

1. Introduction

The sensitivity, adaptive capacity, and vulnerability of natural and human systems to climate change, and the potential consequences of climate change, are assessed in the report of Working Group II of the Intergovernmental Panel on Climate Change (IPCC), *Climate Change 2001: Impacts, Adaptation, and Vulnerability*.¹ This report builds upon the past assessment reports of the IPCC, reexamining key conclusions of the earlier assessments and incorporating results from more recent research.^{2,3}

Observed changes in climate, their causes, and potential future changes are assessed in the report of Working Group I of the IPCC, *Climate Change 2001: The Scientific Basis*. The Working Group I report concludes, *inter alia*, that the globally averaged surface temperatures have increased by $0.6 \pm 0.2^\circ\text{C}$ over the 20th century; and that, for the range of scenarios developed in the IPCC *Special Report on Emission Scenarios* (SRES), the globally averaged surface air temperature is projected by models to warm 1.4 to 5.8°C by 2100 relative to 1990, and globally averaged sea level is projected by models to rise 0.09 to 0.88 m by 2100. These projections indicate that the warming would vary by region, and be accompanied by increases and decreases in precipitation. In addition, there would be changes in the variability of climate, and changes in the frequency and intensity of some extreme climate phenomena. These general features of climate change act on natural and human systems and they set the context for the Working Group II assessment. The available literature has not yet investigated climate change impacts, adaptation, and vulnerability associated with the upper end of the projected range of warming.

This Summary for Policymakers, which was approved by IPCC member governments in Geneva in February 2001, describes the current state of understanding of the impacts, adaptation, and vulnerability to climate change and their uncertainties. Further details can be found in the underlying report.⁴ Section 2 of the Summary presents a number of general findings that emerge from integration of information across the full report. Each of these findings addresses a different dimension of climate change impacts, adaptation, and vulnerability, and no one dimension is paramount. Section 3 presents findings regarding individual natural and human systems, and Section 4 highlights some of the issues of concern for different regions of the world. Section 5 identifies priority research areas to further advance understanding of the potential consequences of and adaptation to climate change.

2. Emergent Findings

2.1. Recent Regional Climate Changes, particularly Temperature Increases, have Already Affected Many Physical and Biological Systems

Available observational evidence indicates that regional changes in climate, particularly increases in temperature, have

already affected a diverse set of physical and biological systems in many parts of the world. Examples of observed changes include shrinkage of glaciers, thawing of permafrost, later freezing and earlier break-up of ice on rivers and lakes, lengthening of mid-to high-latitude growing seasons, poleward and altitudinal shifts of plant and animal ranges, declines of some plant and animal populations, and earlier flowering of trees, emergence of insects, and egg-laying in birds (see Figure SPM-1). Associations between changes in regional temperatures and observed changes in physical and biological systems have been documented in many aquatic, terrestrial, and marine environments. [2.1, 4.3, 4.4, 5.7, and 7.1]

The studies mentioned above and illustrated in Figure SPM-1 were drawn from a literature survey, which identified long-term studies, typically 20 years or more, of changes in biological and physical systems that could be correlated with regional changes in temperature.⁵ In most cases where changes in biological and physical systems were detected, the direction of change was that expected on the basis of known mechanisms. The probability that the observed changes in the expected direction (with no reference to magnitude) could occur by chance alone is negligible. In many parts of the world, precipitation-related impacts may be important. At present, there is a lack of systematic concurrent climatic and biophysical data of sufficient length (2 or more decades) that are considered necessary for assessment of precipitation impacts.

Factors such as land-use change and pollution also act on these physical and biological systems, making it difficult to attribute changes to particular causes in some specific cases. However, taken together, the observed changes in these systems are consistent in direction and coherent across diverse localities

¹Climate change in IPCC usage refers to any change in climate over time, whether due to natural variability or as a result of human activity. This usage differs from that in the Framework Convention on Climate Change, where *climate change* refers to a change of climate that is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and that is in addition to natural climate variability observed over comparable time periods. Attribution of climate change to natural forcing and human activities has been addressed by Working Group I.

²The report has been written by 183 Coordinating Lead Authors and Lead Authors, and 243 Contributing Authors. It was reviewed by 440 government and expert reviewers, and 33 Review Editors oversaw the review process.

³Delegations from 100 IPCC member countries participated in the Sixth Session of Working Group II in Geneva on 13-16 February 2001.

⁴A more comprehensive summary of the report is provided in the Technical Summary, and relevant sections of that volume are referenced in brackets at the end of paragraphs of the Summary for Policymakers for readers who need more information.

⁵There are 44 regional studies of over 400 plants and animals, which varied in length from about 20 to 50 years, mainly from North America, Europe, and the southern polar region. There are 16 regional studies covering about 100 physical processes over most regions of the world, which varied in length from about 20 to 150 years. See Section 7.1 of the Technical Summary for more detail.

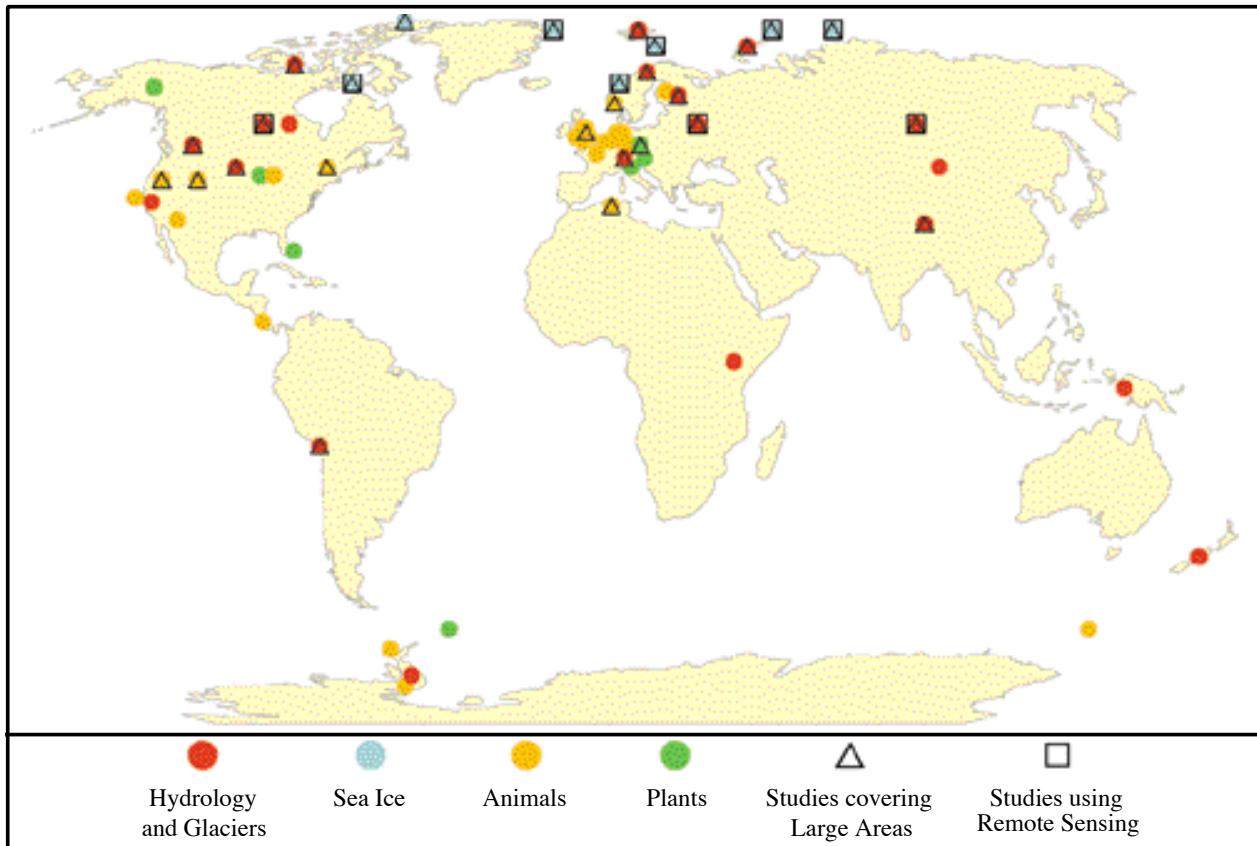

Figure SPM-1: Locations at which systematic long-term studies meet stringent criteria documenting recent temperature-related regional climate change impacts on physical and biological systems. Hydrology, glacial retreat, and sea-ice data represent decadal to century trends. Terrestrial and marine ecosystem data represent trends of at least 2 decades. Remote-sensing studies cover large areas. Data are for single or multiple impacts that are consistent with known mechanisms of physical/biological system responses to observed regional temperature-related changes. For reported impacts spanning large areas, a representative location on the map was selected.

and/or regions (see Figure SPM-1) with the expected effects of regional changes in temperature. Thus, from the collective evidence, there is *high confidence*⁶ that recent regional changes in temperature have had discernible impacts on many physical and biological systems.

⁶In this Summary for Policymakers, the following words have been used where appropriate to indicate judgmental estimates of confidence (based upon the collective judgment of the authors using the observational evidence, modeling results, and theory that they have examined): *very high* (95% or greater), *high* (67-95%), *medium* (33-67%), *low* (5-33%), and *very low* (5% or less). In other instances, a qualitative scale to gauge the level of scientific understanding is used: *well established*, *established-but-incomplete*, *competing explanations*, and *speculative*. The approaches used to assess confidence levels and the level of scientific understanding, and the definitions of these terms, are presented in Section 1.4 of the Technical Summary. Each time these terms are used in the Summary for Policymakers, they are footnoted and in *italics*.

2.2. *There are Preliminary Indications that Some Human Systems have been Affected by Recent Increases in Floods and Droughts*

There is emerging evidence that some social and economic systems have been affected by the recent increasing frequency of floods and droughts in some areas. However, such systems are also affected by changes in socioeconomic factors such as demographic shifts and land-use changes. The relative impact of climatic and socioeconomic factors are generally difficult to quantify. [4.6 and 7.1]

2.3. *Natural Systems are Vulnerable to Climate Change, and Some will be Irreversibly Damaged*

Natural systems can be especially vulnerable to climate change because of limited adaptive capacity (see Box SPM-1), and some of these systems may undergo significant and irreversible damage. Natural systems at risk include glaciers, coral reefs and

atolls, mangroves, boreal and tropical forests, polar and alpine ecosystems, prairie wetlands, and remnant native grasslands. While some species may increase in abundance or range, climate change will increase existing risks of extinction of some more vulnerable species and loss of biodiversity. It is well-established⁶ that the geographical extent of the damage or loss, and the number of systems affected, will increase with the magnitude and rate of climate change (see Figure SPM-2). [4.3 and 7.2.1]

2.4. Many Human Systems are Sensitive to Climate Change, and Some are Vulnerable

Human systems that are sensitive to climate change include mainly water resources; agriculture (especially food security) and forestry; coastal zones and marine systems (fisheries); human settlements, energy, and industry; insurance and other financial services; and human health. The vulnerability of these systems varies with geographic location, time, and social, economic, and environmental conditions. [4.1, 4.2, 4.3, 4.4, 4.5, 4.6, and 4.7]

Projected adverse impacts based on models and other studies include:

- A general reduction in potential crop yields in most tropical and sub-tropical regions for most projected increases in temperature [4.2]
- A general reduction, with some variation, in potential crop yields in most regions in mid-latitudes for increases in annual-average temperature of more than a few °C [4.2]
- Decreased water availability for populations in many water-scarce regions, particularly in the sub-tropics [4.1]
- An increase in the number of people exposed to vector-borne (e.g., malaria) and water-borne diseases (e.g., cholera), and an increase in heat stress mortality [4.7]
- A widespread increase in the risk of flooding for many human settlements (tens of millions of inhabitants in settlements studied) from both increased heavy precipitation events and sea-level rise [4.5]
- Increased energy demand for space cooling due to higher summer temperatures. [4.5]

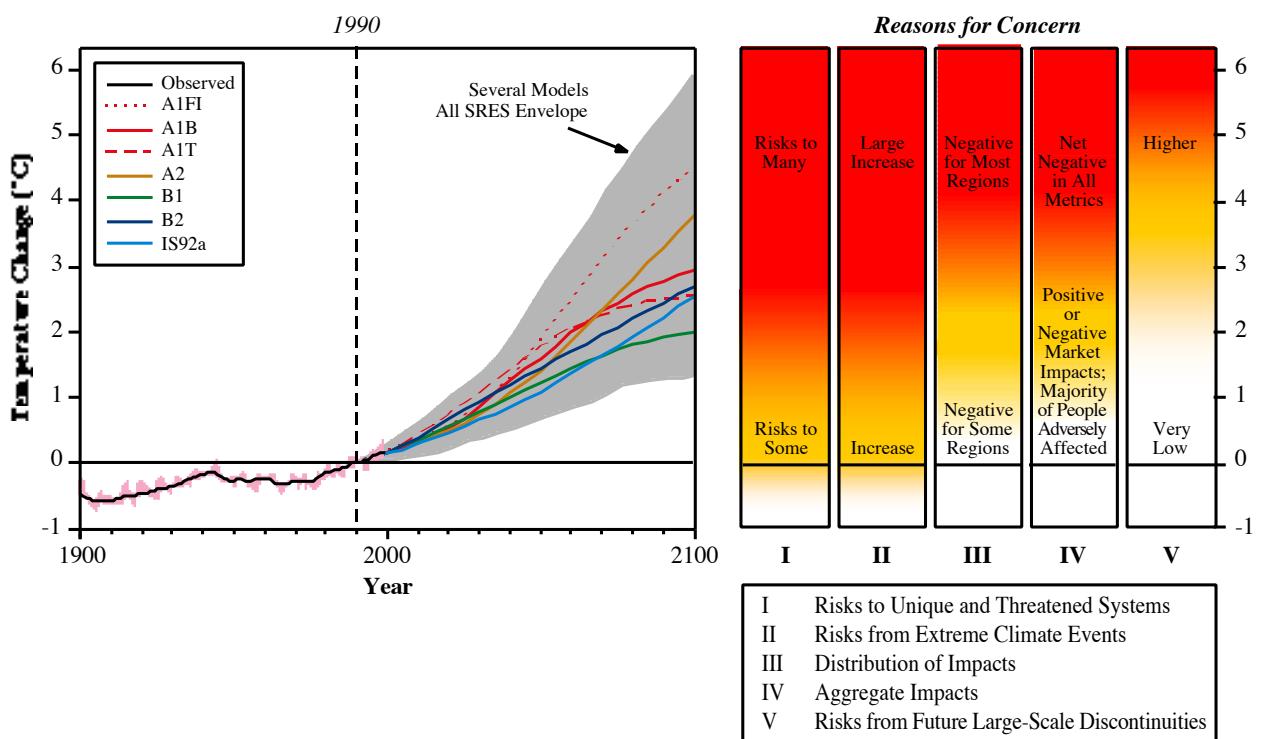

Figure SPM-2: Reasons for concern about projected climate change impacts. The risks of adverse impacts from climate change increase with the magnitude of climate change. The left part of the figure displays the observed temperature increase relative to 1990 and the range of projected temperature increase after 1990 as estimated by Working Group I of the IPCC for scenarios from the *Special Report on Emissions Scenarios*. The right panel displays conceptualizations of five reasons for concern regarding climate change risks evolving through 2100. White indicates neutral or small negative or positive impacts or risks, yellow indicates negative impacts for some systems or low risks, and red means negative impacts or risks that are more widespread and/or greater in magnitude. The assessment of impacts or risks takes into account only the magnitude of change and not the rate of change. Global mean annual temperature change is used in the figure as a proxy for the magnitude of climate change, but projected impacts will be a function of, among other factors, the magnitude and rate of global and regional changes in mean climate, climate variability and extreme climate phenomena, social and economic conditions, and adaptation.

Box SPM-1. Climate Change Sensitivity, Adaptive Capacity, and Vulnerability

Sensitivity is the degree to which a system is affected, either adversely or beneficially, by climate-related stimuli. Climate-related stimuli encompass all the elements of climate change, including mean climate characteristics, climate variability, and the frequency and magnitude of extremes. The effect may be direct (e.g., a change in crop yield in response to a change in the mean, range, or variability of temperature) or indirect (e.g., damages caused by an increase in the frequency of coastal flooding due to sea-level rise).

Adaptive capacity is the ability of a system to adjust to climate change (including climate variability and extremes) to moderate potential damages, to take advantage of opportunities, or to cope with the consequences.

Vulnerability is the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude, and rate of climate change and variation to which a system is exposed, its sensitivity, and its adaptive capacity.

Projected beneficial impacts based on models and other studies include:

- Increased potential crop yields in some regions at mid-latitudes for increases in temperature of less than a few °C [4.2]
- A potential increase in global timber supply from appropriately managed forests [4.3]
- Increased water availability for populations in some water-scarce regions—for example, in parts of southeast Asia [4.1]
- Reduced winter mortality in mid- and high-latitudes [4.7]
- Reduced energy demand for space heating due to higher winter temperatures. [4.5]

2.5. Projected Changes in Climate Extremes could have Major Consequences

The vulnerability of human societies and natural systems to climate extremes is demonstrated by the damage, hardship, and death caused by events such as droughts, floods, heat waves, avalanches, and windstorms. While there are uncertainties attached to estimates of such changes, some extreme events are projected to increase in frequency and/or severity during the 21st century due to changes in the mean and/or variability of climate, so it can be expected that the severity of their impacts will also increase in concert with global warming (see Figure SPM-2). Conversely, the frequency and magnitude of extreme low temperature events, such as cold spells, is projected to

decrease in the future, with both positive and negative impacts. The impacts of future changes in climate extremes are expected to fall disproportionately on the poor. Some representative examples of impacts of these projected changes in climate variability and climate extremes are presented in Table SPM-1. [3.5, 4.6, 6, and 7.2.4]

2.6. The Potential for Large-Scale and Possibly Irreversible Impacts Poses Risks that have yet to be Reliably Quantified

Projected climate changes⁷ during the 21st century have the potential to lead to future large-scale and possibly irreversible changes in Earth systems resulting in impacts at continental and global scales. These possibilities are very climate scenario-dependent and a full range of plausible scenarios has not yet been evaluated. Examples include significant slowing of the ocean circulation that transports warm water to the North Atlantic, large reductions in the Greenland and West Antarctic Ice Sheets, accelerated global warming due to carbon cycle feedbacks in the terrestrial biosphere, and releases of terrestrial carbon from permafrost regions and methane from hydrates in coastal sediments. The likelihood of many of these changes in Earth systems is not well-known, but is probably very low; however, their likelihood is expected to increase with the rate, magnitude, and duration of climate change (see Figure SPM-2). [3.5, 5.7, and 7.2.5]

If these changes in Earth systems were to occur, their impacts would be widespread and sustained. For example, significant slowing of the oceanic thermohaline circulation would impact deep-water oxygen levels and carbon uptake by oceans and marine ecosystems, and would reduce warming over parts of Europe. Disintegration of the West Antarctic Ice Sheet or melting of the Greenland Ice Sheet could raise global sea level up to 3 m each over the next 1,000 years⁸, submerge many islands, and inundate extensive coastal areas. Depending on the rate of ice loss, the rate and magnitude of sea-level rise could greatly exceed the capacity of human and natural systems to adapt without substantial impacts. Releases of terrestrial carbon from permafrost regions and methane from hydrates in coastal sediments, induced by warming, would further increase greenhouse gas concentrations in the atmosphere and amplify climate change. [3.5, 5.7, and 7.2.5]

2.7. Adaptation is a Necessary Strategy at All Scales to Complement Climate Change Mitigation Efforts

Adaptation has the potential to reduce adverse impacts of climate change and to enhance beneficial impacts, but will incur costs

⁷Details of projected climate changes, illustrated in Figure SPM-2, are provided in the Working Group I Summary for Policymakers.

⁸Details of projected contributions to sea-level rise from the West Antarctic Ice Sheet and Greenland Ice Sheet are provided in the Working Group I Summary for Policymakers.

Table SPM-1: Examples of impacts resulting from projected changes in extreme climate events.

Projected Changes during the 21st Century in Extreme Climate Phenomena and their Likelihood^a	Representative Examples of Projected Impacts^b (all high confidence of occurrence in some areas^c)
Simple Extremes	
Higher maximum temperatures; more hot days and heat waves ^d over nearly all land areas (<i>very likely</i> ^a)	<ul style="list-style-type: none"> Increased incidence of death and serious illness in older age groups and urban poor [4.7] Increased heat stress in livestock and wildlife [4.2 and 4.3] Shift in tourist destinations [Table TS-4 and 5.8] Increased risk of damage to a number of crops [4.2] Increased electric cooling demand and reduced energy supply reliability [Table TS-4 and 4.5]
Higher (increasing) minimum temperatures; fewer cold days, frost days, and cold waves ^d over nearly all land areas (<i>very likely</i> ^a)	<ul style="list-style-type: none"> Decreased cold-related human morbidity and mortality [4.7] Decreased risk of damage to a number of crops, and increased risk to others [4.2] Extended range and activity of some pest and disease vectors [4.2 and 4.3] Reduced heating energy demand [4.5]
More intense precipitation events (<i>very likely</i> ^a over many areas)	<ul style="list-style-type: none"> Increased flood, landslide, avalanche, and mudslide damage [4.5] Increased soil erosion [5.2.4] Increased flood runoff could increase recharge of some floodplain aquifers [4.1] Increased pressure on government and private flood insurance systems and disaster relief [Table TS-4 and 4.6]
Complex Extremes	
Increased summer drying over most mid-latitude continental interiors and associated risk of drought (<i>likely</i> ^a)	<ul style="list-style-type: none"> Decreased crop yields [4.2] Increased damage to building foundations caused by ground shrinkage [Table TS-4] Decreased water resource quantity and quality [4.1 and 4.5] Increased risk of forest fire [5.4.2]
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities (<i>likely</i> ^a over some areas) ^e	<ul style="list-style-type: none"> Increased risks to human life, risk of infectious disease epidemics, and many other risks [4.7] Increased coastal erosion and damage to coastal buildings and infrastructure [4.5 and 7.2.4] Increased damage to coastal ecosystems such as coral reefs and mangroves [4.4]
Intensified droughts and floods associated with El Niño events in many different regions (<i>likely</i> ^a) (see also under droughts and intense precipitation events)	<ul style="list-style-type: none"> Decreased agricultural and rangeland productivity in drought- and flood-prone regions [4.3] Decreased hydro-power potential in drought-prone regions [5.1.1 and Figure TS-7]
Increased Asian summer monsoon precipitation variability (<i>likely</i> ^a)	<ul style="list-style-type: none"> Increased flood and drought magnitude and damages in temperate and tropical Asia [5.2.4]
Increased intensity of mid-latitude storms (little agreement between current models) ^d	<ul style="list-style-type: none"> Increased risks to human life and health [4.7] Increased property and infrastructure losses [Table TS-4] Increased damage to coastal ecosystems [4.4]

^aLikelihood refers to judgmental estimates of confidence used by TAR WGI: *very likely* (90-99% chance); *likely* (66-90% chance). Unless otherwise stated, information on climate phenomena is taken from the Summary for Policymakers, TAR WGI.

^bThese impacts can be lessened by appropriate response measures.

^cHigh confidence refers to probabilities between 67 and 95% as described in Footnote 6.

^dInformation from TAR WGI, Technical Summary, Section F.5.

^eChanges in regional distribution of tropical cyclones are possible but have not been established.

and will not prevent all damages. Extremes, variability, and rates of change are all key features in addressing vulnerability and adaptation to climate change, not simply changes in average climate conditions. Human and natural systems will to some degree adapt autonomously to climate change. Planned adaptation can supplement autonomous adaptation, though options and incentives are greater for adaptation of human systems than for adaptation to protect natural systems. Adaptation is a necessary strategy at all scales to complement climate change mitigation efforts. [6]

Experience with adaptation to climate variability and extremes can be drawn upon to develop appropriate strategies for adapting to anticipated climate change. Adaptation to current climate variability and extremes often produces benefits as well as forming a basis for coping with future climate change. However, experience also demonstrates that there are constraints to achieving the full measure of potential adaptation. In addition, maladaptation, such as promoting development in risk-prone locations, can occur due to decisions based on short-term considerations, neglect of known climatic variability, imperfect foresight, insufficient information, and over-reliance on insurance mechanisms. [6]

2.8 Those with the Least Resources have the Least Capacity to Adapt and are the Most Vulnerable

The ability of human systems to adapt to and cope with climate change depends on such factors as wealth, technology, education, information, skills, infrastructure, access to resources, and management capabilities. There is potential for developed and developing countries to enhance and/or acquire adaptive capabilities. Populations and communities are highly variable in their endowments with these attributes, and the developing countries, particularly the least developed countries, are generally poorest in this regard. As a result, they have lesser capacity to adapt and are more vulnerable to climate change damages, just as they are more vulnerable to other stresses. This condition is most extreme among the poorest people. [6.1; see also 5.1.7, 5.2.7, 5.3.5, 5.4.6, 5.6.1, 5.6.2, 5.7, and 5.8.1 for regional-scale information]

Benefits and costs of climate change effects have been estimated in monetary units and aggregated to national, regional, and global scales. These estimates generally exclude the effects of changes in climate variability and extremes, do not account for the effects of different rates of change, and only partially account for impacts on goods and services that are not traded in markets. These omissions are likely to result in underestimates of economic losses and overestimates of economic gains. Estimates of aggregate impacts are controversial because they treat gains for some as canceling out losses for others and because the weights that are used to aggregate across individuals are necessarily subjective. [7.2.2 and 7.2.3]

Notwithstanding the limitations expressed above, based on a few published estimates, increases in global mean temperature⁹ would

produce net economic losses in many developing countries for all magnitudes of warming studied (*low confidence*⁶), and losses would be greater in magnitude the higher the level of warming (*medium confidence*⁶). In contrast, an increase in global mean temperature of up to a few °C would produce a mixture of economic gains and losses in developed countries (*low confidence*⁶), with economic losses for larger temperature increases (*medium confidence*⁶). The projected distribution of economic impacts is such that it would increase the disparity in well-being between developed countries and developing countries, with disparity growing for higher projected temperature increases (*medium confidence*⁶). The more damaging impacts estimated for developing countries reflects, in part, their lesser adaptive capacity relative to developed countries. [7.2.3]

Further, when aggregated to a global scale, world gross domestic product (GDP) would change by ± a few percent for global mean temperature increases of up to a few °C (*low confidence*⁶), and increasing net losses would result for larger increases in temperature (*medium confidence*⁶) (see Figure SPM-2). More people are projected to be harmed than benefited by climate change, even for global mean temperature increases of less than a few °C (*low confidence*⁶). These results are sensitive to assumptions about changes in regional climate, level of development, adaptive capacity, rate of change, the valuation of impacts, and the methods used for aggregating monetary losses and gains, including the choice of discount rate. [7.2.2]

The effects of climate change are expected to be greatest in developing countries in terms of loss of life and relative effects on investment and the economy. For example, the relative percentage damages to GDP from climate extremes have been substantially greater in developing countries than in developed countries. [4.6]

2.9 Adaptation, Sustainable Development, and Enhancement of Equity can be Mutually Reinforcing

Many communities and regions that are vulnerable to climate change are also under pressure from forces such as population growth, resource depletion, and poverty. Policies that lessen pressures on resources, improve management of environmental risks, and increase the welfare of the poorest members of society can simultaneously advance sustainable development and equity, enhance adaptive capacity, and reduce vulnerability to climate and other stresses. Inclusion of climatic risks in the design and implementation of national and international development initiatives can promote equity and development that is more sustainable and that reduces vulnerability to climate change. [6.2]

⁹Global mean temperature change is used as an indicator of the magnitude of climate change. Scenario-dependent exposures taken into account in these studies include regionally differentiated changes in temperature, precipitation, and other climatic variables.

