in the region to assess the impact of climate change on annual crop yields. Most of these studies use crop simulation models with GCMs and incremental (temperature and precipitation) scenarios as climatic inputs. Baethgen and Magrin (1995) have shown that winter crop yields in Uruguay and Argentina are more sensitive to expected variations in temperature than precipitation. Under nonlimiting water and nutrient conditions and doubled-CO₂, the results for Argentina have shown that maize, wheat, and sunflower yield variations are inversely

related to temperature increments, whereas soybean would not be affected for temperature increments up to 3°C (Magrin *et al.*, 1997b, 1999a,b,c). Results obtained under rainfed conditions for different crops and management approaches in the region are summarized in Table 14-5; most of these results predict negative impacts, particularly for maize.

Adaptive measures to alleviate negative impacts have been assessed in the region. In Mexico, Conde *et al.* (1997a) found that increasing nitrogen fertilization would be the best option to increase maize yields, although it would not be economically feasible at all levels. In Argentina, the best option to improve wheat, maize, and sunflower yields would be to adjust planting dates to take advantage of the more favorable thermal conditions resulting from fewer late frosts (Travasso *et al.*, 1999). However, this adaptive measure would be insufficient for maintaining actual wheat and maize yield levels. Genetic improvement will be necessary to obtain cultivars that are better adapted to the new growing conditions. For wheat and barley crops in Uruguay and Argentina, a longer growth season could be achieved by increasing photoperiodical sensitivity (Hofstadter *et al.*, 1997; Travasso *et al.*, 1999).

Subsistence farming could be severely threatened in some parts of Latin America. The global agricultural model of Rosenzweig *et al.* (1993) identifies northeastern Brazil as suffering yield impacts that are among the most severe in the world (see Reilly *et al.*, 1996; Canziani *et al.*, 1998; Rosenzweig and Hillel, 1998). Because northeastern Brazil is home to more than 45 million people and is prone to periodic droughts and famines even in the absence of expected climate changes, any changes in this region would have major human consequences.

Climate changes can be expected to lead to changes in soil stocks of carbon and nitrogen. In the Argentinean pampas, chemical degradation of soils, based on climate changes predicted by the GISS GCM (Hansen *et al.*, 1988) at an atmospheric CO₂ concentration of 550 ppm, would reduce organic nitrogen by 6–10% and organic carbon by 7–20% in the topsoil as a result of lower dry-matter production and an increased mineralization rate (Díaz *et al.*, 1997).

Tree crops in locations where frost risk presents a limitation—such as coffee in Paraná, Brazil—benefit from higher minimum temperatures resulting from global warming (Marengo and Rogers, 2000).

14.2.2.2. Ranching

Ranching is a major land use in many parts of Latin America. In the three countries that dominate the region's agriculture and ranching sector (Brazil, Argentina, and Mexico), pastures occupy four to eight times more area than agriculture (Baethgen, 1997). In much of Latin America, livestock is almost exclusively raised on rangelands, with no storage of hay or other alternative feeds. Grass production in rangelands depends on rainfall, and limited grass availability during dry

periods limits cattle stocking rates over most of the region. In areas that are subject to prolonged droughts, such as northeastern Brazil and many rangeland areas in Mexico, production would be negatively affected by increased variability of precipitation from climate change. In the case of cattle in central Amazonia (*várzea*), higher peak flood stages would cause losses to cattle kept on platforms (*marombas*) during the high-water period.

In Argentina, some cattle are fed on alfalfa and other forage crops. A 1°C rise in temperature would increase alfalfa yields by 4–8% on average for most varieties, but yields would be reduced by 16–25% in areas north of 36°S and increased by 50–100% south of this latitude (Magrin *et al.*, 1997b).

14.2.2.3. Plantation Silviculture

Plantation forestry is a major land use in Brazil and is expected to expand substantially over coming decades (Fearnside, 1998). Climatic change can be expected to reduce silvicultural yields to the extent that the climate becomes drier in major plantation states such as Minas Gerais, Espírito Santo, São Paulo, and Paraná as a result of global warming and/or reduced water vapor transport from Amazonia (e.g., Eagleson, 1986). Dry-season changes can be expected to have the greatest impact on silvicultural yields. Water often limits growth during this part of the year under present conditions, yet there may be water to spare during the雨iest part of the year. In areas outside of

Table 14-5: Assessments of climate change impacts on annual crops in Latin America.

Study	Climate Scenario	Scope	Crop	Yield Impact (%)

Brazil's extreme south, annual rings that are evident in the wood of plantation trees correspond to dry (as opposed to cold) seasons.

The effect of precipitation changes on plantation yields can be approximated by using a regression equation developed by Ferraz (1993) that relates biomass increment in Eucalyptus to precipitation at three sites in the state of São Paulo (Fearnside, 1999). UKMO model results (Gates *et al.*, 1992) indicate that annual rainfall changes for regions of Brazil would cause yields to decrease by 6% in Amazonia and 8% in southern Brazil and increase by 4% in the northeast. During the June-July-August (JJA) rainfall period, yields would decrease by 12% in Amazonia, 14% in southern Brazil, and 21% in the northeast (Fearnside, 1999).

The foregoing discussion of precipitation decreases considers only the effect of global warming. Brazil is likely to suffer additional losses of precipitation as a result of reductions in evapotranspiration caused by deforestation in Amazonia (see Section 14.5.1.1.1). Some of the water vapor originating in Amazonia is transported to southern Brazil (Salati and Vose, 1984; Eagleson, 1986). Decreased water vapor supply to southern Brazil, where most of the country's silviculture is located, would aggravate precipitation declines stemming from global warming.

The direct effects of rainfall reduction on yields are likely to underestimate the true effect of climate change. Synergistic effects with other factors could reduce yield substantially more—for example, through attack by pests (Cammell and Knight, 1992).

Adrier climate in plantation areas also could be expected to lead to greater fire hazard. Fire is a problem in plantation silviculture even in the absence of climatic change, requiring a certain level of investment in fire control and a certain level of losses when burns occur. Pine plantations in Paraná require continuous vigilance (Soares, 1990). Eucalyptus also is fire-prone because of the high content of volatile oils in the leaves and bark.