3. Effects on and Vulnerability of Natural and Human Systems

3.1. Hydrology and Water Resources

The effect of climate change on streamflow and groundwater recharge varies regionally and between climate scenarios, largely following projected changes in precipitation. A consistent projection across most climate change scenarios is for increases in annual mean streamflow in high latitudes and southeast Asia, and decreases in central Asia, the area around the Mediterranean, southern Africa, and Australia (*medium confidence*⁶) (see Figure SPM-3); the amount of change, however, varies between scenarios. For other areas, including mid-latitudes, there is no strong consistency in projections of streamflow, partly because of differences in projected rainfall and partly because of differences in projected evaporation, which can offset rainfall increases. The retreat of most glaciers is projected to accelerate, and many small glaciers may disappear (*high confidence*⁶). In general, the projected changes in average annual runoff are less robust than impacts based solely on temperature change because precipitation changes vary more between scenarios. At the catchment scale, the effect of a given change in climate varies with physical properties and vegetation of catchments, and may be in addition to land-cover changes. [4.1]

Approximately 1.7 billion people, one-third of the world's population, presently live in countries that are water-stressed (defined as using more than 20% of their renewable water supply, a commonly used indicator of water stress). This number is projected to increase to around 5 billion by 2025, depending on the rate of population growth. The projected climate change could further decrease the streamflow and groundwater recharge in many of these water-stressed countries—for example in central Asia, southern Africa, and countries around the Mediterranean Sea—but may increase it in some others. [4.1; see also 5.1.1, 5.2.3, 5.3.1, 5.4.1, 5.5.1, 5.6.2, and 5.8.4 for regional-scale information]

Demand for water is generally increasing due to population growth and economic development, but is falling in some countries because of increased efficiency of use. Climate change is unlikely to have a big effect on municipal and industrial water demands in general, but may substantially affect irrigation withdrawals, which depend on how increases in evaporation are offset or exaggerated by changes in precipitation. Higher temperatures, hence higher crop evaporative demand, mean that the general tendency would be towards an increase in irrigation demands. [4.1]

Flood magnitude and frequency could increase in many regions as a consequence of increased frequency of heavy precipitation events, which can increase runoff in most areas as well as groundwater recharge in some floodplains. Land-use change could exacerbate such events. Streamflow during seasonal low flow periods would decrease in many areas due to greater evaporation; changes in precipitation may exacerbate or offset the effects of increased evaporation. The projected

climate change would degrade water quality through higher water temperatures and increased pollutant load from runoff and overflows of waste facilities. Quality would be degraded further where flows decrease, but increases in flows may mitigate to a certain extent some degradations in water quality by increasing dilution. Where snowfall is currently an important component of the water balance, a greater proportion of winter precipitation may fall as rain, and this can result in a more intense peak streamflow which in addition would move from spring to winter. [4.1]

The greatest vulnerabilities are likely to be in unmanaged water systems and systems that are currently stressed or poorly and unsustainably managed due to policies that discourage efficient water use and protection of water quality, inadequate watershed management, failure to manage variable water supply and demand, or lack of sound professional guidance. In unmanaged systems there are few or no structures in place to buffer the effects of hydrologic variability on water quality and supply. In unsustainably managed systems, water and land uses can add stresses that heighten vulnerability to climate change. [4.1]

Water resource management techniques, particularly those of integrated water resource management, can be applied to adapt to hydrologic effects of climate change, and to additional uncertainty, so as to lessen vulnerabilities. Currently, supply-side approaches (e.g., increasing flood defenses, building weirs, utilizing water storage areas, including natural systems, improving infrastructure for water collection and distribution) are more widely used than demand-side approaches (which alter the exposure to stress); the latter is the focus of increasing attention. However, the capacity to implement effective management responses is unevenly distributed around the world and is low in many transition and developing countries. [4.1]

3.2. Agriculture and Food Security

Based on experimental research, crop yield responses to climate change vary widely, depending upon species and cultivar; soil properties; pests, and pathogens; the direct effects of carbon dioxide (CO₂) on plants; and interactions between CO₂, air temperature, water stress, mineral nutrition, air quality, and adaptive responses. Even though increased CO₂ concentration can stimulate crop growth and yield, that benefit may not always overcome the adverse effects of excessive heat and drought (*medium confidence*⁶). These advances, along with advances in research on agricultural adaptation, have been incorporated since the Second Assessment Report (SAR) into models used to assess the effects of climate change on crop yields, food supply, farm incomes, and prices. [4.2]

Costs will be involved in coping with climate-induced yield losses and adaptation of livestock production systems. These agronomic and husbandry adaptation options could include, for example, adjustments to planting dates, fertilization rates, irrigation applications, cultivar traits, and selection of animal species. [4.2]

When autonomous agronomic adaptation is included, crop modeling assessments indicate, with *medium to low confidence*⁶, that climate change will lead to generally positive responses at less than a few °C warming and generally negative responses for more than a few °C in mid-latitude crop yields. Similar assessments

indicate that yields of some crops in tropical locations would decrease generally with even minimal increases in temperature, because such crops are near their maximum temperature tolerance and dryland/rainfed agriculture predominates. Where there is also a large decrease in rainfall, tropical crop yields would be

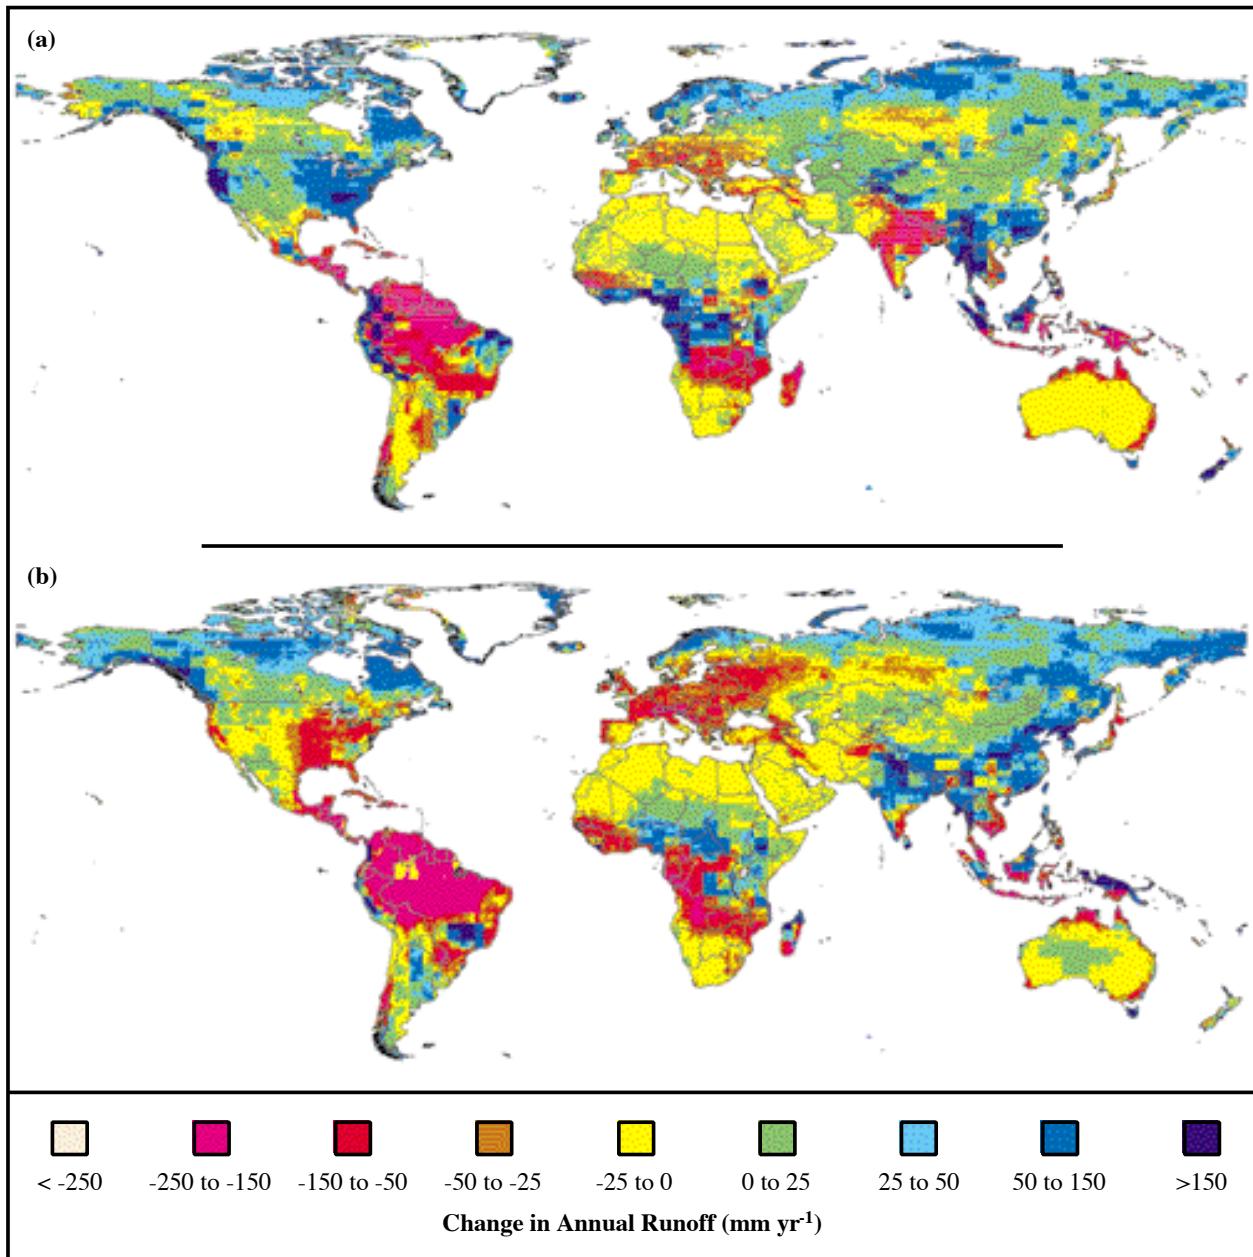

Figure SPM-3: Projected changes in average annual water runoff by 2050, relative to average runoff for 1961–1990, largely follow projected changes in precipitation. Changes in runoff are calculated with a hydrologic model using as inputs climate projections from two versions of the Hadley Centre atmosphere-ocean general circulation model (AOGCM) for a scenario of 1% per annum increase in effective carbon dioxide concentration in the atmosphere: (a) HadCM2 ensemble mean and (b) HadCM3. Projected increases in runoff in high latitudes and southeast Asia, and decreases in central Asia, the area around the Mediterranean, southern Africa, and Australia are broadly consistent across the Hadley Centre experiments, and with the precipitation projections of other AOGCM experiments. For other areas of the world, changes in precipitation and runoff are scenario- and model-dependent.

even more adversely affected. With autonomous agronomic adaptation, crop yields in the tropics tend to be less adversely affected by climate change than without adaptation, but they still tend to remain below levels estimated with current climate. [4.2]

Most global and regional economic studies not incorporating climate change indicate that the downward trend in global real commodity prices in the 20th century is likely to continue into the 21st, although confidence in these predictions decreases farther into the future. Economic modeling assessments indicate that impacts of climate change on agricultural production and prices are estimated to result in small percentage changes in global income (*low confidence*⁶), with larger increases in more developed regions and smaller increases or declines in developing regions. Improved confidence in this finding depends on further research into the sensitivity of economic modeling assessments to their base assumptions. [4.2 and Box 5-5]

Most studies indicate that global mean annual temperature increases of a few °C or greater would prompt food prices to increase due to a slowing in the expansion of global food supply relative to growth in global food demand (*established, but incomplete*⁶). At lesser amounts of warming than a few °C, economic models do not clearly distinguish the climate change signal from other sources of change based on those studies included in this assessment. Some recent aggregated studies have estimated economic impacts on vulnerable populations such as smallholder producers and poor urban consumers. These studies find that climate change would lower incomes of the vulnerable populations and increase the absolute number of people at risk of hunger, though this is uncertain and requires further research. It is established, though incompletely, that climate change, mainly through increased extremes and temporal/spatial shifts, will worsen food security in Africa. [4.2]

3.3. Terrestrial and Freshwater Ecosystems

Vegetation modeling studies continue to show the potential for significant disruption of ecosystems under climate change (*high confidence*⁶). Migration of ecosystems or biomes as discrete units is unlikely to occur; instead at a given site, species composition and dominance will change. The results of these changes will lag behind the changes in climate by years to decades to centuries (*high confidence*⁶). [4.3]

Distributions, population sizes, population density, and behavior of wildlife have been, and will continue to be, affected directly by changes in global or regional climate and indirectly through changes in vegetation. Climate change will lead to poleward movement of the boundaries of freshwater fish distributions along with loss of habitat for cold- and cool-water fishes and gain in habitat for warm-water fishes (*high confidence*⁶). Many species and populations are already at high risk, and are expected to be placed at greater risk by the synergy between climate change rendering portions of current habitat unsuitable for many species, and land-use change fragmenting habitats and raising obstacles to species migration. Without appropriate

management, these pressures will cause some species currently classified as “critically endangered” to become extinct and the majority of those labeled “endangered or vulnerable” to become rarer, and thereby closer to extinction, in the 21st century (*high confidence*⁶). [4.3]

Possible adaptation methods to reduce risks to species could include: 1) establishment of refuges, parks, and reserves with corridors to allow migration of species, and 2) use of captive breeding and translocation. However, these options may have limitations due to costs. [4.3]

Terrestrial ecosystems appear to be storing increasing amounts of carbon. At the time of the SAR, this was largely attributed to increasing plant productivity because of the interaction between elevated CO₂ concentration, increasing temperatures, and soil moisture changes. Recent results confirm that productivity gains are occurring but suggest that they are smaller under field conditions than indicated by plant-pot experiments (*medium confidence*⁶). Hence, the terrestrial uptake may be due more to change in uses and management of land than to the direct effects of elevated CO₂ and climate. The degree to which terrestrial ecosystems continue to be net sinks for carbon is uncertain due to the complex interactions between the factors mentioned above (e.g., arctic terrestrial ecosystems and wetlands may act as both sources and sinks) (*medium confidence*⁶). [4.3]

Contrary to the SAR, global timber market studies that include adaptations through land and product management, even without forestry projects that increase the capture and storage of carbon, suggest that a small amount of climate change would increase global timber supply and enhance existing market trends towards rising market share in developing countries (*medium confidence*⁶). Consumers may benefit from lower timber prices while producers may gain or lose depending on regional changes in timber productivity and potential dieback effects. [4.3]

3.4. Coastal Zones and Marine Ecosystems

Large-scale impacts of climate change on oceans are expected to include increases in sea surface temperature and mean global sea level, decreases in sea-ice cover, and changes in salinity, wave conditions, and ocean circulation. The oceans are an integral and responsive component of the climate system with important physical and biogeochemical feedbacks to climate. Many marine ecosystems are sensitive to climate change. Climate trends and variability as reflected in multiyear climate-ocean regimes (e.g., Pacific Decadal Oscillation) and switches from one regime to another are now recognized to strongly affect fish abundance and population dynamics, with significant impacts on fish-dependent human societies. [4.4]

Many coastal areas will experience increased levels of flooding, accelerated erosion, loss of wetlands and mangroves, and seawater intrusion into freshwater sources as a result of climate change. The extent and severity of storm impacts, including storm-surge floods and shore erosion, will increase as a result

of climate change including sea-level rise. High-latitude coasts will experience added impacts related to higher wave energy and permafrost degradation. Changes in relative sea level will vary locally due to uplift and subsidence caused by other factors. [4.4]

Impacts on highly diverse and productive coastal ecosystems such as coral reefs, atolls and reef islands, salt marshes and mangrove forests will depend upon the rate of sea-level rise relative to growth rates and sediment supply, space for and obstacles to horizontal migration, changes in the climate-ocean environment such as sea surface temperatures and storminess, and pressures from human activities in coastal zones. Episodes of coral bleaching over the past 20 years have been associated with several causes, including increased ocean temperatures. Future sea surface warming would increase stress on coral reefs and result in increased frequency of marine diseases (*high confidence*⁶). [4.4]

Assessments of adaptation strategies for coastal zones have shifted emphasis away from hard protection structures of shorelines (e.g., seawalls, groins) toward soft protection measures (e.g., beach nourishment), managed retreat, and enhanced resilience of biophysical and socioeconomic systems in coastal regions. Adaptation options for coastal and marine management are most effective when incorporated with policies in other areas, such as disaster mitigation plans and land-use plans. [4.4]

3.5. Human Health

The impacts of short-term weather events on human health have been further elucidated since the SAR, particularly in relation to periods of thermal stress, the modulation of air pollution impacts, the impacts of storms and floods, and the influences of seasonal and interannual climatic variability on infectious diseases. There has been increased understanding of the determinants of population vulnerability to adverse health impacts and the possibilities for adaptive responses. [4.7]

Many vector-, food-, and water-borne infectious diseases are known to be sensitive to changes in climatic conditions. From results of most predictive model studies, there is *medium to high confidence*⁶ that, under climate change scenarios, there would be a net increase in the geographic range of potential transmission of malaria and dengue—two vector-borne infections each of which currently impinge on 40–50% of the world population.¹⁰ Within their present ranges, these and many other infectious diseases would tend to increase in incidence and seasonality—although regional decreases would occur in some infectious diseases. In all cases, however, actual disease occurrence is strongly influenced by local environmental conditions, socioeconomic circumstances, and public health infrastructure. [4.7]

¹⁰ Eight studies have modeled the effects of climate change on these diseases, five on malaria and three on dengue. Seven use a biological, or process-based approach, and one uses an empirical, statistical approach.

Projected climate change will be accompanied by an increase in heat waves, often exacerbated by increased humidity and urban air pollution, which would cause an increase in heat-related deaths and illness episodes. The evidence indicates that the impact would be greatest in urban populations, affecting particularly the elderly, sick, and those without access to air-conditioning (*high confidence*⁶). Limited evidence indicates that in some temperate countries reduced winter deaths would outnumber increased summer deaths (*medium confidence*⁶); yet, published research has been largely confined to populations in developed countries, thus precluding a generalized comparison of changes in summer and winter mortality. [3.5 and 4.7]

Extensive experience makes clear that any increase in flooding will increase the risk of drowning, diarrhoeal and respiratory diseases, and, in developing countries, hunger and malnutrition (*high confidence*⁶). If cyclones were to increase regionally, devastating impacts would often occur, particularly in densely settled populations with inadequate resources. A reduction in crop yields and food production because of climate change in some regions, particularly in the tropics, will predispose food-insecure populations to malnutrition, leading to impaired child development and decreased adult activity. Socioeconomic disruptions could occur in some regions, impairing both livelihoods and health. [3.5, 4.1, 4.2, 4.5, and 4.7]

For each anticipated adverse health impact there is a range of social, institutional, technological, and behavioral adaptation options to lessen that impact. Adaptations could, for example, encompass strengthening of the public health infrastructure, health-oriented management of the environment (including air and water quality, food safety, urban and housing design, and surface water management), and the provision of appropriate medical care facilities. Overall, the adverse health impacts of climate change will be greatest in vulnerable lower income populations, predominantly within tropical/subtropical countries. Adaptive policies would, in general, reduce these impacts. [4.7]

3.6. Human Settlements, Energy, and Industry

A growing and increasingly quantitative literature shows that human settlements are affected by climate change in one of three major ways:

- 1) The economic sectors that support the settlement are affected because of changes in resource productivity or changes in market demand for the goods and services produced there. [4.5]
- 2) Some aspects of physical infrastructure (including energy transmission and distribution systems), buildings, urban services (including transportation systems), and specific industries (such as agroindustry, tourism, and construction) may be directly affected. [4.5]
- 3) Populations may be directly affected through extreme weather, changes in health status, or migration. The problems are somewhat different in the largest (<1 million) and mid- to small-sized population centers. [4.5]

The most widespread direct risk to human settlements from climate change is flooding and landslides, driven by projected increases in rainfall intensity and, in coastal areas, sea-level rise. Riverine and coastal settlements are particularly at risk (*high confidence*⁶), but urban flooding could be a problem anywhere that storm drains, water supply, and waste management systems have inadequate capacity. In such areas, squatter and other informal urban settlements with high population density, poor shelter, little or no access to resources such as safe water and public health services, and low adaptive capacity are highly vulnerable. Human settlements currently experience other significant environmental problems which could be exacerbated under higher temperature/increased precipitation regimes, including water and energy resources and infrastructure, waste treatment, and transportation [4.5]

Rapid urbanization in low-lying coastal areas of both the developing and developed world is greatly increasing population densities and the value of human-made assets exposed to coastal climatic extremes such as tropical cyclones. Model-based projections of the mean annual number of people who would be flooded by coastal storm surges increase several fold (by 75 to 200 million people depending on adaptive responses) for mid-range scenarios of a 40-cm sea-level rise by the 2080s relative to scenarios with no sea-level rise. Potential damages to infrastructure in coastal areas from sea-level rise have been projected to be tens of billions US\$ for individual countries—for example, Egypt, Poland, and Vietnam. [4.5]

Settlements with little economic diversification and where a high percentage of incomes derive from climate-sensitive primary resource industries (agriculture, forestry, and fisheries) are more vulnerable than more diversified settlements (*high confidence*⁶). In developed areas of the Arctic, and where the permafrost is ice-rich, special attention will be required to mitigate the detrimental impacts of thawing, such as severe damage to buildings and transport infrastructure (*very high confidence*⁶). Industrial, transportation, and commercial infrastructure is generally vulnerable to the same hazards as settlement infrastructure. Energy demand is expected to increase for space cooling and decrease for space heating, but the net effect is scenario- and location-dependent. Some energy production and distribution systems may experience adverse impacts that would reduce supplies or system reliability while other energy systems may benefit. [4.5 and 5.7]

Possible adaptation options involve the planning of settlements and their infrastructure, placement of industrial facilities, and making similar long-lived decisions in a manner to reduce the adverse effects of events that are of low (but increasing) probability and high (and perhaps rising) consequences. [4.5]

3.7. Insurance and Other Financial Services

The costs of ordinary and extreme weather events have increased rapidly in recent decades. Global economic losses from catastrophic events increased 10.3-fold from 3.9 billion

US\$ yr⁻¹ in the 1950s to 40 billion US\$ yr⁻¹ in the 1990s (all in 1999US\$, unadjusted for purchasing power parity), with approximately one-quarter of the losses occurring in developing countries. The insured portion of these losses rose from a negligible level to 9.2 billion US\$ yr⁻¹ during the same period. Total costs are a factor of two larger when losses from smaller, non-catastrophic weather-related events are included. As a measure of increasing insurance industry vulnerability, the ratio of global property/casual insurance premiums to weather related losses fell by a factor of three between 1985 and 1999. [4.6]

The costs of weather events have risen rapidly despite significant and increasing efforts at fortifying infrastructure and enhancing disaster preparedness. Part of the observed upward trend in disaster losses over the past 50 years is linked to socioeconomic factors, such as population growth, increased wealth, and urbanization in vulnerable areas, and part is linked to climatic factors such as the observed changes in precipitation and flooding events. Precise attribution is complex and there are differences in the balance of these two causes by region and type of event. [4.6]

Climate change and anticipated changes in weather-related events perceived to be linked to climate change would increase actuarial uncertainty in risk assessment (*high confidence*⁶). Such developments would place upward pressure on insurance premiums and/or could lead to certain risks being reclassified as uninsurable with subsequent withdrawal of coverage. Such changes would trigger increased insurance costs, slow the expansion of financial services into developing countries, reduce the availability of insurance for spreading risk, and increase the demand for government-funded compensation following natural disasters. In the event of such changes, the relative roles of public and private entities in providing insurance and risk management resources can be expected to change. [4.6]

The financial services sector as a whole is expected to be able to cope with the impacts of climate change, although the historic record demonstrates that low-probability high-impact events or multiple closely spaced events severely affect parts of the sector, especially if adaptive capacity happens to be simultaneously depleted by non-climate factors (e.g., adverse financial market conditions). The property/casualty insurance and reinsurance segments and small specialized or undiversified companies have exhibited greater sensitivity, including reduced profitability and bankruptcy triggered by weather-related events. [4.6]

Adaptation to climate change presents complex challenges, but also opportunities, to the sector. Regulatory involvement in pricing, tax treatment of reserves, and the (in)ability of firms to withdraw from at-risk markets are examples of factors that influence the resilience of the sector. Public- and private-sector actors also support adaptation by promoting disaster preparedness, loss-prevention programs, building codes, and improved land-use planning. However, in some cases, public insurance and

Table SPM-2: Regional adaptive capacity, vulnerability, and key concerns.^{a,b}

Region	Adaptive Capacity, Vulnerability, and Key Concerns
Africa	<ul style="list-style-type: none"> Adaptive capacity of human systems in Africa is low due to lack of economic resources and technology, and vulnerability high as a result of heavy reliance on rain-fed agriculture, frequent droughts and floods, and poverty. [5.1.7] Grain yields are projected to decrease for many scenarios, diminishing food security, particularly in small food-importing countries (<i>medium to high confidence</i>⁶). [5.1.2] Major rivers of Africa are highly sensitive to climate variation; average runoff and water availability would decrease in Mediterranean and southern countries of Africa (<i>medium confidence</i>⁶). [5.1.1] Extension of ranges of infectious disease vectors would adversely affect human health in Africa (<i>medium confidence</i>⁶). [5.1.4] Desertification would be exacerbated by reductions in average annual rainfall, runoff, and soil moisture, especially in southern, North, and West Africa (<i>medium confidence</i>⁶). [5.1.6] Increases in droughts, floods, and other extreme events would add to stresses on water resources, food security, human health, and infrastructures, and would constrain development in Africa (<i>high confidence</i>⁶). [5.1] Significant extinctions of plant and animal species are projected and would impact rural livelihoods, tourism, and genetic resources (<i>medium confidence</i>⁶). [5.1.3] Coastal settlements in, for example, the Gulf of Guinea, Senegal, Gambia, Egypt, and along the East–Southern African coast would be adversely impacted by sea-level rise through inundation and coastal erosion (<i>high confidence</i>⁶). [5.1.5]
Asia	<ul style="list-style-type: none"> Adaptive capacity of human systems is low and vulnerability is high in the developing countries of Asia; the developed countries of Asia are more able to adapt and less vulnerable. [5.2.7] Extreme events have increased in temperate and tropical Asia, including floods, droughts, forest fires, and tropical cyclones (<i>high confidence</i>⁶). [5.2.4] Decreases in agricultural productivity and aquaculture due to thermal and water stress, sea-level rise, floods and droughts, and tropical cyclones would diminish food security in many countries of arid, tropical, and temperate Asia; agriculture would expand and increase in productivity in northern areas (<i>medium confidence</i>⁶). [5.2.1] Runoff and water availability may decrease in arid and semi-arid Asia but increase in northern Asia (<i>medium confidence</i>⁶). [5.2.3] Human health would be threatened by possible increased exposure to vector-borne infectious diseases and heat stress in parts of Asia (<i>medium confidence</i>⁶). [5.2.6] Sea-level rise and an increase in the intensity of tropical cyclones would displace tens of millions of people in low-lying coastal areas of temperate and tropical Asia; increased intensity of rainfall would increase flood risks in temperate and tropical Asia (<i>high confidence</i>⁶). [5.2.5 and Table TS-8] Climate change would increase energy demand, decrease tourism attraction, and influence transportation in some regions of Asia (<i>medium confidence</i>⁶). [5.2.4 and 5.2.7] Climate change would exacerbate threats to biodiversity due to land-use and land-cover change and population pressure in Asia (<i>medium confidence</i>⁶). Sea-level rise would put ecological security at risk, including mangroves and coral reefs (<i>high confidence</i>⁶). [5.2.2] Poleward movement of the southern boundary of the permafrost zones of Asia would result in a change of thermokarst and thermal erosion with negative impacts on social infrastructure and industries (<i>medium confidence</i>⁶). [5.2.2]

relief programs have inadvertently fostered complacency and maladaptation by inducing development in at-risk areas such as U.S. flood plains and coastal zones. [4.6]

The effects of climate change are expected to be greatest in the developing world, especially in countries reliant on primary production as a major source of income. Some countries experience impacts on their GDP as a consequence of natural disasters, with damages as high as half of GDP in one case. Equity issues and development constraints would arise if weather-related risks become uninsurable, prices increase, or

availability becomes limited. Conversely, more extensive access to insurance and more widespread introduction of micro-financing schemes and development banking would increase the ability of developing countries to adapt to climate change. [4.6]

4. Vulnerability Varies across Regions

The vulnerability of human populations and natural systems to climate change differs substantially across regions and across

Table SPM-2 (continued)

Region	Adaptive Capacity, Vulnerability, and Key Concerns
Australia and New Zealand	<ul style="list-style-type: none"> Adaptive capacity of human systems is generally high, but there are groups in Australia and New Zealand, such as indigenous peoples in some regions, with low capacity to adapt and consequently high vulnerability. [5.3 and 5.3.5] The net impact on some temperate crops of climate and CO₂ changes may initially be beneficial, but this balance is expected to become negative for some areas and crops with further climate change (<i>medium confidence</i>⁶). [5.3.3] Water is likely to be a key issue (<i>high confidence</i>⁶) due to projected drying trends over much of the region and change to a more El Niño-like average state. [5.3 and 5.3.1] Increases in the intensity of heavy rains and tropical cyclones (<i>medium confidence</i>⁶), and region-specific changes in the frequency of tropical cyclones, would alter the risks to life, property, and ecosystems from flooding, storm surges, and wind damage. [5.3.4] Some species with restricted climatic niches and which are unable to migrate due to fragmentation of the landscape, soil differences, or topography could become endangered or extinct (<i>high confidence</i>⁶). Australian ecosystems that are particularly vulnerable to climate change include coral reefs, arid and semi-arid habitats in southwest and inland Australia, and Australian alpine systems. Freshwater wetlands in coastal zones in both Australia and New Zealand are vulnerable, and some New Zealand ecosystems are vulnerable to accelerated invasion by weeds. [5.3.2]
Europe	<ul style="list-style-type: none"> Adaptive capacity is generally high in Europe for human systems; southern Europe and the European Arctic are more vulnerable than other parts of Europe. [5.4 and 5.4.6] Summer runoff, water availability, and soil moisture are likely to decrease in southern Europe, and would widen the difference between the north and drought-prone south; increases are likely in winter in the north and south (<i>high confidence</i>⁶). [5.4.1] Half of alpine glaciers and large permafrost areas could disappear by end of the 21st century (<i>medium confidence</i>⁶). [5.4.1] River flood hazard will increase across much of Europe (<i>medium to high confidence</i>⁶); in coastal areas, the risk of flooding, erosion, and wetland loss will increase substantially with implications for human settlement, industry, tourism, agriculture, and coastal natural habitats. [5.4.1 and 5.4.4] There will be some broadly positive effects on agriculture in northern Europe (<i>medium confidence</i>⁶); productivity will decrease in southern and eastern Europe (<i>medium confidence</i>⁶). [5.4.3] Upward and northward shift of biotic zones will take place. Loss of important habitats (wetlands, tundra, isolated habitats) would threaten some species (<i>high confidence</i>⁶). [5.4.2] Higher temperatures and heat waves may change traditional summer tourist destinations, and less reliable snow conditions may impact adversely on winter tourism (<i>medium confidence</i>⁶). [5.4.4]
Latin America	<ul style="list-style-type: none"> Adaptive capacity of human systems in Latin America is low, particularly with respect to extreme climate events, and vulnerability is high. [5.5] Loss and retreat of glaciers would adversely impact runoff and water supply in areas where glacier melt is an important water source (<i>high confidence</i>⁶). [5.5.1] Floods and droughts would become more frequent with floods increasing sediment loads and degrade water quality in some areas (<i>high confidence</i>⁶). [5.5] Increases in intensity of tropical cyclones would alter the risks to life, property, and ecosystems from heavy rain, flooding, storm surges, and wind damages (<i>high confidence</i>⁶). [5.5] Yields of important crops are projected to decrease in many locations in Latin America, even when the effects of CO₂ are taken into account; subsistence farming in some regions of Latin America could be threatened (<i>high confidence</i>⁶). [5.5.4] The geographical distribution of vector-borne infectious diseases would expand poleward and to higher elevations, and exposures to diseases such as malaria, dengue fever, and cholera will increase (<i>medium confidence</i>⁶). [5.5.5] Coastal human settlements, productive activities, infrastructure, and mangrove ecosystems would be negatively affected by sea-level rise (<i>medium confidence</i>⁶). [5.5.3] The rate of biodiversity loss would increase (<i>high confidence</i>⁶). [5.5.2]

populations within regions. Regional differences in baseline climate and expected climate change give rise to different exposures to climate stimuli across regions. The natural and social systems of different regions have varied characteristics, resources, and institutions, and are subject to varied pressures

that give rise to differences in sensitivity and adaptive capacity. From these differences emerge different key concerns for each of the major regions of the world. Even within regions however, impacts, adaptive capacity, and vulnerability will vary. [5]

Table SPM-2 (continued)

Region	Adaptive Capacity, Vulnerability, and Key Concerns
North America	<ul style="list-style-type: none"> • Adaptive capacity of human systems is generally high and vulnerability low in North America, but some communities (e.g., indigenous peoples and those dependent on climate-sensitive resources) are more vulnerable; social, economic, and demographic trends are changing vulnerabilities in subregions. [5.6 and 5.6.1] • Some crops would benefit from modest warming accompanied by increasing CO₂, but effects would vary among crops and regions (<i>high confidence</i>⁶), including declines due to drought in some areas of Canada's Prairies and the U.S. Great Plains, potential increased food production in areas of Canada north of current production areas, and increased warm-temperate mixed forest production (<i>medium confidence</i>⁶). However, benefits for crops would decline at an increasing rate and possibly become a net loss with further warming (<i>medium confidence</i>⁶). [5.6.4] • Snowmelt-dominated watersheds in western North America will experience earlier spring peak flows (<i>high confidence</i>⁶), reductions in summer flows (<i>medium confidence</i>⁶), and reduced lake levels and outflows for the Great Lakes-St. Lawrence under most scenarios (<i>medium confidence</i>⁶); adaptive responses would offset some, but not all, of the impacts on water users and on aquatic ecosystems (<i>medium confidence</i>⁶). [5.6.2] • Unique natural ecosystems such as prairie wetlands, alpine tundra, and cold-water ecosystems will be at risk and effective adaptation is unlikely (<i>medium confidence</i>⁶). [5.6.5] • Sea-level rise would result in enhanced coastal erosion, coastal flooding, loss of coastal wetlands, and increased risk from storm surges, particularly in Florida and much of the U.S. Atlantic coast (<i>high confidence</i>⁶). [5.6.1] • Weather-related insured losses and public sector disaster relief payments in North America have been increasing; insurance sector planning has not yet systematically included climate change information, so there is potential for surprise (<i>high confidence</i>⁶). [5.6.1] • Vector-borne diseases—including malaria, dengue fever, and Lyme disease—may expand their ranges in North America; exacerbated air quality and heat stress morbidity and mortality would occur (<i>medium confidence</i>⁶); socioeconomic factors and public health measures would play a large role in determining the incidence and extent of health effects. [5.6.6]
Polar	<ul style="list-style-type: none"> • Natural systems in polar regions are highly vulnerable to climate change and current ecosystems have low adaptive capacity; technologically developed communities are likely to adapt readily to climate change, but some indigenous communities, in which traditional lifestyles are followed, have little capacity and few options for adaptation. [5.7] • Climate change in polar regions is expected to be among the largest and most rapid of any region on the Earth, and will cause major physical, ecological, sociological, and economic impacts, especially in the Arctic, Antarctic Peninsula, and Southern Ocean (<i>high confidence</i>⁶). [5.7] • Changes in climate that have already taken place are manifested in the decrease in extent and thickness of Arctic sea ice, permafrost thawing, coastal erosion, changes in ice sheets and ice shelves, and altered distribution and abundance of species in polar regions (<i>high confidence</i>⁶). [5.7] • Some polar ecosystems may adapt through eventual replacement by migration of species and changing species composition, and possibly by eventual increases in overall productivity; ice edge systems that provide habitat for some species would be threatened (<i>medium confidence</i>⁶). [5.7] • Polar regions contain important drivers of climate change. Once triggered, they may continue for centuries, long after greenhouse gas concentrations are stabilized, and cause irreversible impacts on ice sheets, global ocean circulation, and sea-level rise (<i>medium confidence</i>⁶). [5.7]

In light of the above, all regions are likely to experience some adverse effects of climate change. Table SPM-2 presents in a highly summarized fashion some of the key concerns for the different regions. Some regions are particularly vulnerable because of their physical exposure to climate change hazards and/or their limited adaptive capacity. Most less-developed regions are especially vulnerable because a larger share of their economies are in climate-sensitive sectors and their adaptive capacity is low due to low levels of human, financial, and natural resources, as well as limited institutional and technological capability. For example, small island states and low-lying coastal areas are particularly vulnerable to increases in sea level and storms, and most of them have limited capabilities for

adaptation. Climate change impacts in polar regions are expected to be large and rapid, including reduction in sea-ice extent and thickness and degradation of permafrost. Adverse changes in seasonal river flows, floods and droughts, food security, fisheries, health effects, and loss of biodiversity are among the major regional vulnerabilities and concerns of Africa, Latin America, and Asia where adaptation opportunities are generally low. Even in regions with higher adaptive capacity, such as North America and Australia and New Zealand, there are vulnerable communities, such as indigenous peoples, and the possibility of adaptation of ecosystems is very limited. In Europe, vulnerability is significantly greater in the south and in the Arctic than elsewhere in the region. [5]

Table SPM-2 (continued)

Region	Adaptive Capacity, Vulnerability, and Key Concerns
Small Island States	<ul style="list-style-type: none"> • Adaptive capacity of human systems is generally low in small island states, and vulnerability high; small island states are likely to be among the countries most seriously impacted by climate change. [5.8] • The projected sea-level rise of 5 mm yr⁻¹ for the next 100 years would cause enhanced coastal erosion, loss of land and property, dislocation of people, increased risk from storm surges, reduced resilience of coastal ecosystems, saltwater intrusion into freshwater resources, and high resource costs to respond to and adapt to these changes (<i>high confidence</i>⁶). [5.8.2 and 5.8.5] • Islands with very limited water supplies are highly vulnerable to the impacts of climate change on the water balance (<i>high confidence</i>⁶). [5.8.4] • Coral reefs would be negatively affected by bleaching and by reduced calcification rates due to higher CO₂ levels (<i>medium confidence</i>⁶); mangrove, sea grass bed, and other coastal ecosystems and the associated biodiversity would be adversely affected by rising temperatures and accelerated sea-level rise (<i>medium confidence</i>⁶). [4.4 and 5.8.3] • Declines in coastal ecosystems would negatively impact reef fish and threaten reef fisheries, those who earn their livelihoods from reef fisheries, and those who rely on the fisheries as a significant food source (<i>medium confidence</i>⁶). [4.4 and 5.8.4] • Limited arable land and soil salinization makes agriculture of small island states, both for domestic food production and cash crop exports, highly vulnerable to climate change (<i>high confidence</i>⁶). [5.8.4] • Tourism, an important source of income and foreign exchange for many islands, would face severe disruption from climate change and sea-level rise (<i>high confidence</i>⁶). [5.8.5]

^a Because the available studies have not employed a common set of climate scenarios and methods, and because of uncertainties regarding the sensitivities and adaptability of natural and social systems, the assessment of regional vulnerabilities is necessarily qualitative.

^b The regions listed in Table SPM-2 are graphically depicted in Figure TS-2 of the Technical Summary.

5. Improving Assessments of Impacts, Vulnerabilities, and Adaptation

Advances have been made since previous IPCC assessments in the detection of change in biotic and physical systems, and steps have been taken to improve the understanding of adaptive capacity, vulnerability to climate extremes, and other critical impact-related issues. These advances indicate a need for initiatives to begin designing adaptation strategies and building adaptive capacities. Further research is required, however, to strengthen future assessments and to reduce uncertainties in order to assure that sufficient information is available for policymaking about responses to possible consequences of climate change, including research in and by developing countries. [8]

The following are high priorities for narrowing gaps between current knowledge and policymaking needs:

- Quantitative assessment of the sensitivity, adaptive capacity, and vulnerability of natural and human systems to climate change, with particular emphasis on changes in the range of climatic variation and the frequency and severity of extreme climate events
- Assessment of possible thresholds at which strongly discontinuous responses to projected climate change and other stimuli would be triggered
- Understanding dynamic responses of ecosystems to multiple stresses, including climate change, at global, regional, and finer scales
- Development of approaches to adaptation responses, estimation of the effectiveness and costs of adaptation

options, and identification of differences in opportunities for and obstacles to adaptation in different regions, nations, and populations

- Assessment of potential impacts of the full range of projected climate changes, particularly for non-market goods and services, in multiple metrics and with consistent treatment of uncertainties, including but not limited to numbers of people affected, land area affected, numbers of species at risk, monetary value of impact, and implications in these regards of different stabilization levels and other policy scenarios
- Improving tools for integrated assessment, including risk assessment, to investigate interactions between components of natural and human systems and the consequences of different policy decisions
- Assessment of opportunities to include scientific information on impacts, vulnerability, and adaptation in decisionmaking processes, risk management, and sustainable development initiatives
- Improvement of systems and methods for long-term monitoring and understanding the consequences of climate change and other stresses on human and natural systems.

Cutting across these foci are special needs associated with strengthening international cooperation and coordination for regional assessment of impacts, vulnerability, and adaptation, including capacity-building and training for monitoring, assessment, and data gathering, especially in and for developing countries (particularly in relation to the items identified above).

TECHNICAL SUMMARY

CLIMATE CHANGE 2001: IMPACTS, ADAPTATION, AND VULNERABILITY

A Report of Working Group II of the Intergovernmental Panel on Climate Change

This summary was accepted but not approved in detail at the Sixth Session of IPCC Working Group II (Geneva, Switzerland • 13-16 February 2001). “Acceptance” of IPCC reports at a session of the Working Group or Panel signifies that the material has not been subject to line-by-line discussion and agreement, but nevertheless presents a comprehensive, objective, and balanced view of the subject matter.

1. Scope and Approach of the Assessment

1.1. Mandate of the Assessment

The Intergovernmental Panel on Climate Change (IPCC) was established by World Meteorological Organization and United Nations Environmental Programme (UNEP) in 1988 to assess scientific, technical, and socioeconomic information that is relevant in understanding human-induced climate change, its potential impacts, and options for mitigation and adaptation. The IPCC currently is organized into three Working Groups: Working Group I (WGI) addresses observed and projected changes in climate; Working Group II (WGII) addresses vulnerability, impacts, and adaptation related to climate change; and Working Group III (WGIII) addresses options for mitigation of climate change.

This volume—*Climate Change 2001: Impacts, Adaptation, and Vulnerability*—is the WGII contribution to the IPCC’s Third Assessment Report (TAR) on scientific, technical, environmental, economic, and social issues associated with the climate system and climate change.¹ WGII’s mandate for the TAR is to assess the vulnerability of ecological systems, socioeconomic sectors, and human health to climate change as well as potential impacts of climate change, positive and negative, on these systems. This assessment also examines the feasibility of adaptation to enhance the positive effects of climate change and ameliorate negative effects. This new assessment builds on previous IPCC assessments, reexamining key findings of earlier assessments and emphasizing new information and implications from more recent studies.

1.2. What is Potentially at Stake?

Human activities—primarily burning of fossil fuels and changes in land cover—are modifying the concentration of atmospheric constituents or properties of the surface that absorb or scatter radiant energy. The WGI contribution to the TAR—*Climate Change 2001: The Scientific Basis*—found, “In the light of new evidence and taking into account the remaining uncertainties, most of the observed warming over the last 50 years is likely to have been due to the increase in greenhouse gas concentrations.” Future changes in climate are expected to include additional warming, changes in precipitation patterns and amounts, sea-level rise, and changes in the frequency and intensity of some extreme events.

The stakes associated with projected changes in climate are high. Numerous Earth systems that sustain human societies are sensitive to climate and will be impacted by changes in climate (very high confidence). Impacts can be expected in ocean circulation; sea level; the water cycle; carbon and nutrient cycles; air quality; the productivity and structure of natural ecosystems; the productivity of agricultural, grazing, and timber lands; and the geographic distribution, behavior, abundance, and survival of plant and animal species, including vectors and hosts of human disease. Changes in these systems in response

Box 1. Climate Change Sensitivity, Adaptability, and Vulnerability

Sensitivity is the degree to which a system is affected, either adversely or beneficially, by climate-related stimuli. Climate-related stimuli encompass all the elements of climate change, including mean climate characteristics, climate variability, and the frequency and magnitude of extremes. The effect may be direct (e.g., a change in crop yield in response to a change in the mean, range or variability of temperature) or indirect (e.g., damages caused by an increase in the frequency of coastal flooding due to sea-level rise).

Adaptive capacity is the ability of a system to adjust to climate change, including climate variability and extremes, to moderate potential damages, to take advantage of opportunities, or to cope with the consequences.

Vulnerability is the degree to which a system is susceptible to, or unable to cope with, adverse effects of climate change, including climate variability and extremes. Vulnerability is a function of the character, magnitude and rate of climate change and variation to which a system is exposed, its sensitivity, and its adaptive capacity.

to climate change, as well as direct effects of climate change on humans, would affect human welfare, positively and negatively. Human welfare would be impacted through changes in supplies of and demands for water, food, energy, and other tangible goods that are derived from these systems; changes in opportunities for nonconsumptive uses of the environment for recreation and tourism; changes in non-use values of the environment such as cultural and preservation values; changes in incomes; changes in loss of property and lives from extreme climate phenomena; and changes in human health. Climate change impacts will affect the prospects for sustainable development in different parts of the world and may further widen existing inequalities. Impacts will vary in distribution across people, places, and times (very high confidence), raising important questions about equity.

Although the stakes are demonstrably high, the risks associated with climate change are less easily established. Risks are a function of the probability and magnitude of different types of impacts. The WGII report assesses advances in the state of

¹Climate change in IPCC usage refers to any change in climate over time, whether due to natural variability or as a result of human activity. This usage differs from the definition in Article 1 of the United Nations Framework Convention on Climate Change, where *climate change* refers to a change of climate which is attributed directly or indirectly to human activity that alters the composition of the global atmosphere and which is in addition to natural climate variability observed over comparable time periods.

knowledge regarding impacts of climate stimuli to which systems may be exposed, the sensitivity of exposed systems to changes in climate stimuli, their adaptive capacity to alleviate or cope with adverse impacts or enhance beneficial ones, and their vulnerability to adverse impacts (see Box 1). Possible impacts include impacts that threaten substantial and irreversible damage to or loss of some systems within the next century; modest impacts to which systems may readily adapt; and impacts that would be beneficial for some systems.

Figure TS-1 illustrates the scope of the WGII assessment and its relation to other parts of the climate change system. Human activities that change the climate expose natural and human systems to an altered set of stresses or stimuli. Systems that are sensitive to these stimuli are affected or impacted by the changes, which can trigger autonomous, or expected, adaptations. These autonomous adaptations will reshape the residual or net impacts of climate change. Policy responses in reaction to impacts already perceived or in anticipation of potential future impacts can take the form of planned adaptations to lessen adverse effects or enhance beneficial ones. Policy responses also can take the form of actions to mitigate climate change through greenhouse gas (GHG) emission reductions and enhancement of sinks. The WGII assessment focuses on the central box of Figure TS-1—exposure, impacts, and vulnerabilities—and the adaptation policy loop.

1.3. Approach of the Assessment

The assessment process involves evaluation and synthesis of available information to advance understanding of climate change impacts, adaptation, and vulnerability. The information comes predominately from peer-reviewed published literature. Evidence also is drawn from published, non-peer-reviewed literature and unpublished sources, but only after evaluation of its quality and validity by the authors of this report.

WGII's assessment has been conducted by an international group of experts nominated by governments and scientific bodies and selected by the WGII Bureau of the IPCC for their scientific and technical expertise and to achieve broad geographical balance. These experts come from academia, governments, industry, and scientific and environmental organizations. They participate without compensation from the IPCC, donating substantial time to support the work of the IPCC.