Temperature changes can affect plantation yields. The models reviewed in the IPCC's Second Assessment Report (SAR) indicate a temperature increase of 2–3°C in Amazonia (Mitchell *et al.*, 1995; Kattenberg *et al.*, 1996). Considering a hypothetical increase of 1.5°C by the year 2050 in Espírito Santo and Minas Gerais, Reis *et al.* (1994) conclude that the present plantation area would have to be moved to a higher elevation (a shift that is considered impractical) or the genetic material would have to be completely replaced, following the global strategy proposed by Ledig and Kitzmiller (1992). In addition to direct effects of temperature considered by Reis *et al.* (1994), temperature increases have a synergistic effect with drought; the impact of dryness is worse at higher temperatures (lower elevations) as a result of higher water demands in plantations.

CO₂ enrichment would be beneficial for plantations. Higher atmospheric concentrations of CO₂ increase the water-use efficiency (WUE) of Eucalyptus. Photosynthetic rate increased

in these experiments from 96% (*E. urophylla*) to 134% (*E. grandis*). Growth of different plant parts showed similar responses. Higher levels of CO₂ also stimulate nitrogen fixation, which could be expected to lower the fertilizer demands of plantations (Hall *et al.*, 1992).

Climatic change would require larger areas of plantations (and consequently greater expense) to meet the same levels of demand. The percentage increase in areas required can be greater than the percentage decline in per-hectare yields caused by climatic change because expansion of plantation area implies moving onto progressively poorer sites where productivity will be lower. Taking as examples rainfall reductions of 5, 10, 25, and 50%, plantation area requirements are calculated to increase as much as 38% over those without climatic change, which would bring the total plantation area by 2050 to 4.5 times the 1991 area (Fearnside, 1999).

14.2.3. Sea-Level Rise

14.2.3.1. General Impacts

Information on areas of land loss in several countries of Latin America as a result of sea-level rise is synthesized in Table 6-5 of the IPCC *Special Report on Regional Impacts of Climate Change* (IPCC, 1998). Fishing production is a sector that would suffer as a consequence of sea-level rise. Along the Central American coastline, sea-level rise will affect infrastructure, agriculture, and natural resources, as well as potentially exacerbate coastal erosion and salinization of aquifers and increase flood risks and the impact of severe storms (Campos *et al.*, 1997; MINAE-IMN, 2000).

Chapter 6 of the Special Report identified information on the economic cost of sea-level rise in Latin America as assessed by Saizar (1997) and Olivo (1997) for the Uruguayan and Venezuelan coastlines, respectively. Saizar (1997) assessed the potential impacts of a 0.5-m sea-level rise on the coast of Montevideo (Uruguay). Given no adaptive response, the cost of such a rise in sea level was estimated to be US\$23 million, with a shoreline recession of 56 m and land loss of 6.8 ha. Olivo (1997) studied the potential economic impacts of a 0.5-m sea-level rise on the coast of Venezuela. At six study sites, she identified land and infrastructure at risk—such as oil infrastructure, urban areas, and tourist infrastructure. Evaluating four scenarios, Olivo (1997) suggests that Venezuela cannot afford the costs of sea-level rise, either in terms of land and infrastructure lost under a no-protection policy or in terms of the costs involved in any of three protection policies.

Coastal wetlands in the region endure the impact of population growth, expansion of the agricultural activity, and land-use changes.

Observed sea-level rise at the local or regional level in Latin America could be greater than the global average value (Field, 1995; Codignotto, 1997; Kjerve and Macintosh, 1997). Negative

trends in river streamflow along the Patagonian coast may result in reduction of sediments toward deposition areas. Coastal erosion would be affected by this effect as well as increased sea level (Codignotto, 1997; Kokot, 1999).

14.2.3.1.1. Mangrove ecosystem

The response of mangrove forests to changes in sea level within 50–100 years under climate change conditions is complex and controversial; it depends on physiography as well as ecological and biological factors (Villamizar, 1994; Ellison and Farnsworth, 1996; Ewel and Twilley, 1998; Rull *et al.*, 1999).

The land-building function of mangrove vegetation has very important implications in coastal management because it works as a natural barrier to protect adjacent agricultural land by reducing erosion caused by wave action, tides, and river flow. This is important for shallow estuaries that are prone to flooding, especially where the land is below sea level (Twilley *et al.*, 1997; Villamizar and Fonseca, 1999).

In the tropical Americas, the loss of coastal forests, mainly mangroves, occurs at a rate of approximately 1% yr⁻¹. The rate is much faster in the Caribbean—approximately 1.7% yr⁻¹ (Ellison and Farnsworth, 1997). Because most commercial shellfish and finfish use mangal for nurseries and refuge, fisheries in mangrove regions are declining at a similar rate as mangrove communities (Martínez *et al.*, 1995; Ewel and Twilley, 1998).

14.2.3.1.2. Coral reefs

The second largest coral reef system in the world dominates the offshore area of the western Caribbean (Milliman, 1993), and all but the northern Gulf coast have extensive reef systems. Growth of individual coral organisms is estimated to be 1–20 cm yr⁻¹ (Vicent *et al.*, 1993), and reef growth rates as a whole are known to be up to 1.5 cm yr⁻¹ (Hendry, 1993). Reefs that accumulate at these rates could keep pace with a sea-level rise of 20 cm by 2025 (UNEP, 1993) if other factors do not alter growth conditions.

Accurate predictions on the effect of sea-level rise may be possible in reefs that already have been physically and biologically monitored, such as in Panama, Jamaica, Puerto Rico, and Belize (UNEP, 1993; Gischler and Hudson, 1998).

14.2.3.1.3. Socioeconomic issues

Latin America coastal zones with economies that are based in fishing and tourism are particularly vulnerable to physical changes associated with sea-level rise.