This assessment is structured to examine climate change impacts, adaptations, and vulnerabilities of systems and regions and to provide a global synthesis of cross-system and cross-regional issues. To the extent feasible, given the available literature, climate change is examined in the context of sustainable development and equity. The first section sets the stage for the

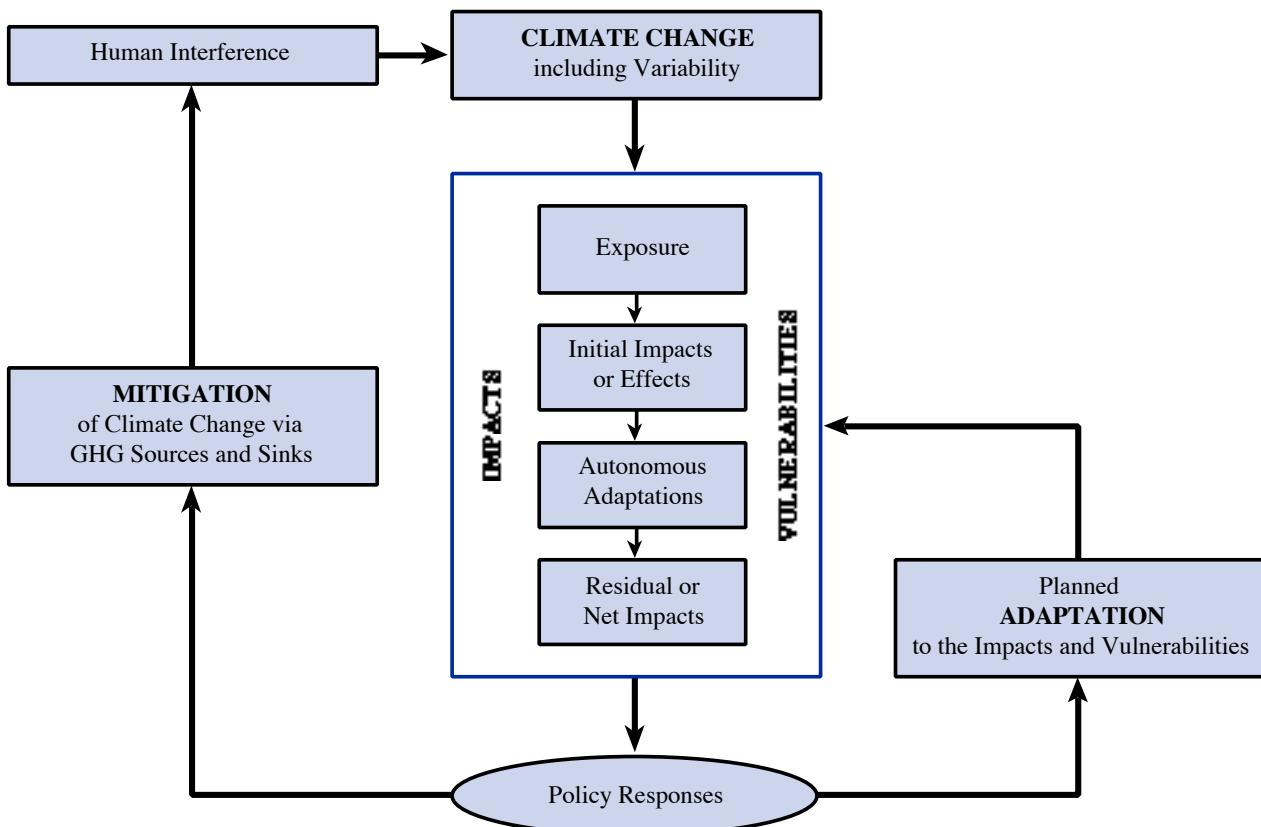

Figure TS-1: Scope of the Working Group II assessment.

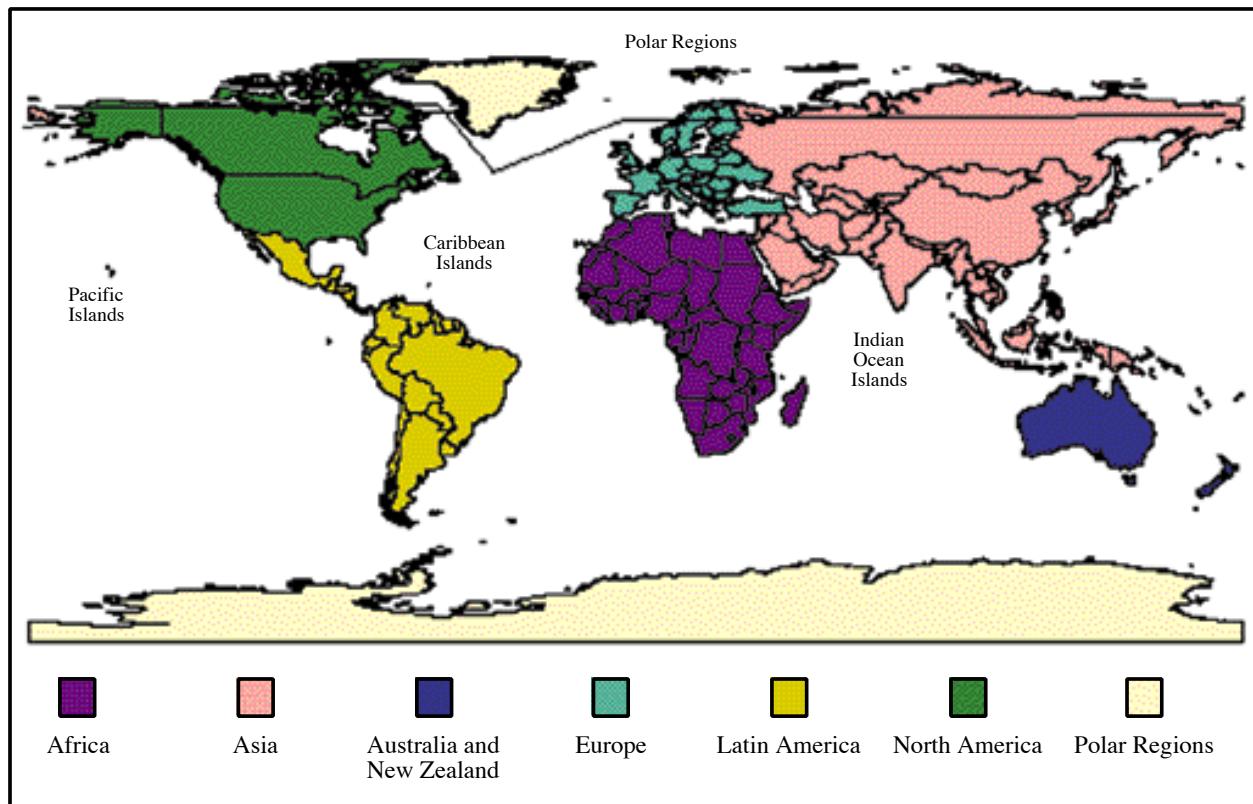

Figure TS-2: Regions for the IPCC Working Group II Third Assessment Report. Note that regions in which small island states are located include the Pacific, Indian, and Atlantic Oceans, and the Caribbean and Mediterranean Seas. The boundary between Europe and Asia runs along the eastern Ural Mountains, River Ural, and Caspian Sea. For the polar regions, the Arctic consists of the area north of the Arctic Circle, including Greenland; the Antarctic consists of the Antarctic continent, together with the Southern Ocean south of ~58°S.

assessment by discussing the context of climate change, methods and tools, and scenarios. Individual chapters assess vulnerabilities of water systems, terrestrial ecosystems (including agriculture and forestry), ocean and coastal systems, human settlements (including energy and industrial sectors), insurance and other financial services, and human health. A chapter is devoted to each of eight major regions of the world: Africa, Asia, Australia and New Zealand, Europe, Latin America, North America, polar regions, and small island states. These regions are shown in Figure TS-2. All of the regions are highly heterogeneous, and climate change impacts, adaptive capacity, and vulnerability will vary in important ways within each of the regions. The final section of the report synthesizes adaptation capacity and its potential to alleviate adverse impacts, enhance beneficial effects, and increase sustainable development and equity and reviews information that is relevant for interpretation of Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC) and key provisions of international agreements to address climate change. The report also contains a Summary for Policymakers, which provides a brief synthesis of the conclusions of the report that have particular relevance to those who have responsibility for making climate change response decisions. This Technical Summary provides a more

comprehensive summary of the assessment; it references sections of the underlying report in brackets at the end of the paragraphs for readers who would like more information on a particular topic. [1.1]

1.4. Treatment of Uncertainties

Since the SAR, greater emphasis has been placed on developing methods for characterizing and communicating uncertainties. Two approaches to evaluate uncertainties are applied in the WGII assessment. A quantitative approach is adopted to assess confidence levels in instances for which present understanding of relevant processes, system behavior, observations, model simulations, and estimates is sufficient to support broad agreement among authors of the report about Bayesian probabilities associated with selected findings. A more qualitative approach is used to assess and report the quality or level of scientific understanding that supports a conclusion (see Box 2). These approaches, and the rationale for them, are explained in more detail in *Third Assessment Report: Cross-Cutting Issues Guidance Papers* (<http://www.gispri.or.jp>), supporting material prepared by the IPCC to increase the use of consistent terms

and concepts within and across the Working Group volumes of the TAR. [1.1, 2.6]

2. Methods and Tools of the Assessment

Assessment of climate change impacts, adaptations, and vulnerability draws on a wide range of physical, biological, and social science disciplines and consequently employs an enormous variety of methods and tools. Since the SAR, such methods have improved detection of climate change in biotic and physical systems and produced new substantive findings. In addition, cautious steps have been taken since the SAR to expand the “tool-box” to address more effectively the human dimensions of climate as both causes and consequences of change and to deal more directly with cross-sectoral issues concerning vulnerability, adaptation, and decisionmaking. In particular, a greater number of studies have begun to apply methods and tools for costing and valuing effects, treating uncertainties, integrating effects across sectors and regions, and applying decision analytic frameworks for evaluating adaptive capacity. Overall, these modest methodological developments are encouraging analyses that will build a more solid foundation for understanding how decisions regarding adaptation to future climate change might be taken. [2.8]

2.1. Detecting Responses to Climate Change using Indicator Species or Systems

Since the SAR, methods have been developed and applied to the detection of present impacts of 20th century climate change on abiotic and biotic systems. Assessment of impacts on human and natural systems that already have occurred as a result of recent climate change is an important complement to model projections of future impacts. Such detection is impeded by multiple, often inter-correlated, nonclimatic forces that concurrently affect those systems. Attempts to overcome this problem have involved the use of indicator species (e.g., butterflies, penguins, frogs, and sea anemones) to detect responses to climate change and to infer more general impacts of climate change on natural systems (e.g., in native meadows, coastal Antarctica, tropical cloud forest, and the Pacific rocky intertidal, respectively). An important component of this detection process is the search for systematic patterns of change across many studies that are consistent with expectations, based on observed or predicted changes in climate. Confidence in attribution of these observed changes to climate change increases as studies are replicated across diverse systems and geographic regions. Even though studies now number in the hundreds, some regions and systems remain underrepresented. [2.2]

To investigate possible links between observed changes in regional climate and biological or physical processes in ecosystems, the author team gathered more than 2,500 articles on climate and one of the following entities: animals, plants, glaciers, sea ice, and ice on lakes or streams. To determine if these entities have been influenced by changing climate, only

Box 2. Confidence Levels and State of Knowledge

Quantitative Assessment of Confidence Levels

In applying the *quantitative* approach, authors of the report assign a confidence level that represents the degree of belief among the authors in the validity of a conclusion, based on their collective expert judgment of observational evidence, modeling results, and theory that they have examined. Five confidence levels are used. In the tables of the Technical Summary, symbols are substituted for words:

Very High (*****)	95% or greater
High (****)	67–95%
Medium(***)	33–67%
Low (**)	5–33%
Very Low (*)	5% or less

Qualitative Assessment of the State of Knowledge

In applying the *qualitative* approach, authors of the report evaluate the level of scientific understanding in support of a conclusion, based on the amount of supporting evidence and the level of agreement among experts about the interpretation of the evidence. Four qualitative classifications are employed:

- *Well-established:* Models incorporate known processes, observations are consistent with models, or multiple lines of evidence support the finding.
- *Established but incomplete:* Models incorporate most known processes, although some parameterizations may not be well tested; observations are somewhat consistent but incomplete; current empirical estimates are well founded, but the possibility of changes in governing processes over time is considerable; or only one or a few lines of evidence support the finding.
- *Competing explanations:* Different model representations account for different aspects of observations or evidence or incorporate different aspects of key processes, leading to competing explanations.
- *Speculative:* Conceptually plausible ideas that are not adequately represented in the literature or that contain many difficult-to-reduce uncertainties [Box 1-1]

studies meeting at least two of the following criteria were included:

- A trait of these entities (e.g., range boundary, melting date) shows a change over time.
- The trait is correlated with changes in local temperature.
- Local temperature changed over time.

At least two of these three criteria had to exhibit a statistically significant correlation. Only temperature was considered because it is well established in the literature how it influences the entities examined and because temperature trends are more globally homogeneous than other locally varying climatic factors, such as precipitation changes. Selected studies must also have examined at least 10 years of data; more than 90% had a time span of more than 20 years.

These stringent criteria reduced the number of studies used in the analysis to 44 animal and plant studies that cover more than 600 species. Of these species, about 90% (more than 550) show changes in traits over time. Of these 550+ species, about 80% (more than 450) show change in a direction expected given scientific understanding of known mechanisms that relate temperature to each of the species traits. The probability that more than 450 species of 550+ would show changes in the directions expected by random chance is negligible.

Sixteen studies examining glaciers, sea ice, snow cover extent/snow melt, or ice on lakes or streams included more than 150 sites. Of these 150+ sites, 67% (100+) show changes in traits over time. Of these 100+ sites, about 99% (99+) exhibited trends in a direction expected, given scientific understanding of known mechanisms that relate temperatures to physical processes that govern change in that trait. The probability that 99+ of 100+ sites would show changes in the directions expected by chance alone is negligible. [5.2, 5.4, 19.2]

2.2. Anticipating the Effects of Future Climate Change

Since the SAR, improvements in methods and tools for studying impacts of future changes in climate have included greater emphasis on the use of process-oriented models, transient climate change scenarios, refined socioeconomic baselines, and higher resolution spatial and temporal scales. Country studies and regional assessments in every continent have tested models and tools in a variety of contexts. First-order impact models have been linked to global systems models. Adaptation has been included in many assessments, often for the first time.

Methodological gaps remain concerning scales, data, validation, and integration of adaptation and the human dimensions of climate change. Procedures for assessing regional and local vulnerability and long-term adaptation strategies require high-resolution assessments, methodologies to link scales, and dynamic modeling that uses corresponding and new data sets. Validation at different scales often is lacking. Regional integration across sectors is required to place vulnerability in the context of local and regional development. Methods and tools to assess vulnerability to extreme events have improved but are constrained by low confidence in climate change scenarios and the sensitivity of impact models to major climatic anomalies. Understanding and integrating higher order economic effects and other human dimensions of global change are required. Adaptation models and vulnerability indices to prioritize adaptation options are at early stages of development in many

fields. Methods to enable stakeholder participation in assessments need improvement. [2.3]

2.3. Integrated Assessment

Integrated assessment is an interdisciplinary process that combines, interprets, and communicates knowledge from diverse scientific disciplines from the natural and social sciences to investigate and understand causal relationships within and between complicated systems. Methodological approaches employed in such assessments include computer-aided modeling, scenario analyses, simulation gaming and participatory integrated assessment, and qualitative assessments that are based on existing experience and expertise. Since the SAR, significant progress has been made in developing and applying such approaches to integrated assessment, globally and regionally.

However, progress to date, particularly with regard to integrated modeling, has focused largely on mitigation issues at the global or regional scale and only secondarily on issues of impacts, vulnerability, and adaptation. Greater emphasis on the development of methods for assessing vulnerability is required, especially at national and subnational scales where impacts of climate change are felt and responses are implemented. Methods designed to include adaptation and adaptive capacity explicitly in specific applications must be developed. [2.4]

2.4. Costing and Valuation

Methods of economic costing and valuation rely on the notion of opportunity cost of resources used, degraded, or saved. Opportunity cost depends on whether the market is competitive or monopolistic and on whether any externalities are internalized. It also depends on the rate at which the future is discounted, which can vary across countries, over time, and over generations. The impact of uncertainty also can be valued if the probabilities of different possible outcomes are known. Public and nonmarket goods and services can be valued through willingness to pay for them or willingness to accept compensation for lack of them. Impacts on different groups, societies, nations, and species must be assessed. Comparison of alternative distributions of welfare across individuals and groups within a country can be justified if they are made according to internally consistent norms. Comparisons across nations with different societal, ethical, and governmental structures cannot yet be made meaningfully.

Since the SAR, no new fundamental developments in costing and valuation methodology have taken place. Many new applications of existing methods to a widening range of climate change issues have demonstrated, however, the strengths and limitations of some of these methods. Research efforts are required to strengthen methods for multi-objective assessments. Multi-objective assessments are increasingly preferred, but the means by which their underlying metrics might more accurately reflect diverse social, political, economic, and cultural contexts

must be developed. In addition, methods for integrating across these multiple metrics are still missing from the methodological repertoire. [2.5]

2.5. Decision Analytic Frameworks

Policymakers who are responsible for devising and implementing adaptive policies should be able to rely on results from one or more of a diverse set of decision analytical frameworks. Commonly used methods include cost-benefit and cost-effectiveness analysis, various types of decision analysis (including multi-objective studies), and participatory techniques such as policy exercises.

Very few cases in which policymakers have used decision analytical frameworks in evaluating adaptation options have been reported. Among the large number of assessments of climate change impacts reviewed in the TAR, only a small fraction include comprehensive and quantitative estimates of adaptation options and their costs, benefits, and uncertainty characteristics. This information is necessary for meaningful applications of any decision analytical method to issues of adaptation. Greater use of such methods in support of adaptation decisions is needed to establish their efficacy and to identify directions for necessary research in the context of vulnerability and adaptation to climate change. [2.7]

3. Scenarios of Future Change

3.1. Scenarios and their Role

A scenario is a coherent, internally consistent, and plausible description of a possible future state of the world. Scenarios are commonly required in climate change impact, adaptation, and vulnerability assessments to provide alternative views of future conditions considered likely to influence a given system or activity. A distinction is made between climate scenarios, which describe the forcing factor of focal interest to the IPCC, and nonclimatic scenarios, which provide the socioeconomic and environmental context within which climate forcing operates. Most assessments of the impacts of future climate change are based on results from impact models that rely on quantitative climate and nonclimatic scenarios as inputs. [3.1.1, Box 3-1]

3.2. Socioeconomic, Land-Use, and Environmental Scenarios

Nonclimatic scenarios describing future socioeconomic, land-use, and environmental changes are important for characterizing the sensitivity of systems to climate change, their vulnerability, and the capacity for adaptation. Such scenarios only recently have been widely adopted in impact assessments alongside climate scenarios.

Socioeconomic scenarios. Socioeconomic scenarios have been used more extensively for projecting GHG emissions than for

assessing climate vulnerability and adaptive capacity. Most socioeconomic scenarios identify several different topics or domains, such as population or economic activity, as well as background factors such as the structure of governance, social values, and patterns of technological change. Scenarios make it possible to establish baseline socioeconomic vulnerability, pre-climate change; determine climate change impacts; and assess post-adaptation vulnerability. [3.2]

Land-use and land-cover change scenarios. Land-use change and land-cover change (LUC-LCC) involve several processes that are central to the estimation of climate change and its impacts. First, LUC-LCC influences carbon fluxes and GHG emissions, which directly alter atmospheric composition and radiative forcing properties. Second, LUC-LCC modifies land-surface characteristics and, indirectly, climatic processes. Third, land-cover modification and conversion may alter the properties of ecosystems and their vulnerability to climate change. Finally, several options and strategies for mitigating GHG emissions involve land cover and changed land-use practices. A great diversity of LUC-LCC scenarios have been constructed. Most of these scenarios do not address climate change issues explicitly, however; they focus on other issues—for example, food security and carbon cycling. Large improvements have been made since the SAR in defining current and historic land-use and land-cover patterns, as well as in estimating future scenarios. Integrated assessment models currently are the most appropriate tools for developing LUC-LCC scenarios. [3.3.1, 3.3.2]

Environmental scenarios. Environmental scenarios refer to changes in environmental factors other than climate that will occur in the future regardless of climate change. Because these factors could have important roles in modifying the impacts of future climate change, scenarios are required to portray possible future environmental conditions such as atmospheric composition [e.g., carbon dioxide (CO₂), tropospheric ozone, acidifying compounds, and ultraviolet-B (UV-B) radiation]; water availability, use, and quality; and marine pollution. Apart from the direct effects of CO₂ enrichment, changes in other environmental factors rarely have been considered alongside climate changes in past impact assessments, although their use is increasing with the emergence of integrated assessment methods. [3.4.1]

3.3. Sea-Level Rise Scenarios

Sea-level rise scenarios are required to evaluate a diverse range of threats to human settlements, natural ecosystems, and landscape in the coastal zone. Relative sea-level scenarios (i.e., sea-level rise with reference to movements of the local land surface) are of most interest for impact and adaptation assessments. Tide gauge and wave-height records of 50 years or more are required, along with information on severe weather and coastal processes, to establish baseline levels or trends. Recent techniques of satellite altimetry and geodetic leveling have enhanced and standardized baseline determinations of relative sea level over large areas of the globe. [3.6.2]

Although some components of future sea-level rise can be modeled regionally by using coupled ocean-atmosphere models, the most common method of obtaining scenarios is to apply global mean estimates from simple models. Changes in the occurrence of extreme events such as storm surges and wave setup, which can lead to major coastal impacts, sometimes are investigated by superimposing historically observed events onto a rising mean sea level. More recently, some studies have begun to express future sea-level rise in probabilistic terms, enabling rising levels to be evaluated in terms of the risk of exceeding a critical threshold of impact. [3.6.3, 3.6.4, 3.6.5, 3.6.6]

3.4. Climate Scenarios

Three main types of climate scenarios have been employed in impact assessments: incremental scenarios, analog scenarios, and climate model-based scenarios. Incremental scenarios are simple adjustments of the baseline climate according to anticipated future changes that can offer a valuable aid for testing system sensitivity to climate. However, because they involve arbitrary adjustments, they may not be realistic meteorologically. Analogs of a changed climate from the past record or from other regions may be difficult to identify and are seldom applied, although they sometimes can provide useful insights into impacts of climate conditions outside the present-day range. [3.5.2]

The most common scenarios use outputs from general circulation models (GCMs) and usually are constructed by adjusting a baseline climate (typically based on regional observations of climate over a reference period such as 1961–1990) by the absolute or proportional change between the simulated present

and future climates. Most recent impact studies have constructed scenarios on the basis of transient GCM outputs, although some still apply earlier equilibrium results. The great majority of scenarios represent changes in mean climate; some recent scenarios, however, also have incorporated changes in variability and extreme weather events, which can lead to important impacts for some systems. Regional detail is obtained from the coarse-scale outputs of GCMs by using three main methods: simple interpolation, statistical downscaling, and high-resolution dynamical modeling. The simple method, which reproduces the GCM pattern of change, is the most widely applied in scenario development. In contrast, the statistical and modeling approaches can produce local climate changes that are different from large-scale GCM estimates. More research is needed to evaluate the value added to impact studies of such regionalization exercises. One reason for this caution is the large uncertainty of GCM projections, which requires further quantification through model intercomparisons, new model simulations, and pattern scaling methods. [3.5.2, 3.5.4, 3.5.5]

3.5. Scenarios of the 21st Century

In 2000, the IPCC completed a *Special Report on Emissions Scenarios* (SRES) to replace the earlier set of six IS92 scenarios developed for the IPCC in 1992. These newer scenarios consider the period 1990 to 2100 and include a range of socioeconomic assumptions (e.g., global population and gross domestic product). Their implications for other aspects of global change also have been calculated; some of these implications are summarized for 2050 and 2100 in Table TS-1. For example, mean ground-level ozone concentrations in July over the industrialized

Table TS-1: The SRES scenarios and their implications for atmospheric composition, climate, and sea level. Values of population, GDP, and per capita income ratio (a measure of regional equity) are those applied in integrated assessment models used to estimate emissions (based on Tables 3-2 and 3-9).

Date	Global Population (billions) ^a	Global GDP (10^{12} US\$ yr ⁻¹) ^b	Per Capita Income Ratio ^c	Ground-Level O ₃ Concentration (ppm) ^d	CO ₂ Concentration (ppm) ^e	Global Temperature Change (°C) ^f	Global Sea-Level Rise (cm) ^g
1990	5.3	21	16.1	—	354	0	0
2000	6.1–6.2	25–28	12.3–14.2	40	367	0.2	2
2050	8.4–11.3	59–187	2.4–8.2	~60	463–623	0.8–2.6	5–32
2100	7.0–15.1	197–550	1.4–6.3	>70	478–1099	1.4–5.8	9–88

^a Values for 2000 show range across the six illustrative SRES emissions scenarios; values for 2050 and 2100 show range across all 40 SRES scenarios.

^b See footnote a; gross domestic product (trillion 1990 US\$ yr⁻¹).

^c See footnote a; ratio of developed countries and economies-in-transition (Annex I) to developing countries (non-Annex I).

^d Model estimates for industrialized continents of northern hemisphere assuming emissions for 2000, 2060, and 2100 from the A1F and A2 illustrative SRES emissions scenarios at high end of the SRES range (Chapter 4, TAR WG I).

^e Observed 1999 value (Chapter 3, WG I TAR); values for 1990, 2050, and 2100 are from simple model runs across the range of 35 fully quantified SRES emissions scenarios and accounting for uncertainties in carbon cycle feedbacks related to climate sensitivity (data from S.C.B. Raper, Chapter 9, WG I TAR). Note that the ranges for 2050 and 2100 differ from those presented by TAR WGI (Appendix II), which were ranges across the six illustrative SRES emissions scenarios from simulations using two different carbon cycle models.

^f Change in global mean annual temperature relative to 1990 averaged across simple climate model runs emulating results of seven AOGCMs with an average climate sensitivity of 2.8°C for the range of 35 fully quantified SRES emissions scenarios (Chapter 9, WG I TAR).

^g Based on global mean temperature changes but also accounting for uncertainties in model parameters for land ice, permafrost, and sediment deposition (Chapter 11, WG I TAR).

continents of the northern hemisphere are projected to rise from about 40 ppb in 2000 to more than 70 ppb in 2100 under the highest illustrative SRES emissions scenarios; by comparison, the clean-air standard is below 80 ppb. Peak levels of ozone in local smog events could be many times higher. Estimates of CO₂ concentration range from 478 ppm to 1099 ppm by 2100, given the range of SRES emissions and uncertainties about the carbon cycle (Table TS-1). This range of implied radiative forcing gives rise to an estimated global warming from 1990 to 2100 of 1.4–5.8°C, assuming a range of climate sensitivities. This range is higher than the 0.7–3.5°C of the SAR because of higher levels of radiative forcing in the SRES scenarios than in the IS92a-f scenarios—primarily as a result of lower sulfate aerosol emissions, especially after 2050. The equivalent range of estimates of global sea-level rise (for this range of global temperature change in combination with a range of ice melt sensitivities) to 2100 is 9–88 cm (compared to 15–95 cm in the SAR). [3.2.4.1, 3.4.4, 3.8.1, 3.8.2]

In terms of *mean changes in regional climate*, results from GCMs that have been run assuming the new SRES emissions scenarios display many similarities with previous runs. The WGI contribution to the TAR concludes that rates of warming are expected to be greater than the global average over most land areas and will be most pronounced at high latitudes in winter. As warming proceeds, northern hemisphere snow cover and sea-ice extent will be reduced. Models indicate warming below the global average in the north Atlantic and circumpolar southern ocean regions, as well as in southern and southeast Asia and southern South America in June-August. Globally, there will be increases in average water vapor and precipitation. Regionally, December-February precipitation is expected to increase over the northern extratropics, Antarctica, and tropical Africa. Models also agree on a decrease in precipitation over Central America and little change in southeast Asia. Precipitation in June-August is estimated to increase in high northern latitudes, Antarctica, and south Asia; it is expected to change little in southeast Asia and to decrease in central America, Australia, southern Africa, and the Mediterranean region.