Tourism is one of the most important industries in the region, especially in the Caribbean. Shoreline migration will create

new areas of economic opportunity as new beaches are built, but protection, replenishment, and stabilization of existing beaches represents a principal socioeconomic impact. It is difficult to separate the impact of climate-induced sea-level rise from erosion associated with the persistent interaction of the sea on the coast. In addition, certain sand-mining practices (such as in Trinidad and Tobago) already have important effects on the ecosystem. Indirect socioeconomic effects on tourism from increasing pollution, coral reef mortality, and storm damage also are involved (UNEP, 1993).

Latin American economies could be severely affected by climate change. Coastal wetlands in Central America could generate US\$750 million. Shrimp fisheries at the *Estero Real* in Nicaragua, which could provide US\$60 million annually to the economy of the country, and the Gulf of Fonseca—which supplies important fishing, firewood, and transport to the rural communities of El Salvador, Honduras, and Nicaragua—could be affected by sea-level rise (Quesada and Jiménez, 1988).

Socioeconomic issues in the context of local response to global change—such as tourism, settlements and structures, and cultural heritage—and the influence of tropical storms are considered most important regarding levels of vulnerability (Mainardi, 1996; Tabilo-Baldivieso, 1997; Windovoxhel *et al.*, 1998). Approximately 1,600 km of coral reefs and 870 km of mangroves are located in the region of Central America (Tabilo-Valdivieso, 1997). More than 15,000 species of plants and 800 species of vertebrates identified in the region would be at risk from sea-level rise, along with resources for rural communities (about 450,000 people) that inhabit the coastal areas of Central America (Windovoxhel *et al.*, 1998).

14.2.3.2. Ecological and Local Community Values

Many local communities depend on coastal wetlands for survival; they use a wide range of natural products from the swamps and their surrounding waters (Field, 1997; RAMSAR, 1999). As Section 6.5.4 points out, in some coastal societies, cultural values are of equal—or even greater—significance than economic values. This is particularly true in Ecuador and Colombia on the Pacific coast, as well as the most northern part of Venezuela and Brazil on the Atlantic coast, where shrimp farming and timber exploitation represent the most common uses (Schaeffer-Novelli and Cintron, 1993; Sebastiani *et al.*, 1996; Trujillo, 1998). Girot (1991) identifies the landscape and the aesthetics and spirituality of local people as important social and cultural impacts in the Central American region. An increase in sea level could affect monuments and historic sites of Central America.

Patterns of human development and social organization in a community are important factors in determining the vulnerability of people and social institutions to sea-level rise and other coastal hazards. The most common problems in local subsistence economies in Latin America coastal zones relate to firewood, isolation from enforcement, shrimp ponds, cattle, clearing for

village expansion, coconut plantation, and sewage and garbage disposal (Sebastiani *et al.*, 1996; Ellison and Fansworth, 1997).

14.2.4. Water Resources: Availability and Use

Water resources for domestic, industrial, and agricultural use, averaged per capita among Latin American countries, vary from 28,739 m³ in Argentina (whose population is 34,587,000) to more than 472,813 m³ in Suriname (whose population is 423,000) (see Appendix D of IPCC, 1998). These averages hide the enormous disparity in many areas, such as poor rural areas, which are ill-supplied. In some Latin American regions—especially in areas where it is possible that the combined effect of less rainfall and more evaporation could take place, leading to less runoff—global warming will substantially change the availability of freshwater. Watersheds in arid or semi-arid regions are especially sensitive because annual runoff already is highly variable (Medeiros, 1994). Watersheds in the southern hemisphere where snowmelt is an important source of runoff also can be severely affected (Basso, 1997). Vulnerability of oases between 29°S and 36°S to drier conditions in the high Andes can be observed (Canziani *et al.*, 1997).

Few specific water resources impact studies using climate change scenarios have been conducted in Latin America: Riebsame *et al.* (1995) studied the Uruguay River basin. In the study, all scenarios used indicated a shift of seasonality and a decrease in runoff during low-flow periods. For the Choqueyapu River (La Paz, Bolivia) under a UKMO-89 climate scenario, these studies projected an increase of discharge in the low-water period and in the months of December and January. For some other watersheds (Caire, Mamoré, Guadalquivir, and Miguillas), the magnitude and tendency of the results varies, depending on the scenario used (PNCC, 1997). For the Pirai River, located in a humid area and flowing through urban areas (Santa Cruz City), runoff increases under an increased precipitation scenario (PNCC, 2000). Estimates of water availability in Mexico and Central America (Izmailova and Moiseenko, 1998) indicate that about 70% of the population in those countries will live in regions with low water supply as soon as the first quarter of the 21st century. A study using climate scenarios from GFDL, GISS, and NCAR models, combined with incremental scenarios of 1–2°C temperature rise and 10% precipitation increase, found that decreasing precipitation in Mexico and El Salvador can cause a change in runoff by 5–7% but that in the winter runoff changes by only 0.2–0.7%.

Potential changes in temperature and precipitation might have a dramatic impact on the pattern and magnitude of runoff, soil moisture, and evaporation, as well as the aridity level of some hydrological zones in Mexico (Mendoza *et al.*, 1997). A vulnerability study performed in conjunction with the National GHG Inventory in Argentina foresees a reduction in water availability as a result of changes in snowmelt in the high Andes. Similar studies in Peru show that warming has created several environmental hazards, such as avalanches in Peruvian Andean valleys, with a foreseen critical reduction of water

resources for human and industrial consumption (Morales-Arnao, 1999).

Water use in Latin America is mainly for agricultural activities, averaging nearly 60% of total water use. It ranges from approximately 40% in Colombia and Venezuela to more than 75% in Argentina, Bolivia, Costa Rica, El Salvador, Ecuador, Guatemala, Honduras, Mexico, Panama, Paraguay, Suriname, and Uruguay (Canziani *et al.*, 1998). Even with a potential increase in water availability in some parts of northern Mexico (Mundo and Martínez-Austria, 1993; Magaña and Conde, 1998), demand for water from agricultural, urban, and industrial sectors has shown a much faster growth because of the rapid expansion of these sectors in recent decades.

Some hydrological scenarios for Cuba (Planos and Barros, 1999) show that a significant limitation of potential water resources will occur within the next century as a result of increments in evapotranspiration and changes in precipitation.