Changes in the frequency and intensity of extreme climate events also can be expected. Based on the conclusions of the WGI report and the likelihood scale employed therein, under GHG forcing to 2100, it is very likely that daytime maximum and minimum temperatures will increase, accompanied by an increased frequency of hot days (see Table TS-2). It also is very likely that heat waves will become more frequent, and the number of cold waves and frost days (in applicable regions) will decline. Increases in high-intensity precipitation events are likely at many locations; Asian summer monsoon precipitation variability also is likely to increase. The frequency of summer drought will increase in many interior continental locations, and droughts—as well as floods—associated with El Niño events are likely to intensify. Peak wind intensity and mean and peak precipitation intensities of tropical cyclones are likely to increase. The direction of changes in the average intensity of mid-latitude storms cannot be determined with current climate models. [Table 3-10]

3.6. How can We Improve Scenarios and their Use?

Some features of scenario development and application that are now well established and tested include continued development of global and regional databases for defining baseline conditions, widespread use of incremental scenarios to explore system sensitivity prior to application of model-based scenarios, improved availability and wider application of estimates of long-term mean global changes on the basis of projections produced by specialized international organizations or the use of simple models, and a growing volume of accessible information that enables construction of regional scenarios for some aspects of global change. [3.9.1]

There also are numerous shortcomings of current scenario development, many of which are being actively investigated. These investigations include efforts to properly represent socioeconomic, land-use, and environmental changes in scenarios; to obtain scenarios at higher resolution (in time and space); and to incorporate changes in variability as well as mean conditions in scenarios. Increasing attention is required on construction of scenarios that address policy-related issues such as stabilization of GHG concentrations or adaptation, as well as improving the representation of uncertainties in projections, possibly within a risk assessment framework. [3.9.2]

4. Natural and Human Systems

Natural and human systems are expected to be exposed to climatic variations such as changes in the average, range, and variability of temperature and precipitation, as well as the frequency and severity of weather events. Systems also would be exposed to indirect effects from climate change such as sea-level rise, soil moisture changes, changes in land and water condition, changes in the frequency of fire and pest infestation, and changes in the distribution of infectious disease vectors and hosts. The sensitivity of a system to these exposures depends on system characteristics and includes the potential for adverse and beneficial effects. The potential for a system to sustain adverse impacts is moderated by adaptive capacity. The capacity to adapt human management of systems is determined by access to resources, information and technology, the skill and knowledge to use them, and the stability and effectiveness of cultural, economic, social, and governance institutions that facilitate or constrain how human systems respond.

4.1. Water Resources

There are apparent trends in streamflow volumes—increases and decreases—in many regions. However, confidence that these trends are a result of climate change is low because of factors such as the variability of hydrological behavior over time, the brevity of instrumental records, and the response of river flows to stimuli other than climate change. *In contrast, there is high confidence that observations of widespread accelerated glacier retreat and shifts in the timing of streamflow*

Table TS-2: Examples of impacts resulting from projected changes in extreme climate events.

Projected Changes during the 21st Century in Extreme Climate Phenomena and their Likelihood^a	Representative Examples of Projected Impacts^b (all high confidence of occurrence in some areas^c)
Simple Extremes	
Higher maximum temperatures; more hot days and heat waves ^d over nearly all land areas (<i>Very Likely</i> ^a)	<ul style="list-style-type: none"> Increased incidence of death and serious illness in older age groups and urban poor Increased heat stress in livestock and wildlife Shift in tourist destinations Increased risk of damage to a number of crops Increased electric cooling demand and reduced energy supply reliability
Higher (increasing) minimum temperatures; fewer cold days, frost days, and cold waves ^d over nearly all land areas (<i>Very Likely</i> ^a)	<ul style="list-style-type: none"> Decreased cold-related human morbidity and mortality Decreased risk of damage to a number of crops, and increased risk to others Extended range and activity of some pest and disease vectors Reduced heating energy demand
More intense precipitation events (<i>Very Likely</i> ^a over many areas)	<ul style="list-style-type: none"> Increased flood, landslide, avalanche, and mudslide damage Increased soil erosion Increased flood runoff could increase recharge of some floodplain aquifers Increased pressure on government and private flood insurance systems and disaster relief
Complex Extremes	
Increased summer drying over most mid-latitude continental interiors and associated risk of drought (<i>Likely</i> ^a)	<ul style="list-style-type: none"> Decreased crop yields Increased damage to building foundations caused by ground shrinkage Decreased water resource quantity and quality Increased risk of forest fire
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities (<i>Likely</i> ^a over some areas) ^e	<ul style="list-style-type: none"> Increased risks to human life, risk of infectious disease epidemics, and many other risks Increased coastal erosion and damage to coastal buildings and infrastructure Increased damage to coastal ecosystems such as coral reefs and mangroves
Intensified droughts and floods associated with El Niño events in many different regions (<i>Likely</i> ^a) (see also under droughts and intense precipitation events)	<ul style="list-style-type: none"> Decreased agricultural and rangeland productivity in drought- and flood-prone regions Decreased hydro-power potential in drought-prone regions
Increased Asian summer monsoon precipitation variability (<i>Likely</i> ^a)	<ul style="list-style-type: none"> Increased flood and drought magnitude and damages in temperate and tropical Asia
Increased intensity of mid-latitude storms (little agreement between current models) ^d	<ul style="list-style-type: none"> Increased risks to human life and health Increased property and infrastructure losses Increased damage to coastal ecosystems

^aLikelihood refers to judgmental estimates of confidence used by TAR WGI: *very likely* (90–99% chance); *likely* (66–90% chance). Unless otherwise stated, information on climate phenomena is taken from the Summary for Policymakers, TAR WGI.

^bThese impacts can be lessened by appropriate response measures.

^cBased on information from chapters in this report; high confidence refers to probabilities between 67 and 95% as described in Footnote 6 of TAR WGII, Summary for Policymakers.

^dInformation from TAR WGI, Technical Summary, Section F.5.

^eChanges in regional distribution of tropical cyclones are possible but have not been established.

from spring toward winter in many areas are associated with observed increases in temperature. High confidence in these findings exists because these changes are driven by rising temperature and are unaffected by factors that influence streamflow volumes. Glacier retreat will continue, and many small glaciers may disappear (high confidence). The rate of retreat will depend on the rate of temperature rise. [4.3.6.1, 4.3.11]

The effect of climate change on streamflow and groundwater recharge varies regionally and among scenarios, largely following projected changes in precipitation. In some parts of the world, the direction of change is consistent between scenarios, although the magnitude is not. In other parts of the world, the direction of change is uncertain. Possible streamflow changes under two climate change scenarios are shown in Figure TS-3.

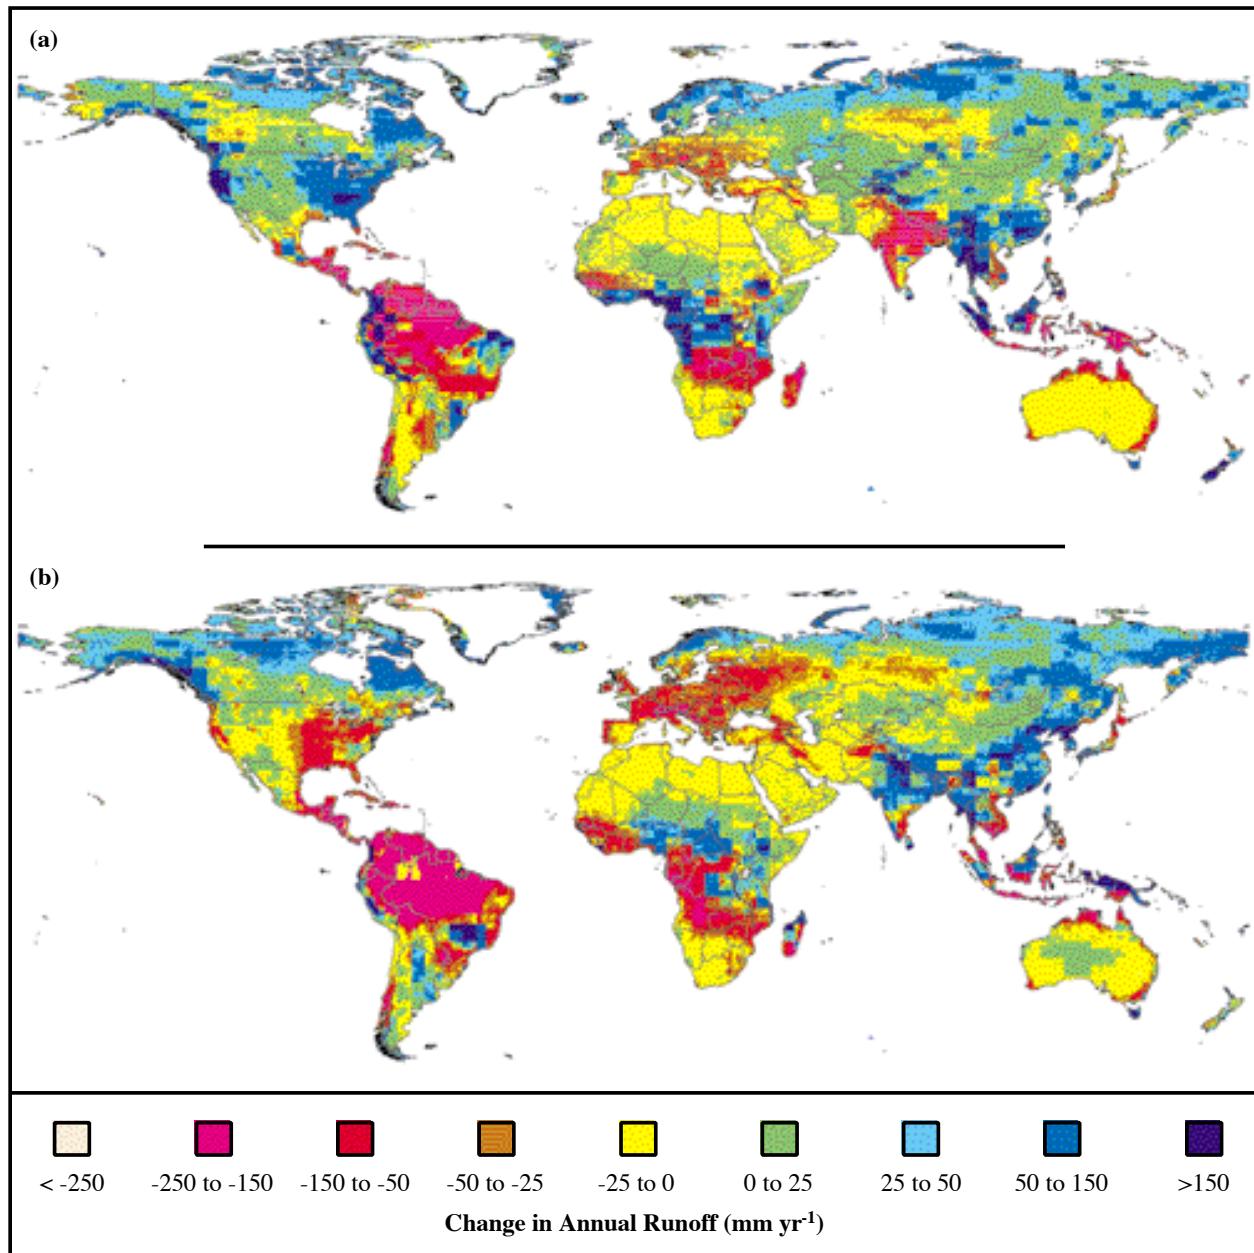

Figure TS-3: The pattern of changes in runoff largely follows the pattern of simulated changes in precipitation, which varies between climate models. The modeled increases in runoff shown in both maps [(a) HadCM2 ensemble mean and (b) HadCM3; see Section 4.3.6.2 of Chapter 4 for discussion of models and scenarios used] for high latitudes and southeast Asia, and decreases in central Asia, the area around the Mediterranean, southern Africa, and Australia are broadly consistent—in terms of direction of change—across most climate models. In other parts of the world, changes in precipitation and runoff vary between climate change scenarios.

Confidence in the projected direction and magnitude of change in streamflow and groundwater recharge is largely dependent on confidence in the projected changes in precipitation. The mapped increase in streamflow in high latitudes and southeast Asia and the decrease in streamflow in central Asia, the area around the Mediterranean, and southern Africa are broadly consistent across climate models. Changes in other areas vary between climate models. [4.3.5, 4.3.6.2]

Peak streamflow will move from spring to winter in many areas where snowfall currently is an important component of the water balance (high confidence). Higher temperatures mean that a greater proportion of winter precipitation falls as rain rather than snow and therefore is not stored on the land surface until it melts in spring. In particularly cold areas, an increase in temperature would still mean that winter precipitation falls as snow, so there would be little change in streamflow timing in these regions. The greatest changes therefore are likely to be in “marginal” zones—including central and eastern Europe and the southern Rocky Mountain chain—where a small temperature rise reduces snowfall substantially. [4.3.6.2]

Water quality generally would be degraded by higher water temperatures (high confidence). The effect of temperature on water quality would be modified by changes in flow volume, which may either exacerbate or lessen the effect of temperature, depending on the direction of change in flow volume. Other things being equal, increasing water temperature alters the rate of operation of biogeochemical processes (some degrading, some cleaning) and, most important, lowers the dissolved oxygen concentration of water. In rivers this effect may be offset to an extent by increased streamflow—which would dilute chemical concentrations further—or enhanced by lower streamflow, which would increase concentrations. In lakes, changes in mixing may offset or exaggerate the effects of increased temperature. [4.3.10]

Flood magnitude and frequency are likely to increase in most regions, and low flows are likely to decrease in many regions. The general direction of change in extreme flows and flow variability is broadly consistent among climate change scenarios, although confidence in the potential magnitude of change in any catchment is low. The general increase in flood magnitude and frequency is a consequence of a projected general increase in the frequency of heavy precipitation events, although the effect of a given change in precipitation depends on catchment characteristics. Changes in low flows are a function of changes in precipitation and evaporation. Evaporation generally is projected to increase, which may lead to lower low flows even where precipitation increases or shows little change. [4.3.8, 4.3.9]

Approximately 1.7 billion people, one-third of the world’s population, presently live in countries that are water-stressed (i.e., using more than 20% of their renewable water supply—a commonly used indicator of water stress). This number is projected to increase to about 5 billion by 2025, depending on the rate of population growth. Projected climate change could further decrease streamflow and groundwater recharge in many

of these water-stressed countries—for example, in central Asia, southern Africa, and countries around the Mediterranean Sea—but may increase it in some others.

Demand for water generally is increasing, as a result of population growth and economic development, but is falling in some countries. Climate change may decrease water availability in some water-stressed regions and increase it in others. Climate change is unlikely to have a large effect on municipal and industrial demands but may substantially affect irrigation withdrawals. In the municipal and industrial sectors, it is likely that nonclimatic drivers will continue to have very substantial effects on demand for water. Irrigation withdrawals, however, are more climatically determined, but whether they increase or decrease in a given area depends on the change in precipitation: Higher temperatures, hence crop evaporative demand, would mean that the general tendency would be toward an increase in irrigation demands. [4.4.2, 4.4.3, 4.5.2]

The impact of climate change on water resources depends not only on changes in the volume, timing, and quality of streamflow and recharge but also on system characteristics, changing pressures on the system, how management of the system evolves, and what adaptations to climate change are implemented. Nonclimatic changes may have a greater impact on water resources than climate change. Water resources systems are evolving continually to meet changing management challenges. Many of the increased pressures will increase vulnerability to climate change, but many management changes will reduce vulnerability. Unmanaged systems are likely to be most vulnerable to climate change. By definition, these systems have no management structures in place to buffer the effects of hydrological variability. [4.5.2]

Climate change challenges existing water resources management practices by adding uncertainty. Integrated water resources management will enhance the potential for adaptation to change. The historic basis for designing and operating infrastructure no longer holds with climate change because it cannot be assumed that the future hydrological regime will be the same as that of the past. The key challenge, therefore, is incorporating uncertainty into water resources planning and management. Integrated water resources management is an increasingly used means of reconciling different and changing water uses and demands, and it appears to offer greater flexibility than conventional water resources management. Improved ability to forecast streamflow weeks or months ahead also would significantly enhance water management and its ability to cope with a changing hydrological variability. [4.6]

Adaptive capacity (specifically, the ability to implement integrated water resources management), however, is very unevenly distributed across the world. In practice, it may be very difficult to change water management practices in a country where, for example, management institutions and market-like processes are not well developed. The challenge, therefore, is to develop ways to introduce integrated water management practices into specific institutional settings—which is necessary even in

the absence of climate change to improve the effectiveness of water management. [4.6.4]

4.2. Agriculture and Food Security

The response of crop yields to climate change varies widely, depending on the species, cultivar, soil conditions, treatment of CO₂ direct effects, and other locational factors. It is established with medium confidence that a few degrees of projected warming will lead to general increases in temperate crop yields, with some regional variation (Table 5-4). At larger amounts of projected warming, most temperate crop yield responses become generally negative. Autonomous agronomic adaptation ameliorates temperate crop yield loss and improves gain in most cases (Figure TS-4). In the tropics, where some crops are near their maximum temperature tolerance and where dryland agriculture predominates, yields would decrease generally with even minimal changes in temperature; where there is a large decrease in rainfall, crop yields would be even more adversely affected (medium confidence). With autonomous agronomic adaptation, it is established with medium confidence that crop yields in the tropics tend to be less adversely affected by climate change than without adaptation, but they still tend to remain below baseline levels. Extreme events also will affect crop yields. Higher minimum temperatures will be beneficial to some crops, especially in temperate regions, and detrimental to other crops, especially in low latitudes (high confidence).

Higher maximum temperatures will be generally detrimental to numerous crops (high confidence). [5.3.3]

Important advances in research since the SAR on the direct effects of CO₂ on crops suggest that beneficial effects may be greater under certain stressful conditions, including warmer temperatures and drought. Although these effects are well established for a few crops under experimental conditions, knowledge of them is incomplete for suboptimal conditions of actual farms. Research on agricultural adaptation to climate change also has made important advances. Inexpensive, farm-level (autonomous) agronomic adaptations such as altering of planting dates and cultivar selections have been simulated in crop models extensively. More expensive, directed adaptations—such as changing land-use allocations and developing and using irrigation infrastructure—have been examined in a small but growing number of linked crop-economic models, integrated assessment models, and econometric models.

Degradation of soil and water resources is one of the major future challenges for global agriculture. It is established with high confidence that those processes are likely to be intensified by adverse changes in temperature and precipitation. Land use and management have been shown to have a greater impact on soil conditions than the indirect effect of climate change; thus, adaptation has the potential to significantly mitigate these impacts. A critical research need is to assess whether resource degradation will significantly increase the risks faced

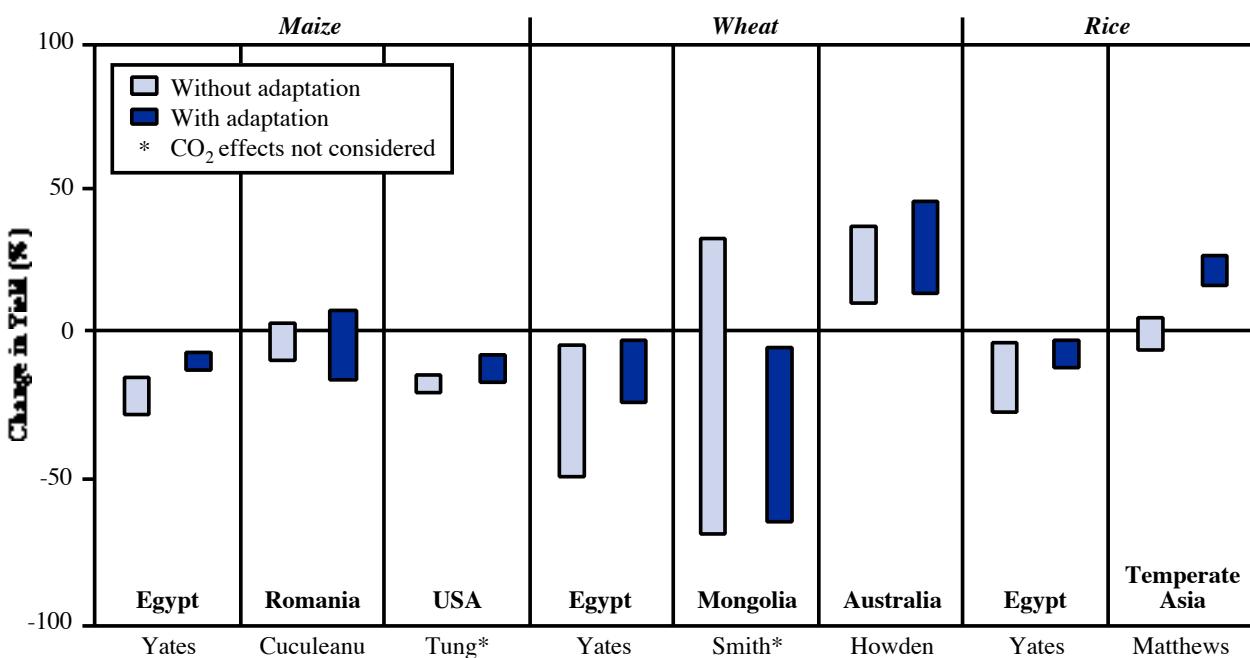

Figure TS-4: Ranges of percentage changes in crop yields (expressed in vertical extent of vertical bars only) spanning selected climate change scenarios—with and without agronomic adaptation—from paired studies listed in Table 5-4. Each pair of ranges is differentiated by geographic location and crop. Pairs of vertical bars represent the range of percentage changes with and without adaptation. Endpoints of each range represent collective high and low percentage change values derived from all climate scenarios used in the study. The horizontal extent of the bars is not meaningful. On the x-axis, the last name of the lead author is listed as it appears in Table 5-4; full source information is provided in the Chapter 5 reference list.

by vulnerable agricultural and rural populations [5.3.2, 5.3.4, 5.3.6].

In the absence of climate change, most global and regional studies project declining real prices for agricultural commodities. Confidence in these projections declines farther into the future. *The impacts of climate change on agriculture are estimated to result in small percentage changes in global income, with positive changes in more developed regions and smaller or negative changes in developing regions (low to medium confidence).* The effectiveness of adaptation (agronomic and economic) in ameliorating the impacts of climate change will vary regionally and depend a great deal on regional resource endowments, including stable and effective institutions. [5.3.1, 5.3.5]

Most studies indicate that mean annual temperature increases of 2.5°C or greater would prompt food prices to increase (low confidence) as a result of slowing in the expansion of global food capacity relative to growth in global food demand. At lesser amounts of warming than 2.5°C, global impact assessment models cannot distinguish the climate change signal from other sources of change. Some recent aggregated studies have estimated economic impacts on vulnerable populations such as smallholder producers and poor urban consumers. These studies indicate that climate change will lower the incomes of vulnerable populations and increase the absolute number of people at risk of hunger (low confidence). [5.3.5, 5.3.6]

Without autonomous adaptation, increases in extreme events are likely to increase heat stress-related livestock deaths, although winter warming may reduce neonatal deaths at temperate latitudes (established but incomplete). Strategies to adapt livestock to physiological stresses of warming are considered effective; however, adaptation research is hindered by the lack of experimentation and simulation. [5.3.3]

Confidence in specific numerical estimates of climate change impacts on production, income, and prices obtained from large, aggregated, integrated assessment models is considered to be low because there are several remaining uncertainties. The models are highly sensitive to some parameters that have been subjected to sensitivity analysis, yet sensitivity to a large number of other parameters has not been reported. Other uncertainties include the magnitude and persistence of effects of rising atmospheric CO₂ on crop yield under realistic farming conditions; potential changes in crop and animal pest losses; spatial variability in crop responses to climate change; and the effects of changes in climate variability and extreme events on crops and livestock. [Box 5-3]

4.3. Terrestrial and Freshwater Ecosystems

Ecosystems are subject to many pressures, such as land-use changes, deposition of nutrients and pollutants, harvesting, grazing by livestock, introduction of exotic species, and natural climate variability. Climate change constitutes an additional pressure that could change or endanger these systems. The

impact of climate change on these systems will be influenced by land and water management adaptation and interactions with other pressures. Adaptive capacity is greater for more intensively managed lands and waters and in production of marketed goods (e.g., timber production in plantations) than in less intensively managed lands and nonmarket values of those lands and waters. [5.1, 5.2]

Populations of many species already are threatened and are expected to be placed at greater risk by the synergy between the stresses of changing climate, rendering portions of current habitat unsuitable, and land-use change that fragments habitats. Without adaptation, some species that currently are classified as “critically endangered” will become extinct, and the majority of those labeled “endangered or vulnerable” will become much rarer in the 21st century (high confidence). This may have the greatest impact on the lowest income human societies, which rely on wildlife for subsistence living. In addition, there is high confidence that loss or reduction of species would impact the services provided by wildlife through roles within an ecosystem (e.g., pollination, natural pest control), recreation (e.g., sport hunting, wildlife viewing), and cultural and religious practices of indigenous people. Possible adaptation methods to reduce risks to species could include establishment of refuges, parks, and reserves with corridors to allow migration of species, as well as use of captive breeding and translocation. However, these options may have limitations of cost. [5.4]

There are now substantial observational and experimental studies demonstrating the link between change in regional climate and biological or physical processes in ecosystems. These include a lengthening of vegetative growing season by 1.2 to 3.6 days per decade in the high northern latitudes (one factor leading to community composition changes); warming of lakes and rivers as a result of shortening duration of ice cover; upward range shifts in alpine herbs; and increased mortality and range contraction of wildlife as a result of heat stress. Others include changes in population sizes, body sizes, and migration times (see TS 2.1 and 7.1, Figure TS-11, and Table TS-16 for additional information). [5.2.1]

Vegetation distribution models since the SAR suggest that mass ecosystem or biome movement is most unlikely to occur because of different climatic tolerance of the species involved, different migration abilities, and the effects of invading species. Species composition and dominance will change, resulting in ecosystem types that may be quite different from those we see today. These changes will lag the changes in climate by years to decades to centuries (high confidence). The effects of changes in disturbances such as fire, blowdown, or pest attacks on vegetation have not been included in these studies. [5.2]

Recent modeling studies continue to show potential for significant disruption of ecosystems under climate change (high confidence). Further development of simple correlative models that were available at the time of the SAR point to areas where ecosystem disruption and the potential for ecosystem migration are high. Observational data and newer dynamic vegetation models

linked to transient climate models are refining the projections. However, the precise outcomes depend on processes that are too subtle to be fully captured by current models. [5.2]

Increasing CO₂ concentration would increase net primary productivity (plant growth, litterfall, and mortality) in most systems, whereas increasing temperature may have positive or negative effects (high confidence). Experiments on tree species grown under elevated CO₂ over several years show continued and consistent stimulation of photosynthesis and little evidence of long-term loss of sensitivity to CO₂. However, changes in net ecosystem productivity (which includes plant growth, litterfall, mortality, litter decomposition, and soil carbon dynamics) and net biome productivity (which includes those effects plus the effects of fire or other disturbances) are less likely to be positive and may be generally negative. Research reported since the SAR confirms the view that the largest and earliest impacts induced by climate change are likely to occur in boreal forests, through changes in weather-related disturbance regimes and nutrient cycling. [5.6.1.1, 5.6.3.1]

Terrestrial ecosystems appear to be storing increasing amounts of carbon. At the time of the SAR, this was attributed largely to increasing plant productivity because of the interaction among elevated CO₂ concentration, increasing temperatures, and soil moisture changes. Recent results confirm that productivity gains are occurring but suggest that they are smaller under field conditions than plant-pot experiments indicate (*medium confidence*). Hence, the terrestrial uptake may be caused more by change in uses and management of land than by the direct effects of elevated CO₂ and climate. The degree to which terrestrial ecosystems continue to be net sinks for carbon is uncertain because of the complex interactions between the aforementioned factors (e.g., arctic terrestrial ecosystems and wetlands may act as sources and sinks) (*medium confidence*).

In arid or semi-arid areas (e.g., rangelands, dry forests/woodlands) where climate change is likely to decrease available soil moisture, productivity is expected to decrease. Increased CO₂ concentrations may counteract some of these losses. However, many of these areas are affected by El Niño/La Niña, other climatic extremes, and disturbances such as fire. Changes in the frequencies of these events and disturbances could lead to loss of productivity thus potential land degradation, potential loss of stored carbon, or decrease in the rate of carbon uptake (*medium confidence*). [5.5]

Some wetlands will be replaced by forests or heathlands, and those overlying permafrost are likely to be disrupted as a result of thawing of permafrost (high confidence). The initial net effect of warming on carbon stores in high-latitude ecosystems is likely to be negative because decomposition initially may respond more rapidly than production. In these systems, changes in albedo and energy absorption during winter are likely to act as a positive feedback to regional warming as a result of earlier melting of snow and, over decades to centuries, poleward movement of the treeline. [5.8, 5.9]

Most wetland processes are dependent on catchment-level hydrology; thus, adaptations for projected climate change may be practically impossible. Arctic and subarctic ombrotrophic bog communities on permafrost, as well as more southern depressional wetlands with small catchment areas, are likely to be most vulnerable to climate change. The increasing speed of peatland conversion and drainage in southeast Asia is likely to place these areas at a greatly increased risk of fires and affect the viability of tropical wetlands. [5.8]

Opportunities for adapting to expected changes in high-latitude and alpine ecosystems are limited because these systems will respond most strongly to globally induced changes in climate. Careful management of wildlife resources could minimize climatic impacts on indigenous peoples. Many high-latitude regions depend strongly on one or a few resources, such as timber, oil, reindeer, or wages from fighting fires. Economic diversification would reduce the impacts of large changes in the availability or economic value of particular goods and services. High levels of endemism in many alpine floras and their inability to migrate upward means that these species are very vulnerable. [5.9]

Contrary to the SAR, global timber market studies that include adaptations through land and product management suggest that climate change would increase global timber supply (medium confidence). At the regional and global scales, the extent and nature of adaptation will depend primarily on wood and non-wood product prices, the relative value of substitutes, the cost of management, and technology. On specific sites, changes in forest growth and productivity will constrain—and could limit—choices regarding adaptation strategies (*high confidence*). In markets, prices will mediate adaptation through land and product management. Adaptation in managed forests will include salvaging dead and dying timber, replanting new species that are better suited to the new climate, planting genetically modified species, and intensifying or decreasing management. Consumers will benefit from lower timber prices; producers may gain or lose, depending on regional changes in timber productivity and potential dieback effects. [5.6]

Climate change will lead to poleward movement of the southern and northern boundaries of fish distributions, loss of habitat for cold- and coolwater fish, and gain in habitat for warmwater fish (high confidence). As a class of ecosystems, inland waters are vulnerable to climatic change and other pressures owing to their small size and position downstream from many human activities (*high confidence*). The most vulnerable elements include reduction and loss of lake and river ice (*very high confidence*), loss of habitat for coldwater fish (*very high confidence*), increases in extinctions and invasions of exotics (*high confidence*), and potential exacerbation of existing pollution problems such as eutrophication, toxics, acid rain, and UV-B radiation (*medium confidence*). [5.7]

4.4. Coastal Zones and Marine Ecosystems

Global climate change will result in increases in sea-surface temperature (SST) and sea level; decreases in sea-ice cover;

and changes in salinity, wave climate, and ocean circulation. Some of these changes already are taking place. Changes in oceans are expected to have important feedback effects on global climate and on the climate of the immediate coastal area (see TAR WGI). They also would have profound impacts on the biological production of oceans, including fish production. For instance, changes in global water circulation and vertical mixing will affect the distribution of biogenic elements and the efficiency of CO₂ uptake by the ocean; changes in upwelling rates would have major impacts on coastal fish production and coastal climates. [6.3]

If warm events associated with El Niños increase in frequency, plankton biomass and fish larvae abundance would decline and adversely impact fish, marine mammals, seabirds, and ocean biodiversity (high confidence). In addition to El Niño-Southern Oscillation (ENSO) variability, the persistence of multi-year climate-ocean regimes and switches from one regime to another have been recognized since the SAR. Changes in recruitment patterns of fish populations have been linked to such switches. Fluctuations in fish abundance are increasingly regarded as biological responses to medium-term climate fluctuations in addition to overfishing and other anthropogenic factors. Similarly, survival of marine mammals and seabirds also is affected by interannual and longer term variability in several oceanographic and atmospheric properties and processes, especially in high latitudes. [6.3.4]

Growing recognition of the role of the climate-ocean system in the management of fish stocks is leading to new adaptive strategies that are based on the determination of acceptable removable percentages of fish and stock resilience. Another consequence of the recognition of climate-related changes in the distribution of marine fish populations suggests that the sustainability of many nations' fisheries will depend on adaptations that increase flexibility in bilateral and multilateral fishing agreements, coupled with international stock assessments and management plans. Creating sustainable fisheries also depends on understanding synergies between climate-related impacts on fisheries and factors such as harvest pressure and habitat conditions. [6.3.4, 6.6.4]

Adaptation by expansion of marine aquaculture may partly compensate for potential reductions in ocean fish catch. Marine aquaculture production has more than doubled since 1990, and in 1997 represented approximately 30% of total commercial fish and shellfish production for human consumption. However, future aquaculture productivity may be limited by ocean stocks of herring, anchovies, and other species that are used to provide fishmeal and fish oils to feed cultured species, which may be negatively impacted by climate change. Decreases in dissolved oxygen levels associated with increased seawater temperatures and enrichment of organic matter creates conditions for the spread of diseases in wild and aquaculture fisheries, as well as outbreaks of algal blooms in coastal areas. Pollution and habitat destruction that can accompany aquaculture also may place limits on its expansion and on the survival success of wild stocks. [6.3.5]

Many coastal areas already are experiencing increased levels of sea flooding, accelerated coastal erosion, and seawater intrusion into freshwater sources; these processes will be exacerbated by climate change and sea-level rise. Sea-level rise in particular has contributed to erosion of sandy and gravel beaches and barriers; loss of coastal dunes and wetlands; and drainage problems in many low-lying, mid-latitude coastal areas. Highly diverse and productive coastal ecosystems, coastal settlements, and island states will continue to be exposed to pressures whose impacts are expected to be largely negative and potentially disastrous in some instances. [6.4]

Low-latitude tropical and subtropical coastlines, particularly in areas where there is significant human population pressure, are highly susceptible to climate change impacts. These impacts will exacerbate many present-day problems. For instance, human activities have increased land subsidence in many deltaic regions by increasing subsurface water withdrawals, draining wetland soils, and reducing or cutting off riverine sediment loads. Problems of inundation, salinization of potable groundwater, and coastal erosion will all be accelerated with global sea-level rise superimposed on local submergence. Especially at risk are large delta regions of Asia and small islands whose vulnerability was recognized more than a decade ago and continues to increase. [6.4.3, 6.5.3]

High-latitude (polar) coastlines also are susceptible to climate warming impacts, although these impacts have been less studied. Except on rock-dominated or rapidly emerging coasts, a combination of accelerated sea-level rise, more energetic wave climate with reduced sea-ice cover, and increased ground temperatures that promote thaw of permafrost and ground ice (with consequent volume loss in coastal landforms) will have severe impacts on settlements and infrastructure and will result in rapid coastal retreat. [6.4.6]

Coastal ecosystems such as coral reefs and atolls, salt marshes and mangrove forests, and submerged aquatic vegetation will be impacted by sea-level rise, warming SSTs, and any changes in storm frequency and intensity. Impacts of sea-level rise on mangroves and salt marshes will depend on the rate of rise relative to vertical accretion and space for horizontal migration, which can be limited by human development in coastal areas. Healthy coral reefs are likely to be able to keep up with sea-level rise, but this is less certain for reefs degraded by coral bleaching, UV-B radiation, pollution, and other stresses. Episodes of coral bleaching over the past 20 years have been associated with several causes, including increased ocean temperatures. Future sea-surface warming would increase stress on coral reefs and result in increased frequency of marine diseases (high confidence). Changes in ocean chemistry resulting from higher CO₂ levels may have a negative impact on coral reef development and health, which would have a detrimental effect on coastal fisheries and on social and economic uses of reef resources. [6.4.4, 6.4.5]

Few studies have examined potential changes in prevailing ocean wave heights and directions and storm waves and surges

as a consequence of climate change. Such changes can be expected to have serious impacts on natural and human-modified coasts because they will be superimposed on a higher sea level than at present.

Vulnerabilities have been documented for a variety of coastal settings, initially by using a common methodology developed in the early 1990s. These and subsequent studies have confirmed the spatial and temporal variability of coastal vulnerability at national and regional levels. Within the common methodology, three coastal adaptation strategies have been identified: protect, accommodate, and retreat. Since the SAR, adaptation strategies for coastal zones have shifted in emphasis away from hard protection structures (e.g., seawalls, groins) toward soft protection measures (e.g., beach nourishment), managed retreat, and enhanced resilience of biophysical and socioeconomic systems, including the use of flood insurance to spread financial risk. [6.6.1, 6.6.2]

Integrated assessments of coastal zones and marine ecosystems and better understanding of their interaction with human development and multi-year climate variability could lead to improvements in sustainable development and management. Adaptation options for coastal and marine management are most effective when they are incorporated with policies in other areas, such as disaster mitigation plans and land-use plans.

4.5. Human Settlements, Energy, and Industry

Human settlements are integrators of many of the climate impacts initially felt in other sectors and differ from each other in geographic location, size, economic circumstances, and political and institutional capacity. As a consequence, it is difficult to make blanket statements concerning the importance of climate or climate change that will not have numerous exceptions. However, classifying human settlements by considering pathways by which climate may affect them, size or other obvious physical considerations, and adaptive capacities (wealth, education of the populace, technological and institutional capacity) helps to explain some of the differences in expected impacts. [7.2]

Human settlements are affected by climate in one of three major ways:

- 1) Economic sectors that support the settlement are affected because of changes in productive capacity (e.g., in agriculture or fisheries) or changes in market demand for goods and services produced there (including demand from people living nearby and from tourism). The importance of this impact depends in part on whether the settlement is rural—which generally means that it is dependent on one or two resource-based industries—or urban, in which case there usually (but not always) is a broader array of alternative resources. It also depends on the adaptive capacity of the settlement. [7.1]

2) Some aspects of physical infrastructure (including energy transmission and distribution systems), buildings, urban services (including transportation systems), and specific industries (such as agroindustry, tourism, and construction) may be directly affected. For example, buildings and infrastructure in deltaic areas may be affected by coastal and river flooding; urban energy demand may increase or decrease as a result of changed balances in space heating and space cooling; and coastal and mountain tourism may be affected by changed seasonal temperature and precipitation patterns and sea-level rise. Concentration of population and infrastructure in urban areas can mean higher numbers of persons and higher value of physical capital at risk, although there also are many economies of scale and proximity in ensuring well-managed infrastructure and service provision. When these factors are combined with other prevention measures, risks can be reduced considerably. However, some larger urban centers in Africa, Asia, Latin America, and the Caribbean, as well as smaller settlements (including villages and small urban centers), often have less wealth, political power, and institutional capacity to reduce risks in this way. [7.1]

3) Population may be directly affected through extreme weather, changes in health status, or migration. Extreme weather episodes may lead to changes in deaths, injuries, or illness. For example, health status may improve as a result of reduced cold stress or deteriorate as a result of increased heat stress and disease. Population movements caused by climate changes may affect the size and characteristics of settlement populations, which in turn changes the demand for urban services. The problems are somewhat different in the largest population centers (e.g., those of more than 1 million population) and mid-sized to small-sized regional centers. The former are more likely to be destinations for migrants from rural areas and smaller settlements and cross-border areas, but larger settlements generally have much greater command over national resource. Thus, smaller settlements actually may be more vulnerable. Informal settlements surrounding large and medium-size cities in the developing world remain a cause for concern because they exhibit several current health and environmental hazards that could be exacerbated by global warming and have limited command over resources. [7.1]

Table TS-3 classifies several types of climate-caused environmental changes discussed in the climate and human settlement literatures. The table features three general types of settlements, each based on the one of the three major mechanisms by which climate affects settlements. The impacts correspond to the mechanism of the effect. Thus, a given settlement may be affected positively by effects of climate change on its resource base (e.g., more agricultural production) and negatively by effects on its infrastructure (e.g., more frequent flooding of its

Table TS-3: Impacts of climate change on human settlements, by impact type and settlement type (impact mechanism).^{a,b}

Type of Settlement, Importance Rating, and Reference												
Impact Type	Resource-Dependent (Effects on Resources)					Coastal-Rivertime-Sleeplands (Effects on Buildings and Infrastructure)				Urban <1 M (Effects on Populations)		
	Urban, High Capacity		Rural, Low Capacity		Capacity	Urban, High Capacity		Rural, Low Capacity		Capacity	Urban 1+ M (Effects on Populations)	
	Urban	M	Rural	H	C	Urban	H	Rural	L	C	High	Low

^a Values in cells in the table were assigned by authors on the basis of direct evidence in the literature or inference from impacts shown in other cells. Typeface indicates source of rating. Boldface indicates direct evidence or study; italic indicates direct inference from similar impacts; regular typeface indicates logical conclusion from settlement type, but cannot be directly corroborated from a study or inferred from similar impacts.

^b Impacts ratings: Low (L) = impacts are barely discernible or easily overcome; moderate (M) = impacts are clearly noticeable, although not disruptive, and may require significant expense or difficulty in adapting; high (H) = impacts are clearly disruptive and may not be overcome or adaptation is so costly that it is disruptive (impacts generally based on 2xCO₂ scenarios or studies describing impact of current weather events, but have been placed in context of the IPCC transient scenarios for mid- to late 21st century). Note that "Urban 1+ M" and "Urban <1 M" refer to populations above and below 1 million, respectively.

^c See Section 1.4 of Technical Summary for key to confidence-level rankings.

water works and overload of its electrical system). Different types of settlements may experience these effects in different relative intensities (e.g., noncoastal settlements do not directly experience impacts through sea-level rise); the impacts are ranked from overall highest to lowest importance. Most settlement effects literature is based on 2xCO₂ scenarios or studies describing the impact of current weather events (analogs) but has been placed in context of the IPCC transient scenarios. [7.1]

Climate change has the potential to create local and regional conditions that involve water deficits and surpluses, sometimes seasonally in the same geographic locations. *The most widespread serious potential impacts are flooding, landslides, mudslides, and avalanches driven by projected increases in rainfall intensity and sea-level rise.* A growing literature suggests that a very wide variety of settlements in nearly every climate zone may be affected (established but incomplete). Riverine and coastal settlements are believed to be particularly at risk, but urban flooding could be a problem anywhere storm drains, water supply, and waste management systems are not designed with enough capacity or sophistication (including conventional hardening and more advanced system design) to avoid being overwhelmed. The next most serious threats are tropical cyclones (hurricanes or typhoons), which may increase in peak intensity in a warmer world. Tropical cyclones combine the effects of heavy rainfall, high winds, and storm surge in coastal areas and can be disruptive far inland, but they are not as universal in location as floods and landslides. Tens of millions of people live in the settlements potentially flooded. For example, estimates of the mean annual number of people who would be flooded by coastal storm surges increase several-fold (by 75 million to 200 million people, depending on adaptive responses) for mid-range scenarios of a 40-cm sea-level rise by the 2080s relative to scenarios with no sea-level rise. Potential damages to infrastructure in coastal areas from sea-level rise have been estimated to be tens of billions of dollars for individual countries such as Egypt, Poland, and Vietnam. In the middle of Table TS-3 are effects such as heat or cold waves, which can be disruptive to the resource base (e.g., agriculture), human health, and demand for heating and cooling energy. Environmental impacts such as reduced air and water quality also are included. Windstorms, water shortages, and fire also are expected to be moderately important in many regions. At the lower end are effects such as permafrost melting and heat island effects—which, although important locally, may not apply to as wide a variety of settlements or hold less importance once adaptation is taken into account. [7.2, 7.3]

Global warming is expected to result in increases in energy demand for spacing cooling and in decreased energy use for space heating. Increases in heat waves add to cooling energy demand, and decreases in cold waves reduce heating energy demand. The projected net effect on annual energy consumption is scenario- and location-specific. Adapting human settlements, energy systems, and industry to climate change provides challenges for the design and operation of settlements (in some cases) during more severe weather and opportunities to take

advantage (in other cases) of more benign weather. For instance, transmission systems of electric systems are known to be adversely affected by extreme events such as tropical cyclones, tornadoes, and ice storms. The existence of local capacity to limit environmental hazards or their health consequences in any settlement generally implies local capacity to adapt to climate change, unless adaptation implies particularly expensive infrastructure investment. Adaptation to warmer climate will require local tuning of settlements to a changing environment, not just warmer temperatures. Urban experts are unanimous that successful environmental adaptation cannot occur without locally based, technically and institutionally competent, and politically supported leadership that have good access to national-level resources. [7.2, 7.3, 7.4, 7.5]

Possible adaptation options involve planning of settlements and their infrastructure, placement of industrial facilities, and making similar long-lived decisions to reduce the adverse effects of events that are of low (but increasing) probability and high (and perhaps rising) consequences. Many specific conventional and advanced techniques can contribute to better environmental planning and management, including market-based tools for pollution control, demand management and waste reduction, mixed-use zoning and transport planning (with appropriate provision for pedestrians and cyclists), environmental impact assessments, capacity studies, strategic environmental plans, environmental audit procedures, and state-of-the-environment reports. Many cities have used a combination of these strategies in developing “Local Agenda 21s.” Many Local Agenda 21s deal with a list of urban problems that could closely interact with climate change in the future. [7.2, 7.5]

4.6. Insurance and Other Financial Services

The financial services sector—broadly defined as private and public institutions that offer insurance and disaster relief, banking, and asset management services—is a unique indicator of potential socioeconomic impacts of climate change because it is sensitive to climate change and it integrates effects on other sectors. The sector is a key agent of adaptation (e.g., through support of building codes and, to a limited extent, land-use planning), and financial services represent risk-spreading mechanisms through which the costs of weather-related events are distributed among other sectors and throughout society. However, insurance, whether provided by public or private entities, also can encourage complacency and maladaptation by fostering development in at-risk areas such as U.S. floodplains or coastal zones. The effects of climate change on the financial services sector are likely to manifest primarily through changes in spatial distribution, frequencies, and intensities of extreme weather events (Table TS-4). [8.1, 8.2, 15.2.7]

The costs of extreme weather events have exhibited a rapid upward trend in recent decades. Yearly global economic losses from large events increased from US\$3.9 billion yr⁻¹ in the 1950s to US\$40 billion yr⁻¹ in the 1990s (all 1999 US\$, uncorrected for purchasing power parity). Approximately one-quarter of

Table TS-4: Extreme climate-related phenomena and their effects on the insurance industry: observed changes and projected changes during 21st century (after Table 3-10; see also Table 8-1).

Changes in Extreme Climate Phenomena	Observed Changes	Projected Changes	Type of Event Relevant to			Sensitive Insurance Branches
	Likelihood		Insurance Sector	Relevant Time Scale	Sensitive Sectors/Activities	
<i>Temperature Extremes</i>						
Higher maximum temperatures, more hot days and heat waves ^b over nearly all land areas	Likely ^a (mixed trends for heat waves in several regions)	Very likely ^a	Heat wave	Daily-weekly maximum	Electric reliability, human settlements	Health, life, property, business interruption
			Heat wave, droughts	Monthly-seasonal maximum	Forests (tree health), natural resources, agriculture, water resources, electricity demand and reliability, industry, health, tourism	Health, crop, business interruption
Higher (increasing) minimum temperatures, fewer cold days, frost days, and cold waves ^b over nearly all land areas	Very likely ^a (cold waves not treated by WGI)	Very likely ^a	Frost, frost heave	Daily-monthly minimum	Agriculture, energy demand, health, transport, human settlements	Health, crop, property, business interruption, vehicle
<i>Rainfall/Precipitation Extremes</i>						
More intense precipitation events	Likely ^a over many Northern Hemisphere mid- to high-latitude land areas	Very likely ^a over many areas	Flash flood	Hourly-daily maximum	Human settlements	Property, flood, vehicle, business interruption, life, health
			Flood, inundation, mudslide	Weekly-monthly maximum	Agriculture, forests, transport, water quality, human settlements, tourism	Property, flood, crop, marine, business interruption
Increased summer drying and associated risk of drought	Likely ^a in a few areas	Likely ^a over most mid-latitude continental interiors (lack of consistent projections in other areas)	Summer drought, land subsidence, wildfire	Monthly-seasonal minimum	Forests (tree health), natural resources, agriculture, water resources, (hydro)energy supply, human settlements	Crop, property, health

the losses occurred in developing countries. The insured portion of these losses rose from a negligible level to US\$9.2 billion annually during the same period. Including events of all sizes doubles these loss totals (see Figure TS-5). The costs of weather events have risen rapidly, despite significant and increasing efforts at fortifying infrastructure and enhancing disaster preparedness. These efforts dampen to an unknown degree the observed rise in loss costs, although the literature attempting to separate natural from human driving forces has not quantified

this effect. As a measure of increasing insurance industry vulnerability, the ratio of global property/casualty insurance premiums to weather-related losses—an important indicator of adaptive capacity—fell by a factor of three between 1985 and 1999. [8.3]

Part of the observed upward trend in historical disaster losses is linked to socioeconomic factors—such as population growth, increased wealth, and urbanization in vulnerable areas—and

Table TS-4 (continued)

Changes in Extreme Climate Phenomena	Observed Changes Likelihood	Projected Changes Likelihood	Type of Event				Sensitive Insurance Branches
			Relevant to Insurance Sector	Relevant Time Scale	Sensitive Sectors/Activities		
<i>Rainfall/Precipitation Extremes (continued)</i>							
Increased intensity of mid-latitude storms ^c	Medium likelihood ^a of increase in Northern Hemisphere, decrease in Southern Hemisphere	Little agreement among current models	Snowstorm, ice storm, avalanche	Hourly-weekly	Forests, agriculture, energy distribution and reliability, human settlements, mortality, tourism	Property, crop, vehicle, aviation, life, business interruption	
			Hailstorm	Hourly	Agriculture, property	Crop, vehicle, property, aviation	
Intensified droughts and floods associated with El Niño events in many different regions (see also droughts and extreme precipitation events)	Inconclusive information	Likely ^a	Drought and floods	Various	Forests (tree health), natural resources, agriculture, water resources, (hydro)energy supply, human settlements	Property, flood, vehicle, crop, marine, business interruption, life, health	
<i>Wind Extremes</i>							
Increased intensity of mid-latitude storms ^b	No compelling evidence for change	Little agreement among current models	Mid-latitude windstorm	Hourly-daily	Forests, electricity distribution and reliability, human settlements	Property, vehicle, aviation, marine, business interruption, life	
			Tornadoes	Hourly	Forests, electricity distribution and reliability, human settlements	Property, vehicle, aviation, marine, business interruption	
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities ^c	Wind extremes not observed in the few analyses available; insufficient data for precipitation	Likely ^a over some areas	Tropical storms, including cyclones, hurricanes, and typhoons	Hourly-weekly	Forests, electricity distribution and reliability, human settlements, agriculture	Property, vehicle, aviation, marine, business interruption, life	

part is linked to climatic factors such as observed changes in precipitation, flooding, and drought events. Precise attribution is complex, and there are differences in the balance of these two causes by region and by type of event. Many of the observed trends in weather-related losses are consistent with what would be expected under climate change. Notably, the growth rate in human-induced and non-weather-related losses has been far lower than that of weather-related events. [8.2.2]

Recent history has shown that weather-related losses can stress insurance companies to the point of impaired profitability, consumer price increases, withdrawal of coverage, and elevated demand for publicly funded compensation and relief. Increased uncertainty will increase the vulnerability of the insurance and government sectors and complicate adaptation and disaster relief efforts under climate change. [8.3, 15.2.7]

Table TS-4 (continued)

Changes in Extreme Climate Phenomena	Observed Changes	Projected Changes	Type of Event				Sensitive Insurance Branches
			Relevant to Insurance Sector	Relevant Time Scale	Sensitive Sectors/Activities		
<i>Other Extremes</i>							
Refer to entries above for higher temperatures, increased tropical and mid-latitude storms	Refer to relevant entries above	Refer to relevant entries above	Lightning	Instantaneous	Electricity distribution and reliability, human settlements, wildfire	Life, property, vehicle, aviation, marine, business interruption	
Refer to entries above for increased tropical cyclones, Asian summer monsoon, and intensity of mid-latitude storms	Refer to relevant entries above	Refer to relevant entries above	Tidal surge (associated with onshore gales), coastal inundation	Daily	Coastal zone infrastructure, agriculture and industry, tourism	Life, marine, property, crop	
Increased Asian summer monsoon precipitation variability	Not treated by WGI	Likely ^a	Flood and drought	Seasonal	Agriculture, human settlements	Crop, property, health, life	

^a Likelihood refers to judgmental estimates of confidence used by Working Group I: *very likely* (90–99% chance); *likely* (66–90% chance). Unless otherwise stated, information on climate phenomena is taken from Working Group I's Summary for Policymakers and Technical Summary. These likelihoods refer to observed and projected changes in extreme climate phenomena and likelihood shown in first three columns of table.