14.2.5. Human Health

Health impacts from climate change can arise via complex processes. The scale of these effects would depend primarily on the size, density, and wealth of human populations or communities (WHO, 1998). Extreme weather variability associated with climate change may add new stress to developing nations that already are vulnerable as a result of environmental degradation, resource depletion, overpopulation, or location (McMichael *et al.*, 1996).

Persistent poverty and population pressure accompanied by inadequate sanitation and inadequate public health infrastructure will limit many populations' capacity to adapt (Kovats *et al.*, 1998; Patz, 1998). Interaction between local environmental degradation and changes on a larger scale—climate change, population growth, and loss of biodiversity—may significantly influence effects on health (Haines and McMichael, 1997; WHO, 1998). The direct impacts of climate change depend mainly on exposure to heat or cold waves or extreme weather events, such as floods and droughts.

14.2.5.1. Effects of Changes in Climate Variables on Health

Kattenberg *et al.* (1996) made generalized tentative assessments concerning extreme weather and climate events. Studies in temperate and subtropical countries have shown increases in daily death rates associated with extreme outdoor temperatures (see Section 14.1.5; McMichael *et al.*, 1996). Climate change scenarios constructed from three models have been used to estimate human mortality with changes in baseline climate conditions for Buenos Aires, Caracas, San José, and Santiago. In Caracas and San José, where present temperatures are close to the comfort temperature for all months, mortality rates (total, cardiovascular, and respiratory) increase for most of the climate change scenarios employed. However, decreases in

winter mortality may offset excess summer mortality in cities with relatively colder climates, such as Santiago (Martens, 1998). People who are more than 65 years old are more temperature sensitive than younger people (Martens, 1998).

There is evidence that people living in poor housing conditions (crowded and poorly ventilated) and urban populations in developing countries are particularly vulnerable to thermal stress enhanced by rapid urbanization (urban heat island) because of few social resources and low preexisting health status (Kilbourne, 1989; Martens, 1998). Furthermore, in rural areas, the relative importance of temperature on mortality may be different from its effect on urban populations (Martens, 1998).

Prolonged heat can enhance production of smog and dispersal of allergens. Both effects have been linked to respiratory symptoms (Epstein, 2000). High temperatures and air pollutants, especially particulates, act synergistically to influence human health. This effect is occurring in large cities, such as Mexico City, Santiago, and more recently Buenos Aires, where such conditions enhance the formation of secondary pollutants (e.g., ozone—Escudero, 1990; Katsouyanni *et al.*, 1993; Canziani, 1994). Saldivia (1994, 1995) has observed an increasing trend in the mortality of elderly people following peaks of air pollution in São Paulo. Daily mortality has been correlated mainly with temperature and ozone concentration, both measured the day before (Sartor *et al.*, 1995). Hyperthermic syndrome (heat stroke) affected children under 2 years old and people over 80 in Peru's coastal regions during the high temperatures of the El Niño phenomenon (Instituto Nacional de Salud, 1998a, 1999).

During droughts, the risk of wildfires increases, causing loss of green areas, property, livestock, and human life, as a result of increasing air pollution from suspended particles (OPS, 1998). The direct effects of wildfires on human health occur from burns and smoke inhalation (Kovats *et al.*, 1999). In *Alta Floresta*, Brazil, there was a 20-fold increase in outpatient visits for respiratory disease in 1997 during a biomass smoke episode (Brauer, 1998).

Increased ambient temperature may have significant effects on the distribution and overgrowth of allergenic plants. Higher temperatures and lower rainfall at the time of pollen dispersal are likely to result in higher concentrations of airborne pollen during the peak season (Emberlin, 1994; Rosas *et al.*, 1989). A relationship between concentrations of algae and weather parameters (temperature and vapor pressure) in Mexico has been correlated. Dispersion of algae has received much attention during recent years as a result of associated inhalant allergies and other respiratory disorders (Rosas *et al.*, 1989). The high degree of seasonality (dry-rainy season) in air-borne enteric bacterial, basidiomycete spore, particle, and protein concentrations also could be associated with temperature and vapor pressure in Mexico City (Rosas *et al.*, 1994, 1995; Calderón *et al.*, 1995). Thus, future changes in climatic variables might have an important effect in the distribution of air-borne bacteria, fungus, pollen, particles, and proteins whose allergenic properties have to be considered.

In 1998, there was an increase in cholera cases in Peru and Ecuador and other countries affected by weather disasters. Hurricane Mitch affected Guatemala (the number of cholera cases increased four-fold), Belize, and Nicaragua (the number of cholera cases was six times the usual number of reported cases) (OPS, 1999).

Global warming could increase the number and severity of extreme weather events, such as storms, floods, droughts, and hurricanes, along with related landslides and wildfires (IPCC, 1996). Such events tend to increase death and disease rates—directly through injuries or indirectly through infectious diseases brought about by damage to agriculture and sanitary infrastructure and potable water supplies (PAHO, 1998a). Floods and droughts could permanently or semi-permanently displace entire populations in developing countries, leading to overcrowding and diseases connected with it, such as tuberculosis and other air-borne and crowd diseases; adverse psychological effects; and other stresses (IPCC, 1996; McMichael and Kovats, 1998a,b; Epstein, 2000). Slums and shantytowns located on hills (e.g., Rio de Janeiro), as well as human settlements located in flood-prone areas, are particularly subject to periodic natural disasters that adversely affect human health and sanitary infrastructure (IPCC, 1996).

In developing countries, populations are becoming more rather than less vulnerable to disasters (McMichael and Kovats, 1998b). Natural disasters may be responsible for outbreaks of cholera, leptospirosis, malaria, and dengue (Moreira, 1986; PAHO, 1998a,b). Hurricane Mitch stalled over Central America in October 1998 for 3 days, claiming 11,000 lives. It was the most deadly hurricane to strike the western hemisphere in 2 centuries (Hellin *et al.*, 1999). After Mitch, Honduras reported thousands of cases of cholera, malaria, and dengue fever (PAHO, 1998a,b; OPS, 1999; Epstein, 2000). As the risk of flooding increases with climate change, so does the importance of the major drainage system, which will determine whether floodwaters drain in minutes, hours, or days (McMichael and Kovats, 1998b). Floodwaters can cause the release of dangerous chemicals from storage and waste disposal sites and precipitate outbreaks of vector- and water-borne diseases (Patz, 1998).