^b Information from Working Group I, Technical Summary, Section F.5.

^c Changes in regional distribution of tropical cyclones are possible but have not been established.

The financial services sector as a whole is expected to be able to cope with the impacts of future climate change, although the historic record shows that low-probability, high-impact events or multiple closely spaced events severely affect parts of the sector, especially if adaptive capacity happens to be simultaneously depleted by nonclimate factors (e.g., adverse market conditions that can deplete insurer loss reserves by eroding the value of securities and other insurer assets). There is high confidence that climate change and anticipated changes in weather-related events that are perceived to be linked to climate change would increase actuarial uncertainty in risk assessment and thus in the functioning of insurance markets. Such developments would place upward pressure on premiums and/or could cause certain risks to be reclassified as uninsurable, with subsequent withdrawal of coverage. This, in turn, would place increased pressure on government-based insurance and relief systems, which already are showing strain in many regions and are attempting to limit their exposures (e.g., by raising deductibles and/or placing caps on maximum claims payable).

Trends toward increasing firm size, diversification, and integration of insurance with other financial services, as well as improved tools to transfer risk, all potentially contribute to robustness. However, the property/casualty insurance and reinsurance segments have greater sensitivity, and individual companies already have experienced catastrophe-related bankruptcies triggered by weather events. Under some conditions and in

some regions, the banking industry as a provider of loans also may be vulnerable to climate change. In many cases, however, the banking sector transfers risk back to insurers, who often purchase their debt products. [8.3, 8.4, 15.2.7]

Adaptation² to climate change presents complex challenges, as well as opportunities, for the financial services sector. Regulatory involvement in pricing, tax treatment of reserves, and the (in)ability of firms to withdraw from at-risk markets are examples of factors that influence the resilience of the sector. Management of climate-related risk varies by country and region. Usually it is a mixture of commercial and public arrangements and self-insurance. In the face of climate change, the relative role of each can be expected to change. Some potential response options offer co-benefits that support sustainable development and climate change mitigation objectives (e.g., energy-efficiency measures that also make buildings more resilient to natural disasters, in addition to helping the sector adapt to climate changes). [8.3.4, 8.4.2]

The effects of climate change are expected to be greatest in developing countries (especially those that rely on primary production as a major source of income) in terms of loss of life,

²The term “mitigation” often is used in the insurance and financial services sectors in much the same way as the term “adaptation” is used in the climate research and policy communities.

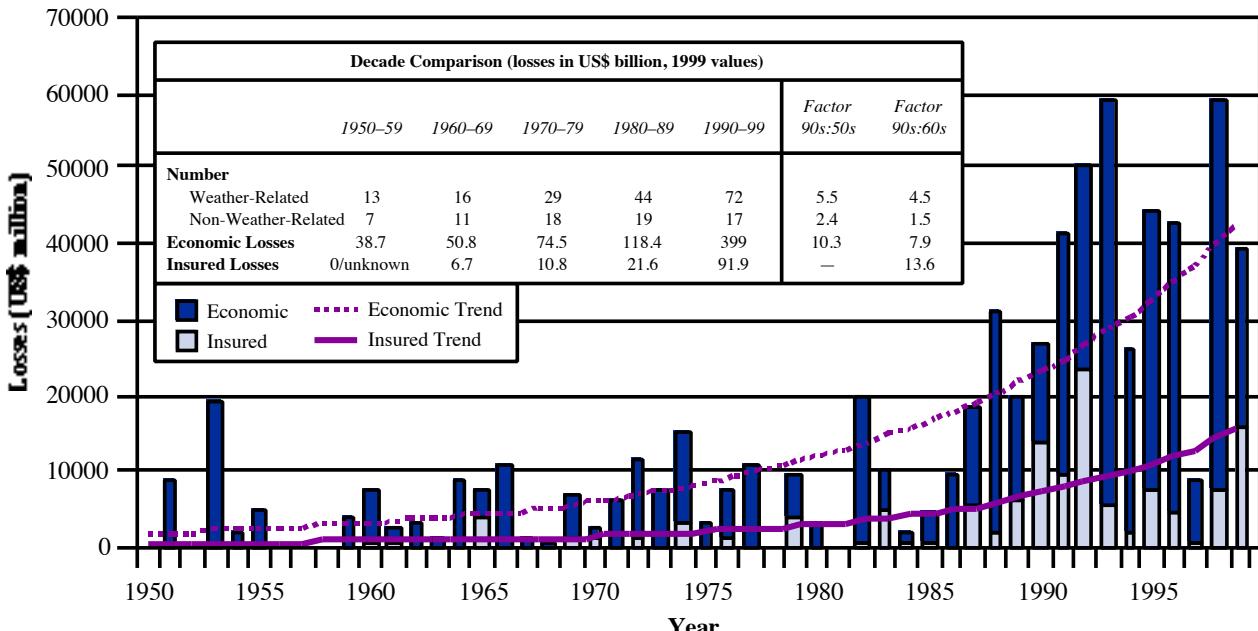

Figure TS-5: The costs of catastrophic weather events have exhibited a rapid upward trend in recent decades. Yearly economic losses from large events increased 10.3-fold from US\$4 billion yr⁻¹ in the 1950s to US\$40 billion yr⁻¹ in the 1990s (all in 1999 US\$). The insured portion of these losses rose from a negligible level to US\$9.2 billion annually during the same period, and the ratio of premiums to catastrophe losses fell by two-thirds. Notably, costs are larger by a factor of 2 when losses from ordinary, noncatastrophic weather-related events are included. The numbers generally include “captive” self-insurers but not the less-formal types of self-insurance.

effects on investment, and effects on the economy. Damages from natural disasters have been as high as half of the gross domestic product (GDP) in one case. Weather disasters set back development, particularly when funds are redirected from development projects to disaster-recovery efforts. [8.5]

Equity issues and development constraints would arise if weather-related risks become uninsurable, insurance prices increase, or the availability of insurance or financing becomes limited. Thus, increased uncertainty could constrain development. Conversely, more extensive penetration of or access to insurance and disaster preparedness/recovery resources would increase the ability of developing countries to adapt to climate change. More widespread introduction of microfinancing schemes and development banking also could be an effective mechanism to help developing countries and communities adapt. [8.3]

This assessment of financial services has identified some areas of improved knowledge and has corroborated and further augmented conclusions reached in the SAR. It also has highlighted many areas where greater understanding is needed—in particular, better analysis of economic losses to determine their causation, assessment of financial resources involved in dealing with climate change damage and adaptation, evaluation of alternative methods to generate such resources, deeper investigation of the sector’s vulnerability and resilience to a range of extreme weather event scenarios, and more research into how the sector (private and public elements) could innovate

to meet the potential increase in demand for adaptation funding in developed and developing countries, to spread and reduce risks from climate change. [8.7]

4.7. Human Health

Global climate change will have diverse impacts on human health—some positive, most negative. Changes in the frequencies of extreme heat and cold, the frequencies of floods and droughts, and the profile of local air pollution and aeroallergens would affect population health directly. Other health impacts would result from the impacts of climate change on ecological and social systems. These impacts would include changes in infectious disease occurrence, local food production and undernutrition, and various health consequences of population displacement and economic disruption.

There is little published evidence that changes in population health status actually have occurred in response to observed trends in climate over recent decades. A recurring difficulty in identifying such impacts is that the causation of most human health disorders is multifactorial, and the “background” socioeconomic, demographic, and environmental context changes significantly over time.

Studies of the health impacts associated with interannual climate variability (particularly those related to the El Niño

cycle) have provided new evidence of human health sensitivity to climate, particularly for mosquito-borne diseases. The combination of existing research-based knowledge, resultant theoretical understandings, and the output of predictive modeling leads to several conclusions about the future impacts of climate change on human population health.

If heat waves increase in frequency and intensity, the risk of death and serious illness would increase, principally in older age groups and the urban poor (high confidence). The effects of an increase in heat waves often would be exacerbated by increased humidity and urban air pollution. The greatest increases in thermal stress are forecast for mid- to high-latitude (temperate) cities, especially in populations with nonadapted architecture and limited air conditioning. Modeling of heat wave impacts in urban populations, allowing for acclimatization, suggests that a number of U.S. cities would experience, on average, several hundred extra deaths each summer. Although the impact of climate change on thermal stress-related mortality in developing country cities may be significant, there has been little research in such populations. Warmer winters and fewer cold spells will decrease cold-related mortality in many temperate countries (high confidence). Limited evidence indicates that in at least some temperate countries, reduced winter deaths would outnumber increased summer deaths (medium confidence). [9.4]

Any increases in the frequency and intensity of extreme events such as storms, floods, droughts, and cyclones would adversely impact human health through a variety of pathways. These natural hazards can cause direct loss of life and injury and can affect health indirectly through loss of shelter, population displacement, contamination of water supplies, loss of food production (leading to hunger and malnutrition), increased risk of infectious disease epidemics (including diarrhoeal and respiratory disease), and damage to infrastructure for provision of health services (very high confidence). If cyclones were to increase regionally, devastating impacts often would occur, particularly in densely settled populations with inadequate resources. Over recent years, major climate-related disasters have had major adverse effects on human health, including floods in China, Bangladesh, Europe, Venezuela, and Mozambique, as well as Hurricane Mitch, which devastated Central America. [9.5]

Climate change will decrease air quality in urban areas with air pollution problems (medium confidence). An increase in temperature (and, in some models, ultraviolet radiation) increases the formation of ground-level ozone, a pollutant with well-established adverse effects on respiratory health. Effects of climate change on other air pollutants are less well established. [9.6]

Higher temperatures, changes in precipitation, and changes in climate variability would alter the geographic ranges and seasonality of transmission of vector-borne infectious diseases—extending the range and season for some infectious diseases and contracting them for others. Vector-borne infectious diseases are transmitted by blood-feeding organisms such as

mosquitoes and ticks. Such organisms depend on the complex interaction of climate and other ecological factors for survival. Currently, 40% of the world population lives in areas with malaria. In areas with limited or deteriorating public health infrastructure, increased temperatures will tend to expand the geographic range of malaria transmission to higher altitudes (high to medium confidence) and higher latitudes (medium to low confidence). Higher temperatures, in combination with conducive patterns of rainfall and surface water, will extend the transmission season in some locations (high confidence). Changes in climate, including changes in climate variability, would affect many other vector-borne infections (such as dengue, leishmaniasis, various types of mosquito-borne encephalitis, Lyme disease, and tick-borne encephalitis) at the margins of their current distributions (medium/high confidence). For some vector-borne diseases in some locations, climate change will decrease transmission via reductions in rainfall or temperatures that are too high for transmission (medium confidence). A range of mathematical models indicate, with high consistency, that climate change scenarios over the coming century would cause a small net increase in the proportion of the world's population living in regions of potential transmission of malaria and dengue (medium to high confidence). A change in climatic conditions will increase the incidence of various types of water- and food-borne infectious diseases. [9.7]

Climate change may cause changes in the marine environment that would alter risks of biotoxin poisoning from human consumption of fish and shellfish. Biotoxins associated with warmer waters, such as ciguatera in tropical waters, could extend their range to higher latitudes (low confidence). Higher SSTs also would increase the occurrence of toxic algal blooms (medium confidence), which have complex relationships with human poisoning and are ecologically and economically damaging. Changes in surface water quantity and quality will affect the incidence of diarrhoeal diseases (medium confidence). [9.8]

Changes in food supply resulting from climate change could affect the nutrition and health of the poor in some regions of the world. Studies of climate change impacts on food production indicate that, globally, impacts could be positive or negative, but the risk of reduced food yields is greatest in developing countries—where 790 million people are estimated to be undernourished at present. Populations in isolated areas with poor access to markets will be particularly vulnerable to local decreases or disruptions in food supply. Undernourishment is a fundamental cause of stunted physical and intellectual development in children, low productivity in adults, and susceptibility to infectious disease. Climate change would increase the number of undernourished people in the developing world (medium confidence), particularly in the tropics. [9.9, 5.3]

In some settings, the impacts of climate change may cause social disruption, economic decline, and population displacement that would affect human health. Health impacts associated with population displacement resulting from natural disasters

Table TS-5: Options for adaptation to reduce health impacts of climate change.

Health Outcome	Legislative	Technical	Educational-Advisory	Cultural and Behavioral
Thermal stress	– Building guidelines	– Housing, public buildings, urban planning to reduce heat island effects, air conditioning	– Early warning systems	– Clothing, siesta
Extreme weather events	– Planning laws – Building guidelines – Forced migration – Economic incentives for building	– Urban planning – Storm shelters	– Early warning systems	– Use of storm shelters
Air quality	– Emission controls – Traffic restrictions	– Improved public transport, catalytic converters, smoke stacks	– Pollution warnings	– Carpooling
Vector-borne diseases		– Vector control – Vaccination, impregnated bednets – Sustainable surveillance, prevention and control programs	– Health education	– Water storage practices
Water-borne diseases	– Watershed protection laws – Water quality regulation	– Genetic/molecular screening of pathogens – Improved water treatment (e.g., filters) – Improved sanitation (e.g., latrines)	– Boil water alerts	– Washing hands and other hygiene behavior – Use of pit latrines

or environmental degradation are substantial (high confidence). [9.10]

For each anticipated adverse health impact there is a range of social, institutional, technological, and behavioral adaptation options to lessen that impact (see Table TS-5). Overall, the adverse health impacts of climate change will be greatest in vulnerable lower income populations, predominately within tropical/subtropical countries. There is a basic and general need for public health infrastructure (programs, services, surveillance systems) to be strengthened and maintained. The ability of affected communities to adapt to risks to health also depends on social, environmental, political, and economic circumstances. [9.11]

exposures to climate stimuli across regions. The natural and social systems of different regions have varied characteristics, resources, and institutions and are subject to varied pressures that give rise to differences in sensitivity and adaptive capacity. From these differences emerge different key concerns for each of the major regions of the world. Even within regions, however, impacts, adaptive capacity, and vulnerability will vary. Because available studies have not employed a common set of climate scenarios and methods and because of uncertainties regarding the sensitivities and adaptability of natural and social systems, assessment of regional vulnerabilities is necessarily qualitative.

5.1. Africa

Africa is highly vulnerable to climate change. Impacts of particular concern to Africa are related to water resources, food production, human health, desertification, and coastal zones, especially in relation to extreme events. A synergy of land-use and climate change will exacerbate desertification. Selected key impacts in Africa are highlighted in Figure TS-6.

5. Regional Analysis

The vulnerability of human populations and natural systems to climate change differs substantially across regions and across populations within regions. Regional differences in baseline climate and expected climate change give rise to different

5.1.1. Water Resources

Water resources are a key area of vulnerability in Africa, affecting water supply for household use, agriculture, and industry. In shared river basins, regional cooperation protocols minimize adverse impacts and potential for conflicts. Trends in regional per capita water availability in Africa over the past half century show that water availability has diminished by 75%. Although the past 2 decades have experienced reductions in river flows, especially in sub-Saharan West Africa, the trend mainly reflects the impact of population growth—which, for most countries, quadrupled in the same period. Population growth and degradation of water quality are significant threats to water security in many parts of Africa, and the combination of continued population increases and global warming impacts is likely to accentuate water scarcity in subhumid regions of Africa.

Africa is the continent with the lowest conversion factor of precipitation to runoff, averaging 15%. Although the equatorial region and coastal areas of eastern and southern Africa are humid, the rest of the continent is dry subhumid to arid. The dominant impact of global warming will be a reduction in soil moisture in subhumid zones and a reduction in runoff. Current trends in major river basins indicate decreasing runoff of about 17% over the past decade.

Most of Africa has invested significantly in hydroelectric power facilities to underpin economic development. Reservoir storage shows marked sensitivity to variations in runoff and periods of drought. Lake storage and major dams have reached critical levels, threatening industrial activity. Model results and some reservoirs and lakes indicate that global warming will increase the frequency of such low storage as a result of flooding or drought conditions that are related to ENSO. [10.2.1]

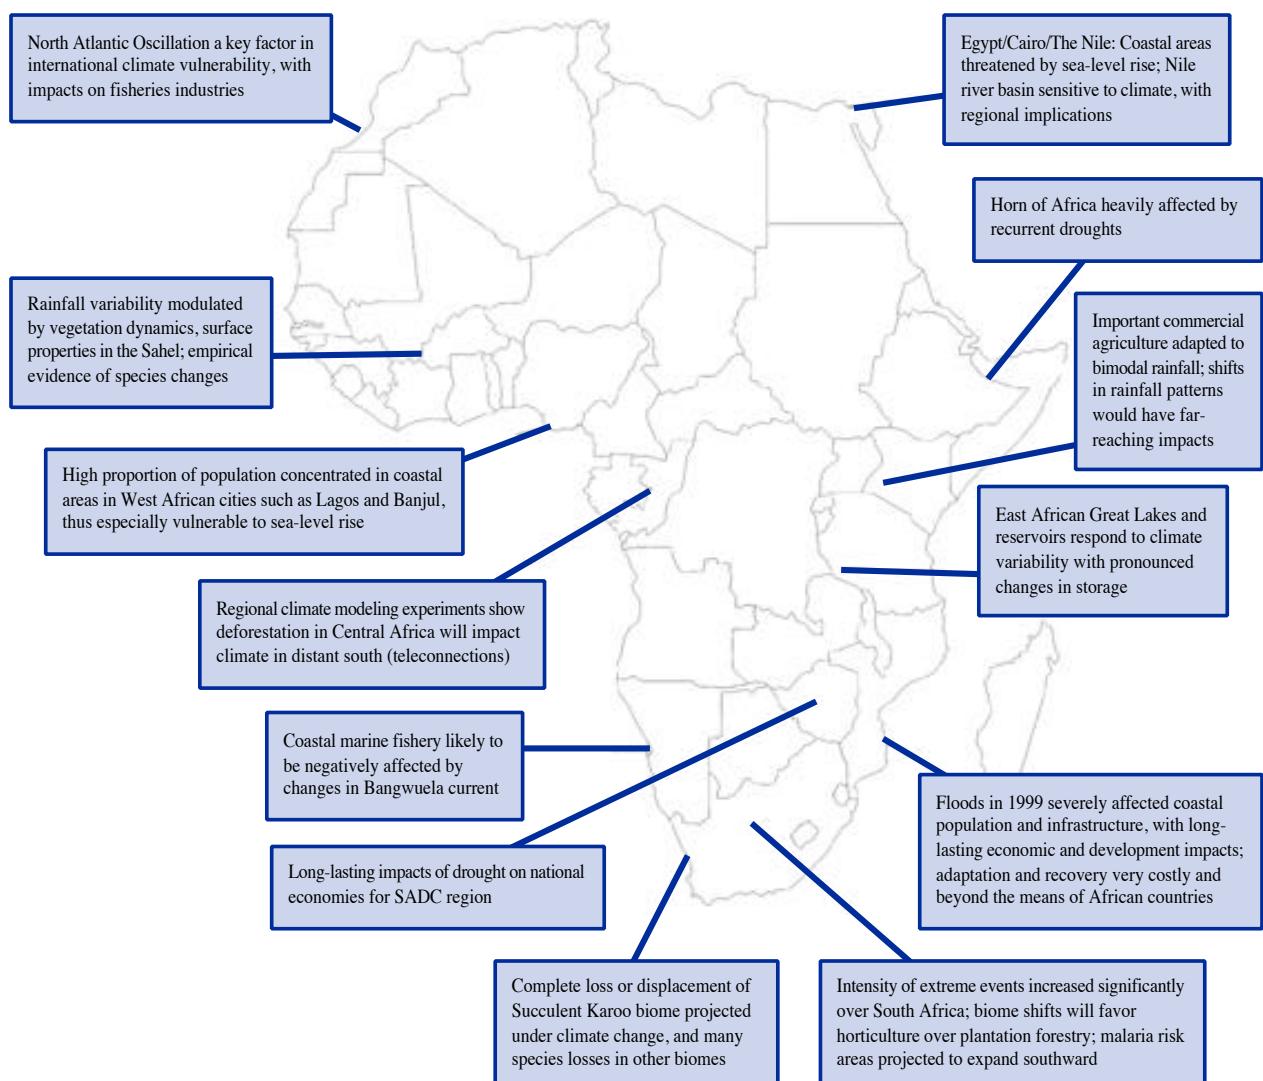

Figure TS-6: Selected key impacts for Africa.

5.1.2. Food Security

There is wide consensus that climate change will worsen food security, mainly through increased extremes and temporal/spatial shifts. The continent already experiences a major deficit in food production in many areas, and potential declines in soil moisture will be an added burden. Food-insecure countries are at a greater risk of adverse impacts of climate change. Inland and marine fisheries provide a significant contribution to protein intake in many African countries. As a result of water stress and land degradation, inland fisheries will be rendered more vulnerable to episodic drought and habitat destruction. Ocean warming is likely to impact coastal marine fisheries. [10.2.2]

5.1.3. Natural Resource Management and Biodiversity

Irreversible losses of biodiversity could be accelerated with climate change. Climate change is expected to lead to drastic shifts of biodiversity-rich biomes such as the Succulent Karoo in South Africa and many losses in species in other biomes. Changes in the frequency, intensity, and extent of vegetation fires and habitat modification from land-use change may negate natural adaptive processes and lead to extinctions. Changes in ecosystems will affect water supply, fuelwood, and other services. [10.2.3.2]

5.1.4. Human Health

Changes in temperature and rainfall will have many negative impacts on human health. Temperature increases will extend disease vector habitats. Where sanitary infrastructure is inadequate, droughts and flooding will result in increased frequency of water-borne diseases. Increased rainfall could lead to more frequent outbreaks of Rift Valley fever. Poor sanitation in urban locations and increased temperatures of coastal waters could aggravate cholera epidemics. [10.2.4.1.1, 10.2.4.4]

5.1.5. Settlements and Infrastructure

Although the basic infrastructure for development—transport, housing, and services—is inadequate in many instances, it nevertheless represents substantial investment by governments. An increase in the frequency of damaging floods, heat waves, dust storms, hurricanes, and other extreme events could degrade the integrity of such critical infrastructures at rates the economies may not be able to tolerate, leading to a serious deterioration of social, health, and economic services delivery systems. This condition will greatly compromise general human welfare. [10.2.5.3]

Sea-level rise, coastal erosion, saltwater intrusion, and flooding will have significant impacts for African communities and economies. Most of Africa's largest cities are along coasts and are highly vulnerable to extreme events, sea-level rise, and coastal erosion because of inadequate physical planning and

escalating urban drift. Rapid unplanned expansion is likely to predispose large populations to infectious diseases from climate-related factors such as flooding. [10.2.5.2]

5.1.6. Desertification

Alteration of spatial and temporal patterns in temperature, rainfall, solar radiation, and winds from a changing climate will exacerbate desertification. Desertification is a critical threat to sustainable resource management in arid, semi-arid, and dry subhumid regions of Africa, undermining food and water security. [10.2.6]

5.1.7. Adaptive Capacity

Given the diversity of constraints facing many nations, the overall capacity for Africa to adapt to climate change currently is very low. National action plans that incorporate long-term changes and pursue “no regrets” strategies could increase the adaptive capacity of the region. Seasonal forecasting—for example, linking SSTs to outbreaks of major diseases—is a promising adaptive strategy that will help save lives. Current technologies and approaches, especially in agriculture and water, are unlikely to be adequate to meet projected demands, and increased climate variability will be an additional stress. It is unlikely that African countries on their own will have sufficient resources to respond effectively.