Indirect effects of disasters can damage the health care sector. After Hurricane Mitch, some countries in Central America regressed decades in health services and transport infrastructure, thereby making it more difficult to assist the affected population (OPS, 1999). Environmental refugees could present the most serious health consequences of climate change. Risks that stem from overcrowding include virtually absent sanitation; scarcity of shelter, food, and safe water; and heightened tensions—potentially leading to social conflicts (Patz, 1998). Weather disasters cause many deaths and have long-term impacts on communities, including psychological effects such as post-traumatic stress disorder (Kovats *et al.*, 1998). In 1999, heavy rains on the coast of Venezuela displaced 80,000–100,000 people and caused 20,000–50,000 deaths, as well as enormous damage in infrastructure (PNUD/CAF, 2000).

14.2.5.2. Vector-Borne Diseases

Arthropod vector organisms for vector-borne diseases (VBDs) are sensitive to climatic and hydrometeorological conditions (especially temperature and humidity, stagnant water pools, and ponds), as are life-cycle stages of the infecting parasite within the vector (Bradley, 1993; Haines *et al.*, 1993; Curto de Casas *et al.*, 1994; Ando *et al.*, 1998). Hence, the geographic range of potential transmission of VBDs may change under conditions of climate change (Leaf, 1989; Shope, 1991; Carcavallo and Curto de Casas, 1996; McMichael *et al.*, 1996; Patz *et al.*, 1996; WHO, 1998). Several studies have concluded that temperature affects the major components of vectorial capacity (Carcavallo *et al.*, 1998; Carcavallo, 1999; Moreno and Carcavallo, 1999).

Mosquitoes, in particular, are highly sensitive to climatic factors (Curto de Casas and Carcavallo, 1995). *Anophelis spp.* and *Aedes aegypti* mosquitoes have established temperature thresholds for survival, and there are temperature-dependent incubation periods for the parasites and viruses within them (the extrinsic incubation period) (Curto de Casas and Carcavallo, 1995; de Garín and Bejarán, 1998a,b; Epstein *et al.*, 1998; de Garín *et al.*, 2000). Climate change may influence the population dynamics of vectors for Chagas' disease (Burgos *et al.*, 1994), as well as the number of blood-feedings of mosquitoes and, therefore, the possibilities of infective direct contacts (Catalá, 1991; Catalá *et al.*, 1992).

Of relevance to infectious disease distribution, minimum temperatures are now increasing at a disproportionate rate compared to average and maximum temperature (Karl *et al.*, 1995). Such conditions may allow dengue and other climate-sensitive VBDs to extend into regions that previously have been free of disease or exacerbate transmission in endemic parts of the world. Temperature is one of the factors that can influence the seasonal transmission of malaria. Near the equator in Iquitos, Peru, seasonality in transmission is driven by small temperature fluctuation (1–2°C) (Patz *et al.*, 1998). The current and projected expansion of the range of vector species into the subtropics and to higher elevations warrant heightened entomological and epidemiological surveillance and control in highland areas and for populations living on the fringes of regions that now are affected (Epstein *et al.*, 1998).

Reemergence of dengue fever in Colombia followed reinvasion of the country by the principal mosquito vector (*Aedes aegypti*), and the disease hit with large upsurges following periods of heavy rain (Epstein *et al.*, 1995). The mosquito vector for dengue and yellow fever has been reported at an elevation of 2,200 m in Colombia (Suárez and Nelson, 1981).

Climate variability, environmental change, and lack of control of vector reproduction already have affected the distribution of VBDs. In Honduras, a sustained increase in ambient temperature makes the southern part too hot for anopheline mosquitoes, and reported cases of malaria have dropped off. Large areas of northeast tropical rainforest have been cleared,

and migrants concentrated there tend not to be immune to malaria (Almendares *et al.*, 1993).

14.2.5.3. Water-Borne Diseases

Extremes of the hydrological cycle, such as water shortages and flooding, could worsen the diarrhea disease problem. In developing countries, water shortages cause diarrhea through poor hygiene. On the other extreme, flooding can contaminate drinking water from watershed runoff or sewage overflow (Patz, 1998). Depending on the disease agent and its transmission maintenance cycle, the effect may be an increase or a decrease in the incidence of infectious diseases (Gubler, 1998).

Between the first case of the current cholera outbreak—reported in Peru in 1991—and December 1996, cholera spread to more than 21 countries, resulting in almost 200,000 cases and more than 11,700 reported deaths (OPS, 1998). Colwell and Huq (1994) have collected data in Bangladesh and Peru suggesting that cholera has a complex route of transmission that is influenced by climate—in particular, SST and sea-level variations (Lobitz *et al.*, 2000). It has been suggested that the spread of *Vibrio cholerae* may be related to the development of various algae and zooplankton. Extensive studies during the past 25 years confirming the hypothesis that *V. cholerae* is autochthonous to the aquatic environment and is a commensal of zooplankton (i.e., copepods), combined with the findings of satellite data analyses, provide strong evidence that cholera epidemics are climate-linked (Lobitz *et al.*, 2000). Increased coastal algae blooms (which are sensitive to changes in climatic conditions) therefore may amplify *V. cholerae* and enhance transmission (Epstein, 2000). Furthermore, *V. cholerae* follows a salinity gradient, which might bring the disease to new shores if sea level rises (WHO, 1998).

In 1998, Ecuador's vulnerability to cholera increased as a result of climatic phenomena (OPS, 1999). In 1997–1998 in Peru, the same areas affected by climatic phenomena showed an increase in cholera cases, probably as a result of floods, problems with drainage, and food contamination in shelters (OPS, 1999). In Peru, persistence in transmission of diarrheal diseases such as *Salmonella typhi* and cholera was related to changes in environmental, climatic, and sanitary conditions (Carrillo, 1991a,b).

Floods foster fungal growth and provide new breeding sites for mosquitoes, whereas droughts concentrate microorganisms and encourage aphids, locusts, and whiteflies and—when interrupted by sudden rains—may spur explosions of rodent populations (Epstein and Chikwenhere, 1994).

The first recorded outbreak of Weil's disease (leptospirosis) in Colombia occurred mainly in children from poor neighborhoods. Symptoms of leptospirosis are similar to those of dengue, and the former can be fatal rapidly in patients not receiving proper treatment. The probable agents and disease seem to be linked with rodents escaping from floods (Epstein *et al.*, 1995).

In Cuba, acute diarrheal diseases occur more often during the warm and rainy period, when ecological conditions are favorable for reproduction of bacteria, viruses, and protozoa. Acute respiratory infection reports diminish after climatic conditions become warmer, more humid, and thermally less contrasting (Ortiz *et al.*, 1998). In Mexico, some rain in semi-arid zones has caused bubonic plague outbreaks (Parmenter *et al.*, 1999).

14.2.5.4. Effects of El Niño Phenomenon on Health

There is good evidence that the ENSO cycle is associated with increased risk of certain diseases (PAHO, 1998b). ENSO events may affect the distribution (reproduction and mortality) of disease vectors (Epstein *et al.*, 1998). El Niño events raise SST over the tropical Pacific, affecting some pathogenic agents. McMichael and Kovats (1998b), Patz (1998), and Instituto Nacional de Salud (1998a,b) have speculated that the last cholera outbreak in Peru, beginning in 1991, was linked with an El Niño phenomenon (1990–1995). The outbreak spread to most of the South American subcontinent, including places as far away as Buenos Aires (OPS, 1999). de Garín *et al.* (2000) have reported that El Niño has important impacts in andean population; they found large amounts of the insect, as well as eggs for the next period, in the northern part of Argentina.

Higher temperatures over coastal Peru associated with ENSO may have an impact on gastrointestinal infections. Salmonella infections increased after a flood in Bolivia, which resulted from the El Niño event of 1983 (Valencia Tellería, 1986). Salazar-Lindo *et al.* (1997) report that the number of patients with diarrhea and dehydration admitted to a rehydration unit in Lima, Peru, was 25% higher than usual during 1997, when temperatures were higher than normal as a result of the emerging El Niño. Increases in the incidence of acute diarrheas and acute respiratory diseases were recorded in Bolivia (Valencia Tellería, 1986) and Peru (Gueri *et al.*, 1986).

The effects of natural events vary by region, and the same weather condition may have the opposite effect in different areas for the same disease (e.g., a dry year may induce malaria epidemics in humid regions but cause malaria decreases in arid regions) (McMichael and Kovats, 1998b). For example, ENSO has been associated with severe drought in Iquitos, Peru, and the state of Roraima, Brazil, where malaria cases have drastically decreased (OPS, 1998; Confalonieri and Costa-Díaz, 2000). In Venezuela, malaria mortality has been shown to be more strongly related to the occurrence of drought in the year preceding outbreaks than to rainfall during epidemic years (Bouma and Dye, 1997). The El Niño phenomenon appears to be responsible in particular for serious epidemics in Peru, including one of malaria in 1983 (Moreira, 1986; Russac, 1986; Valencia Tellería, 1986), as well as cutaneous diseases, leptospirosis, and respiratory infections in 1998 (Instituto Nacional de Salud, 1998b). Compared with other years, malaria cases in Colombia increased 17.3% during an El Niño year and 35.1% in the post-El Niño year. Upsurges of malaria in Colombia during El Niño events are associated with its hydrometeorological variables—in particular, the increase

in air temperature that enhances reproductive and biting rates and decreases the extrinsic incubation period, as well as changes in precipitation rates that favor formation of ponds and stagnant pools and thus create more mosquito breeding sites (Poveda and Rojas, 1997; Poveda *et al.*, 1999a,b).

Global analyses have shown no association between ENSO and the number of flood disasters (Dilley and Heyman, 1995) or between ENSO and the numbers of persons affected by floods and landslides (Bouma *et al.*, 1997). However, the number of persons affected by landslides, particularly in South America, increases in the year after the onset of El Niño (Bouma *et al.*, 1997). In 1983, the impacts of El Niño in Peru increased total mortality by nearly 40% and infant mortality by 103% (Toledo-Tito, 1997).

Predicting malaria risk associated with ENSO and related climate variables may serve as a short-term analog for predicting longer term effects posed by global climate change. The ability to predict years of high and low risk for malaria can be used to improve preventive measures (Bouma *et al.*, 1997).

14.2.5.5. Effects on Food Production and Safety

Climate change would affect human health indirectly by threatening food production, as a result of increased temperature, ultraviolet irradiation, sea-level rise, changes in pest ecology, ecological disruption in agricultural areas as a result of disasters, and socioeconomic shifts in land-use practices (Rosenzweig *et al.*, 1993; Siqueira *et al.*, 1994; Reilly *et al.*, 1996; Haines and McMichael, 1997; Magrin *et al.*, 1997c; Epstein *et al.*, 1998). A link between El Niño and variation of the inter-tropical convergence zone and drought in northeastern Brazil has been described for many years (Hastenrath and Heller, 1977). Periodic occurrences of severe droughts associated with El Niño in this agriculturally rich region have resulted in occasional famines (Kiladis and Díaz, 1986; Hastenrath, 1995). Severe food shortages have occurred in this region in 1988 and 1998 (Kovats *et al.*, 1999).

Developing countries already struggle with large and growing populations, and malnutrition rates would be particularly vulnerable to changes in food production (Patz, 1998). Changes in the distribution of plant pests have implications for food safety. Ocean warming could increase the number of temperature-sensitive toxins produced by phytoplankton, causing contamination of seafood more often and an increased frequency of poisoning. The rapid spread of cholera along the Peruvian coasts and the fact that the *V. cholerae* O1 isolates involved constitute a separate genetic variant that could be a result of environmental change (Wachsmuth *et al.*, 1991, 1993)—as well as the ability of *V. cholerae* to survive in seawater and freshwater—make cholera a persistent health hazard (Tamplin and Carrillo, 1991). Thus, climate-induced changes in the production of aquatic pathogens and biotoxins may jeopardize seafood safety (IPCC, 1996). Increased ambient temperature has been associated with food poisoning; multiplication of pathogenic microorganisms

in food is strongly dependent on temperature (Colwell and Huq, 1994; Bentham and Langford, 1995; Patz, 1998). This indicates the importance of ambient conditions in the food production process, including animal husbandry and slaughtering, to avoid the adverse effects of a warmer climate.

In Argentina, the heavily populated Paraná Delta could be seriously affected by even small changes in sea level (Kovats *et al.*, 1998). The effects of sea-level rise may be counteracted by growing deltas as a result of the large amount of sediment coming down the Paraná and Uruguay Rivers from intense deforestation and consequential water erosion on the land of the upper basins.

Many glaciers and ice fields may soon disappear, potentially jeopardizing local water supplies that are critical for human consumption, regional agriculture, and hydroelectric power generation (Epstein *et al.*, 1998). There is high confidence in the effects of warming on glaciers, which already are disappearing

in Peru and decreasing in the high Andes between 29°S and 36°S (Canziani *et al.*, 1997).

Climate changes are expected to have the greatest effect on health in developing nations in Latin America that already have poor and weak infrastructures. Linkages between local public health and issues of climate change must continue to be considered so that prevention and response mechanisms can be implemented against disease and other threats to human health (Kovats *et al.*, 1998).

14.3. Synthesis

There is ample evidence of climate variability at a wide range of time scales all over Latin America, from intraseasonal to long term. For instance, at decadal scales, multiple climate records throughout the region consistently exhibit a shift in the mean during the mid-1970s, which could be a consequence of

Table 14-6: Variability and impacts of El Niño and La Niña on several Latin American countries and subregions.

Event	Climatic/Hydrological Variable	Subregion or Country	Reference(s)	Observation Period
El Niño ^a	Severe droughts ^b in recent decades	Mexico	Magaña and Conde, 2000	1958–1999 ^c
	Severe droughts	Northeast Brazil	Silva Dias and Marengo, 1999	1901–1997
	Decrease in precipitation	Central America (Pacific)	Magaña and Conde, 2000	1958–1999
	Increase in precipitation	Central America (Atlantic)	Magaña and Conde, 2000	1958–1999
	Decrease in precipitation, soil moisture, river streamflow	Colombia	Poveda and Mesa, 1997 Carvajal <i>et al.</i> , 1999 Poveda <i>et al.</i> , 2001	1958–1995 1957–1997 1958–1998
	Increase in precipitation and floods	Northwest Peru	Marengo <i>et al.</i> , 1998	1930–1998
	Decrease in precipitation during rainy season	Northern Amazonia and northeast Brazil	Aceituno, 1988; Richey <i>et al.</i> , 1989; Marengo, 1992; Uvo, 1998	1931–1998
	Negative large anomalies of rainfall during rainy season	Northeast Brazil	Silva Dias and Marengo, 1999 Hastenrath and Greischar, 1993 Nobre and Shukla, 1996	1930–1998 1912–1989 1849–1984
	Increase in precipitation during November–January time frame	Argentina (Pampas region)	Barros <i>et al.</i> , 1996; Tanco and Berry, 1996; Vila and Berri, 1996; Vila and Grondona, 1996; Magrin <i>et al.</i> , 1998	1900–1996
	Intense snowfalls in high Andes mountains	Central western Argentina and central Chile	Canziani <i>et al.</i> , 1997	1900–1995
	Increase in runoff	Chile and central western Argentina	Compagnucci <i>et al.</i> , 2000 Compagnucci and Vargas, 1998	1906–1994 1909–1998

sudden changes in the climatology of the Pacific Ocean. These changes have important socioeconomic and environmental consequences that could be enhanced by global warming and its associated climate change.

Precipitation changes in Latin America do not follow a consistent trend. In northwestern Mexico there is a clear tendency for more winter precipitation, which has resulted in positive trends in river-water level. In north and northwestern Nicaragua, there is a negative trend in rainfall. In the Amazonian region, the most important finding is the presence of periods with relatively wetter or drier conditions that are more relevant than any unidirectional trend. Rainfall in north-northeast Brazil exhibits a weak positive trend. Precipitation in subtropical Argentina, Paraguay, and Brazil increased abruptly in the 1956–1990 period after a dry period from 1921 to 1995. In the Pampas, there was a positive trend in precipitation over the 1890–1984 period. At higher elevations in northwestern Argentina, records suggest an increase in precipitation over the past 200 years.

The Southern Oscillation is responsible for a large part of the climate variability at interannual scales in Latin America. The region is vulnerable to El Niño, with impacts varying across the continent. For example, El Niño is associated with dry conditions in northeast Brazil, northern Amazonia, the Peruvian-Bolivian Altiplano, and the Pacific coast of Central America, whereas southern Brazil and northwestern Peru exhibit anomalously wet conditions. Extensive studies of the Caribbean watersheds of Mexico and other countries show compelling evidence of more winter and less summer precipitation; in addition, the most severe droughts in Mexico in recent decades

have occurred during El Niño years. In Colombia, La Niña is associated with heavy precipitation and flooding, whereas El Niño is associated with negative anomalies in precipitation and river streamflow. Drought also occurs in southern Brazil during the positive phase of the Southern Oscillation. If El Niño or La Niña were to increase, Latin America would be exposed to these conditions more often (see Table 14-6).

Warming in high mountain regions could lead to disappearance of significant snow and ice surfaces, which could affect mountain sport and tourist activities. Because these areas contribute to river streamflow, it also would affect water availability for irrigation, hydropower generation, and navigation, which represent important sources of income for some economies. It has been well-established that glaciers in Latin America have receded in recent decades.

It is well-established that Latin America accounts for one of the Earth's largest concentrations of biodiversity, and the impacts of climate change can be expected to increase the risk of biodiversity loss. Some adverse impacts on species that can be related to regional climate change have been observed, such as population declines in frogs and small mammals in Central America. Maintenance of remaining Amazonian forest is threatened by the combination of human disturbance and decreased precipitation from evapotranspiration loss, global warming, and El Niño. Fire in standing forest has increased in frequency and scale in Amazonia as a result of greater accumulation of deadwood in the forest from logging activity and from trees killed by past fires, more human settlement providing opportunities for fire initiation, and dry conditions

Table 14-6 (continued)

Event	Climatic/Hydrological Variable	Subregion or Country	Reference(s)	Observation Period
La Niñad	Heavier precipitation and floods	Colombia	Poveda and Mesa, 1997 Carvajal <i>et al.</i> , 1999	1972–1992 1957–1997
	Decrease in precipitation during October–December time frame	Argentina (Pampas region)	Barros <i>et al.</i> , 1996; Tanco and Berry, 1996; Vila and Berri, 1996; Vila and Grondona, 1996; Magrin <i>et al.</i> , 1998	1900–1996
	Increase in precipitation, higher runoff	Northern Amazonia Northeast Brazil	Marengo <i>et al.</i> , 1998 Meggers, 1994	1970–1997 Paleoclimate
	Severe droughts	Southern Brazil	Grimm <i>et al.</i> , 1996, 2000	1956–1992
	Negative anomalies of rainfall	Chile and central western Argentina	Compagnucci, 2000	Paleoclimate

^a Extremes of the Southern Oscillation (SO) are responsible in part for a large portion of climate variability at interannual scales in Latin America. El Niño (or ENSO) events represent the negative (low) phase of the SO.

^b Prolonged periods of reduced summer soil moisture.

^c Six El Niño events occurred during this period.

^d La Niña is the positive (high) phase of the SO.

during ENSO events. Neotropical seasonally dry forest should be considered severely threatened in Mesoamerica.

Mortality of trees has been observed to increase under dry conditions that prevail near newly formed edges in Amazonian forests. Edges, which affect an increasingly large portion of the forest with the advance of deforestation, would be especially susceptible to the effects of reduced rainfall. In Mexico, deciduous tropical forest would be affected in approximately 50% of the area presently covered by these forests. Heavy rain during the 1997–1998 ENSO event generated drastic changes in the dry ecosystems of northern Peru's coastal zone. Increases in biomass burning in Amazonia affected by human activity and by climate increase wind-borne smoke and dust that supply nutrients to the Amazon forests. Global warming would expand the area that is suitable for tropical forests as equilibrium vegetation types. However, the forces driving deforestation make it unlikely that tropical forests will be permitted to occupy these increased areas. Land-use change interacts with climate through positive feedback processes that accelerate loss of humid tropical forests.

Sea-level rise will eliminate the present habitats of mangroves and create new tidally inundated areas to which some mangrove species may shift. Coastal inundation stemming from sea-level rise and riverine and flatland flooding would affect water availability and agricultural land. These changes can exacerbate socioeconomic and health problems in critical areas.

On a scale of decades to centuries, it is well-established that changes in precipitation and catchment runoff may have significant effects on mangrove forest communities. This also would affect the region's fisheries because most commercial shellfish and finfish use mangroves as nurseries and for refuge.

Studies in Argentina, Brazil, Chile, Mexico, and Uruguay, based on GCMs and crop models, project decreased yield for several crops (e.g., maize, wheat, barley, grapes), even when the direct effects of CO₂ fertilization and implementation of moderate adaptation measures at the farm level are considered. Predicted increases in temperature will reduce crops yields in the region by shortening the crop cycle. Although relationships between the amount of precipitation and crop yields are well-established, the lack of consistency in the results of different GCMs means that confidence in the estimated impacts of future precipitation on crop production is necessarily limited.

Over the past 40 years, the contribution of agriculture to the GDP of Latin American countries has been on the order of 10%. Agriculture remains a key sector in the regional economy because it employs 30–40% of the economically active population. It also is very important for the food security of the poorest sectors of the population. Subsistence farming could be severely threatened in some parts of Latin America (e.g., northeastern Brazil).

Evidence is established but incomplete that climate change would reduce silvicultural yields because water often limits

growth during the dry season, which is expected to become longer and more intense in many parts of Latin America.

The scale of health impacts from climate change in Latin America would depend primarily on the size, density, location, and wealth of populations. Evidence has been established but incomplete that exposure to heat or cold waves has impacts on mortality rates in risk groups in the region.

Increases in temperature would affect human health in polluted cities such as Mexico City and Santiago. Ample evidence provides high confidence that the geographical distribution of VBDs in Peru and Cuba (e.g., cholera, meningitis) would change if temperature and precipitation were to increase, although there is speculation about what the changes in patterns of diseases would be in different places. It is well-established that weather disasters (extreme events) tend to increase death and morbidity rates (injuries, infectious diseases, social problems, and damage to sanitary infrastructure)—as occurred in Central America with Hurricane Mitch at the end of 1998, heavy rains in Mexico and Venezuela at the end of 1999, and in Argentina in 2000. It is well-established that the ENSO phenomenon causes changes in disease-vector populations and in the incidence of water-borne diseases in Brazil, Peru, Bolivia, Argentina, and Venezuela. It has been speculated that weather factors and climate change may affect the incidence of diseases such as allergies in Mexico. Increased temperature, ultraviolet radiation, sea-level rise, and changes in pest ecology may threaten food production in Argentina.

In summary, climate change already has a diverse array of impacts in Latin America. Projected future changes in climate, together with future changes in the vulnerability of human and natural systems, could lead to impacts that are much larger than those experienced to date.

Acknowledgments

Both Coordinating Lead Authors (L.J. Mata and M. Campos) wish to thank their respective institutions—Zentrum für Entwicklungsforschung (ZEF) in Bonn and Comité Regional de los Recursos Hidráulicos de Centro América—for the time and support given to us during chapter preparation. We also wish to acknowledge the valuable comments and cooperation of O. Canziani (Argentina), J. Budhooram (Trinidad and Tobago), and the entire staff of the IPCC WGII Technical Support Unit.