Climate change also offers some opportunities. The processes of adapting to global climate change, including technology transfer and carbon sequestration, offer new development pathways that could take advantage of Africa's resources and human potential. Regional cooperation in science, resource management, and development already are increasing, and access to international markets will diversify economies and increase food security.

This assessment of vulnerability to climate change is marked by uncertainty. The diversity of African climates, high rainfall variability, and a very sparse observational network make predictions of future climate change difficult at the subregional and local level. Underlying exposure and vulnerability to climatic changes are well established. Sensitivity to climatic variations is established but incomplete. However, uncertainty over future conditions means that there is low confidence in projected costs of climate change. This assessment can create the framework for individual states to begin to construct methodologies for estimating such costs, based on their individual circumstances.

5.2. Asia

Climate change will impose significant stress on resources throughout the Asian region. Asia has more than 60% of the world's population; natural resources already are under stress,

Table TS-6: Sensitivity of selected Asian regions to climate change.

Change in Climatic Elements and Sea-Level Rise	Vulnerable Region	Primary Change	Impacts Primary	Impacts Secondary
0.5–2°C (10- to 45-cm sea-level rise)	Bangladesh Sundarbans	– Inundation of about 15% (~750 km ²) – Increase in salinity	– Loss of plant species – Loss of wildlife	– Economic loss – Exacerbated insecurity and loss of employment
4°C (+10% rainfall)	Siberian permafrosts	– Reduction in continuous permafrost – Shift in southern limit of Siberian permafrost by ~100–200 km northward	– Change in rock strength – Change in bearing capacity – Change in compressibility of frozen rocks – Thermal erosion	– Effects on construction industries – Effects on mining industry – Effects on agricultural development
>3°C (>+20% rainfall)	Water resources in Kazakhstan	– Change in runoff	– Increase in winter floods – Decrease in summer flows	– Risk to life and property – Summer water stress
~2°C (-5 to 10% rainfall; 45-cm sea-level rise)	Bangladesh lowlands	– About 23–29% increase in extent of inundation	– Change in flood depth category – Change in monsoon rice cropping pattern	– Risk to life and property – Increased health problems – Reduction in rice yield

and the resilience of most sectors in Asia to climate change is poor. Many countries are socioeconomically dependent on natural resources such as water, forests, grassland and rangeland, and fisheries. The magnitude of changes in climate variables would differ significantly across Asian subregions and countries. The climate change sensitivity of a few vulnerable sectors in Asia and the impacts of these limits are presented in Table TS-6. The region's vulnerability to climate change is captured in Table TS-7 for selected categories of regions/issues.

5.2.1. Agriculture and Food Security

Food insecurity appears to be the primary concern for Asia. Crop production and aquaculture would be threatened by thermal and water stresses, sea-level rise, increased flooding, and strong winds associated with intense tropical cyclones (high confidence). In general, it is expected that areas in mid- and high latitudes will experience increases in crop yield; yields in lower latitudes generally will decrease. A longer duration of the summer season should lead to a northward shift of the agroecosystem boundary in boreal Asia and favor an overall increase in agriculture productivity (medium confidence). Climatic variability and change also will affect scheduling of the cropping season, as well as the duration of the growing period of the crop. In China, yields of several major crops are expected to decline as a result of climate change. Acute water shortages combined with thermal stress should adversely affect wheat and, more severely, rice productivity in India even under the positive effects of elevated CO₂ in the future. Crop diseases such as wheat scab, rice blast, and sheath and culm blight of

rice also could become more widespread in temperate and tropical regions of Asia if the climate becomes warmer and wetter. Adaptation measures to reduce the negative effects of climatic variability may include changing the cropping calendar to take advantage of the wet period and to avoid the extreme weather events (e.g., typhoons and strong winds) during the growing season. [11.2.2.1]

Asia dominates world aquaculture, producing 80% of all farmed fish, shrimp, and shellfish. Many wild stocks are under stress as a result of overexploitation, trawling on sea-bottom habitats, coastal development, and pollution from land-based activities. Moreover, marine productivity is greatly affected by plankton shift, such as seasonal shifting of sardine in the Sea of Japan, in response to temperature changes induced during ENSO. Storm surges and cyclonic conditions also routinely lash the coastline, adding sediment loads to coastal waters. Effective conservation and sustainable management of marine and inland fisheries are needed at the regional level so that living aquatic resources can continue to meet regional and national nutritional needs. [11.2.4.4]

5.2.2. Ecosystems and Biodiversity

Climate change would exacerbate current threats to biodiversity resulting from land-use/cover change and population pressure in Asia (medium confidence). Risks to Asia's rich array of living species are climbing. As many as 1,250 of 15,000 higher plant species are threatened in India. Similar trends are evident in China, Malaysia, Myanmar, and Thailand. Many species and a

Table TS-7: Vulnerability of key sectors to impacts of climate change for select subregions in Asia. Key to confidence-level rankings is provided in Section 1.4 of Technical Summary.

Regions	Food and Fiber	Biodiversity	Water Resources	Coastal Ecosystems	Human Health	Settlements
Boreal Asia	Slightly resilient ****	Highly vulnerable ***	Slightly resilient ***	Slightly resilient **	Moderately vulnerable **	Slightly or not vulnerable ***
Arid and Semi-Arid Asia						
– Central Asia	Highly vulnerable ****	Moderately vulnerable **	Highly vulnerable ****	Moderately vulnerable **	Moderately vulnerable ***	Moderately vulnerable ***
– Tibetan Plateau	Slightly or not vulnerable **	Highly vulnerable ***	Moderately vulnerable **	Not applicable	No information	No information
Temperate Asia	Highly vulnerable ****	Moderately vulnerable ***	Highly vulnerable ****	Highly vulnerable ****	Highly vulnerable ***	Highly vulnerable ****
Tropical Asia						
– South Asia	Highly vulnerable ****	Highly vulnerable ***	Highly vulnerable ****	Highly vulnerable ****	Moderately vulnerable ***	Highly vulnerable ***
– Southeast Asia	Highly vulnerable ****	Highly vulnerable ***	Highly vulnerable ****	Highly vulnerable ****	Moderately vulnerable ***	Highly vulnerable ***

large population of many other species in Asia are likely to be exterminated as a result of the synergistic effects of climate change and habitat fragmentation. In desert ecosystems, increased frequency of droughts may result in a decline in local forage around oases, causing mass mortality among local fauna and threatening their existence. With a 1-m rise in sea level, the Sundarbans (the largest mangrove ecosystems) of Bangladesh will completely disappear. [11.2.1, 11.2.1.6]

Permafrost degradation resulting from global warming would increase the vulnerability of many climate-dependent sectors affecting the economy in boreal Asia (medium confidence). Pronounced warming in high latitudes of the northern hemisphere could lead to thinning or disappearance of permafrost in locations where it now exists. Large-scale shrinkage of the permafrost region in boreal Asia is likely. Poleward movement of the southern boundary of the sporadic zone also is likely in Mongolia and northeast China. The boundary between continuous and discontinuous (intermittent or seasonal) permafrost areas on the Tibetan Plateau is likely to shift toward the center of the plateau along the eastern and western margins. [11.2.1.5]

The frequency of forest fires is expected to increase in boreal Asia (medium confidence). Warmer surface air temperatures, particularly during summer, may create favorable conditions for thunderstorms and associated lightning, which could trigger

forest fires in boreal forests more often. Forest fire is expected to occur more frequently in northern parts of boreal Asia as a result of global warming. [11.2.1.3]

5.2.3. Water Resources

Freshwater availability is expected to be highly vulnerable to anticipated climate change (high confidence). Surface runoff increases during winter and summer periods would be pronounced in boreal Asia (medium confidence). Countries in which water use is more than 20% of total potential water resources available are expected to experience severe water stress during drought periods. Surface runoff is expected to decrease drastically in arid and semi-arid Asia under projected climate change scenarios. Climate change is likely to change streamflow volume, as well as the temporal distribution of streamflows throughout the year. With a 2°C increase in air temperature accompanied by a 5–10% decline in precipitation during summer, surface runoff in Kazakhstan would be substantially reduced, causing serious implications for agriculture and livestock. Water would be a scarce commodity in many south and southeast Asian countries, particularly where reservoir facilities to store water for irrigation are minimal. Growing populations and concentration of populations in urban areas will exert increasing pressures on water availability and water quality. [11.2.3.1]

5.2.4. Extreme Weather Events

Developing countries of temperate and tropical Asia already are quite vulnerable to extreme climate events such as typhoons/cyclones, droughts, and floods. Climate change and variability would exacerbate these vulnerabilities (high confidence). Extreme weather events are known to cause adverse effects in widely separated areas of Asia. There is some evidence of increases in the intensity or frequency of some of these extreme events on regional scales throughout the 20th century. [11.1.2.2, 11.1.2.3, 11.4.1]

Increased precipitation intensity, particularly during the summer monsoon, could increase flood-prone areas in temperate and tropical Asia. There is potential for drier conditions in arid and semi-arid Asia during summer, which could lead to more severe droughts (medium confidence). Many countries in temperate and tropical Asia have experienced severe droughts and floods frequently in the 20th century. Flash floods are likely to become more frequent in many regions of temperate and tropical Asia in the future. A decrease in return period for extreme precipitation events and the possibility of more frequent floods in parts of India, Nepal, and Bangladesh is projected. [11.1.3.3, 11.2.2.2, 11.1.2.3, 11.4.1]

Conversion of forestland to cropland and pasture already is a prime force driving forest loss in tropical and temperate Asian countries. With more frequent floods and droughts, these actions will have far-reaching implications for the environment (e.g., soil erosion, loss of soil fertility, loss of genetic variability in crops, and depletion of water resources). [11.1.4.1]

Tropical cyclones and storm surges continue to take a heavy toll on life and property in India and Bangladesh. An increase in the intensity of cyclones combined with sea-level rise would result in more loss of life and property in low-lying coastal areas in cyclone-prone countries of Asia (medium confidence). The expected increase in the frequency and intensity of climatic extremes will have significant potential effects on crop growth and agricultural production, as well as major economic and environmental implications (e.g., tourism, transportation). [11.2.4.5, 11.2.6.3, 11.3]

A wide range of precautionary measures at regional and national levels, including awareness and acceptance of risk factors among regional communities, is warranted to avert or reduce the impacts of disasters associated with more extreme weather events on economic and social structures of countries in temperate and tropical Asia. [11.3.2]

5.2.5. Deltas and Coastal Zones

The large deltas and low-lying coastal areas of Asia would be inundated by sea-level rise (high confidence). Climate-related stresses in coastal areas include loss and salinization of agricultural land as a result of change in sea level and changing frequency and intensity of tropical cyclones. Estimates of potential land loss resulting from sea-level rise and risk to population displacement provided in Table TS-8 demonstrate the scale of the issue for major low-lying regions of coastal Asia. Currently, coastal erosion of muddy coastlines in Asia is not a result of sea-level rise; it is triggered largely by annual river-borne suspended sediments transported into the ocean by human activities and delta evolution. These actions could exacerbate the impacts of climate change in coastal regions of Asia. [11.2.4.2]

5.2.6. Human Health

Warmer and wetter conditions would increase the potential for higher incidence of heat-related and infectious diseases in tropical and temperate Asia (medium confidence). The rise in surface air temperature and changes in precipitation in Asia will have adverse effects on human health. Although warming would result in a reduction in wintertime deaths in temperate countries, there could be greater frequency and duration of heat stress, especially in megalopolises during summer. Global warming also will increase the incidence of respiratory and cardiovascular diseases in parts of arid and semi-arid Asia and temperate and tropical Asia. Changes in environmental temperature and precipitation could expand vector-borne diseases into temperate and arid Asia. The spread of vector-borne diseases into more northern latitudes may pose a serious

Table TS-8: Potential land loss and population exposed in Asian countries for selected magnitudes of sea-level rise, assuming no adaptation.

Country	Sea-Level Rise (cm)	Potential Land Loss (km ²)	Potential Land Loss (%)	Population Exposed (million)	Population Exposed (%)
Bangladesh	45	15,668	10.9	5.5	5.0
	100	29,846	20.7	14.8	13.5
India	100	5,763	0.4	7.1	0.8
Indonesia	60	34,000	1.9	2.0	1.1
Japan	50	1,412	0.4	2.9	2.3
Malaysia	100	7,000	2.1	>0.05	>0.3
Pakistan	20	1,700	0.2	n.a.	n.a.
Vietnam	100	40,000	12.1	17.1	23.1

threat to human health. Warmer SSTs along Asian coastlines would support higher phytoplankton blooms. These blooms are habitats for infectious bacterial diseases. Waterborne diseases—including cholera and the suite of diarrheal diseases caused by organisms such as giardia, salmonella, and cryptosporidium—could become more common in many countries of south Asia in warmer climate. [11.2.5.1, 11.2.5.2, 11.2.5.4]

5.2.7. Adaptive Capacity

Adaptation to climate change in Asian countries depends on the affordability of adaptive measures, access to technology, and biophysical constraints such as land and water resource availability, soil characteristics, genetic diversity for crop breeding (e.g., crucial development of heat-resistant rice cultivars), and topography. Most developing countries of Asia are faced with increasing population, spread of urbanization, lack of adequate water resources, and environmental pollution, which hinder socioeconomic activities. These countries will have to individually and collectively evaluate the tradeoffs between climate change actions and nearer term needs (such as hunger, air and water pollution, energy demand). Coping strategies would have to be developed for three crucial sectors: land resources, water resources, and food productivity. Adaptation measures that are designed to anticipate the potential effects of climate change can help offset many of the negative effects. [11.3.1]

5.3. Australia and New Zealand

The Australia/New Zealand region spans the tropics to mid-latitudes and has varied climates and ecosystems, including deserts, rainforests, coral reefs, and alpine areas. The climate is strongly influenced by the surrounding oceans. Australia has significant vulnerability to the drying trend projected over much of the country for the next 50–100 years (Figure TS-3) because substantial agricultural areas currently are adversely affected by periodic droughts, and there already are large areas of arid and semi-arid land. New Zealand—a smaller, more mountainous country with a generally more temperate, maritime climate—may be more resilient to climate changes than Australia, although considerable vulnerability remains (medium confidence). Table TS-9 shows key vulnerabilities and adaptability to climate change impacts for Australia and New Zealand. [12.9.5]

Comprehensive cross-sectoral estimates of net climate change impact costs for various GHG emission scenarios and different societal scenarios are not yet available. Confidence remains very low in the IPCC *Special Report on Regional Impacts of Climate Change* estimate for Australia and New Zealand of -1.2 to -3.8% of GDP for an equivalent doubling of CO₂ concentrations. This estimate did not account for many of the effects and adaptations currently identified. [12.9]

Extreme events are a major source of current climate impacts, and changes in extreme events are expected to dominate the

impacts of climate change. Return periods for heavy rains, floods, and sea-level surges of a given magnitude at particular locations would be modified by possible increases in intensity of tropical cyclones and heavy rain events and changes in the location-specific frequency of tropical cyclones. Scenarios of climate change that are based on recent coupled atmosphere-ocean (A-O) models suggest that large areas of mainland Australia will experience significant decreases in rainfall during the 21st century. The ENSO phenomenon leads to floods and prolonged droughts, especially in inland Australia and parts of New Zealand. The region would be sensitive to a changes towards a more El Niño-like mean state. [12.1.5]

Before stabilization of GHG concentrations, the north-south temperature gradient in mid-southern latitudes is expected to increase (medium to high confidence), strengthening the westerlies and the associated west-to-east gradient of rainfall across Tasmania and New Zealand. Following stabilization of GHG concentrations, these trends would be reversed (medium confidence). [12.1.5.1]

Climate change will add to existing stresses on achievement of sustainable land use and conservation of terrestrial and aquatic biodiversity. These stresses include invasion by exotic animal and plant species, degradation and fragmentation of natural ecosystems through agricultural and urban development, dryland salinization (Australia), removal of forest cover (Australia and New Zealand), and competition for scarce water resources. Within both countries, economically and socially disadvantaged groups of people, especially indigenous peoples, are particularly vulnerable to stresses on health and living conditions induced by climate change. Major exacerbating problems include rapid population and infrastructure growth in vulnerable coastal areas, inappropriate use of water resources, and complex institutional arrangements. [12.3.2, 12.3.3, 12.4.1, 12.4.2, 12.6.4, 12.8.5]

5.3.1. Water Resources

Water resources already are stressed in some areas and therefore are highly vulnerable, especially with respect to salinization (parts of Australia) and competition for water supply between agriculture, power generation, urban areas, and environmental flows (high confidence). Increased evaporation and possible decreases in rainfall in many areas would adversely affect water supply, agriculture, and the survival and reproduction of key species in parts of Australia and New Zealand (medium confidence). [12.3.1, 12.3.2, 12.4.6, 12.5.2, 12.5.3, 12.5.6]

5.3.2. Ecosystems

A warming of 1°C would threaten the survival of species that currently are growing near the upper limit of their temperature range, notably in marginal alpine regions and in the southwest of Western Australia. Species that are unable to migrate or relocate because of land clearing, soil differences, or topography could become endangered or extinct. Other Australian ecosystems

Table TS-9: Main areas of vulnerability and adaptability to climate change impacts in Australia and New Zealand. Degree of confidence that tabulated impacts will occur is indicated by stars in second column (see Section 1.4 of Technical Summary for key to confidence-level rankings). Confidence levels, and assessments of vulnerability and adaptability, are based on information reviewed in Chapter 12, and assume continuation of present population and investment growth patterns.

Sector	Impact	Vulnerability	Adaptation	Adaptability	Section
Hydrology and water supply	<ul style="list-style-type: none"> – Irrigation and metropolitan supply constraints, and increased salinization—**** – Saltwater intrusion into some island and coastal aquifers—**** 	High in some areas High in limited areas	<ul style="list-style-type: none"> – Planning, water allocation, and pricing – Alternative water supplies, retreat 	Medium Low	12.3.1, 12.3.2 12.3.3

Fish	– Recruitment changes (some species)—**	Unknown net effect	– Monitoring, management	—	12.5.5
Settlements and industry	– Increased impacts of flood, storm, storm surge, sea-level rise—***	High in some places	– Zoning, disaster planning	Moderate	12.6.1, 12.6.4
Human health	– Expansion and spread of vector-borne diseases—**** – Increased photochemical air pollution—****	High Moderate (some cities)	– Quarantine, eradication, or control – Emission controls	Moderate to high High	12.7.1, 12.7.4 12.7.1

that are particularly vulnerable include coral reefs and arid and semi-arid habitats. Freshwater wetlands in coastal zones in Australia and New Zealand are vulnerable, and some New Zealand ecosystems are vulnerable to accelerated spread of weeds. [12.4.2, 12.4.3, 12.4.4, 12.4.5, 12.4.7]

5.3.3. Food Production

Agricultural activities are particularly vulnerable to regional reductions in rainfall in southwest and inland Australia (medium confidence). Drought frequency and consequent stresses on agriculture are likely to increase in parts of Australia and New Zealand as a result of higher temperatures and El Niño changes (medium confidence). Enhanced plant growth and water-use efficiency (WUE) resulting from CO₂ increases may provide initial benefits that offset any negative impacts from climate change (medium confidence), although the balance is expected to become negative with warmings in excess of 2-4°C and associated rainfall changes (medium confidence). This is illustrated in Figure TS-7 for wheat production in Australia, for a range of climate change scenarios. Reliance on exports of agricultural and forest products makes the region very sensitive to changes in production and commodity prices that are induced by changes in climate elsewhere. [12.5.2, 12.5.3, 12.5.6, 12.5.9, 12.8.7]

Australian and New Zealand fisheries are influenced by the extent and location of nutrient upwellings governed by prevailing winds and boundary currents. In addition, ENSO influences recruitment of some fish species and the incidence of toxic algal blooms. [12.5.5]

5.3.4. Settlements, Industry, and Human Health

Marked trends toward greater population and investment in exposed regions are increasing vulnerability to tropical cyclones and storm surges. Thus, projected increases in tropical cyclone intensity and possible changes in their location-specific frequency, along with sea-level rise, would have major

impacts—notably, increased storm-surge heights for a given return period (medium to high confidence). Increased frequency of high-intensity rainfall would increase flood damages to settlements and infrastructure (medium confidence). [12.1.5.1, 12.1.5.3, 12.6.1, 12.6.4]

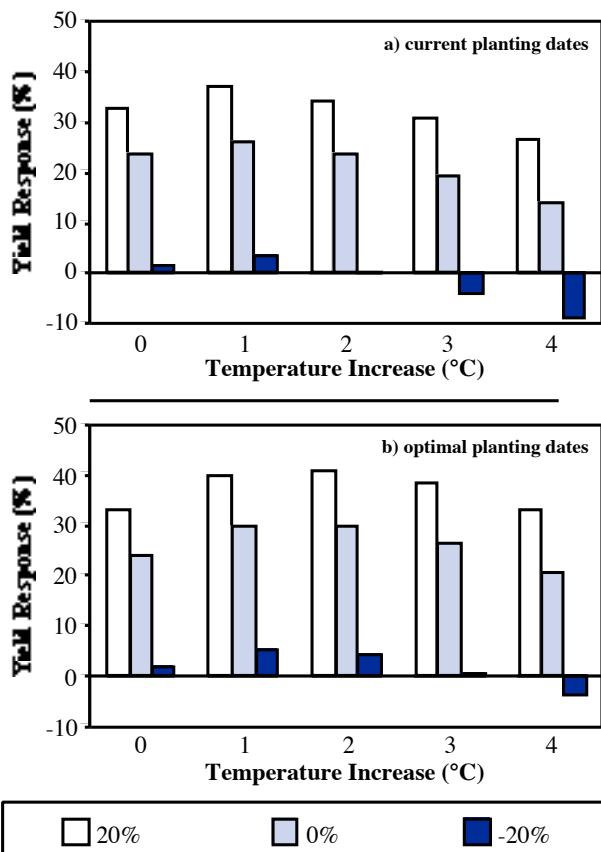

Figure TS-7: Percentage change in average annual total Australian wheat yield for CO₂ (levels of 700 ppm) and a range of changes in temperature and rainfall: a) current planting dates, and b) optimal planting dates. Yield response is shown for rainfall changes of +20% (white), 0 (light blue), and -20% (dark blue), for warmings of 0-4°C.

There is high confidence that projected climate changes will enhance the spread of some disease vectors, thereby increasing the potential for disease outbreaks such as mosquito-borne Ross River virus and Murray Valley encephalitis, despite existing biosecurity and health services. [12.7.1]

5.3.5. Key Adaptation Options

Key adaptation options include improved WUE and effective trading mechanisms for water; more appropriate land-use policies; provision of climate information and seasonal forecasts to land users to help them manage for climate variability and change; improved crop cultivars; revised engineering standards and zoning for infrastructure development; and improved biosecurity and health services. However, many natural ecosystems in Australia and New Zealand have only a limited capacity to adapt, and many managed systems will face limits on adaptation imposed by cost, acceptability, and other factors. [12.3.2, 12.3.3, 12.5.6, 12.7.4, 12.8.4, 12.8.5]

5.4. Europe

Present-day weather conditions affect natural, social, and economic systems in Europe in ways that reveal sensitivities and vulnerabilities to climate change in these systems. Climate change may aggravate such effects (very high confidence). Vulnerability to climate change in Europe differs substantially between subregions. Southern Europe and the European Arctic are more vulnerable than other parts of Europe. More-marginal and less-wealthy areas will be less able to adapt, which leads to important equity implications (very high confidence). Findings in the TAR relating to key vulnerabilities in Europe are broadly consistent with those expressed in the IPCC *Special Report on Regional Impacts of Climate Change* and the SAR, but are more specific about subregional effects and include new information concerning adaptive capacity. [13.1.1, 13.1.4, 13.4]

5.4.1. Water Resources

Water resources and their management in Europe are under pressure now, and these pressures are likely to be exacerbated by climate change (high confidence). Flood hazard is likely to increase across much of Europe—except where snowmelt peak has been reduced—and the risk of water shortage is projected to increase, particularly in southern Europe (medium to high confidence). Climate change is likely to widen water resource differences between northern and southern Europe (high confidence). Half of Europe's alpine glaciers could disappear by the end of the 21st century. [13.2.1]

5.4.2. Ecosystems

Natural ecosystems will change as a result of increasing temperature and atmospheric concentration of CO₂. Permafrost

will decline; trees and shrubs will encroach into current northern tundra; and broad-leaved trees may encroach into current coniferous forest areas. Net primary productivity in ecosystems is likely to increase (also as a result of nitrogen deposition), but increases in decomposition resulting from increasing temperature may negate any additional carbon storage. Diversity in nature reserves is under threat from rapid change. Loss of important habitats (wetlands, tundra, and isolated habitats) would threaten some species (including rare/endemic species and migratory birds). Faunal shifts as a result of ecosystem changes are expected in marine, aquatic, and terrestrial ecosystems (high confidence; established but incomplete evidence). [13.2.1.4, 13.2.2.1, 13.2.2.3-5]

Soil properties will deteriorate under warmer and drier climate scenarios in southern Europe. The magnitude of this effect will vary markedly between geographic locations and may be modified by changes in precipitation (medium confidence; established but incomplete evidence). [13.2.1.2]

In mountain regions, higher temperatures will lead to an upward shift of biotic zones. There will be a redistribution of species with, in some instances, a threat of extinction (high confidence). [13.2.1.4]

Timber harvest will increase in commercial forests in northern Europe (medium confidence; established but incomplete evidence), although forest pests and disease may increase. Reductions are likely in the Mediterranean, with increased drought and fire risk (high confidence; well-established evidence). [13.2.2.1]

5.4.3. Agriculture and Food Security

Agricultural yields will increase for most crops as a result of increasing atmospheric CO₂ concentration. This increase in yields would be counteracted by the risk of water shortage in southern and eastern Europe and by shortening of the duration of growth in many grain crops because of increasing temperature. Northern Europe is likely to experience overall positive effects, whereas some agricultural production systems in southern Europe may be threatened (medium confidence; established but incomplete evidence).

Changes in fisheries and aquaculture production resulting from climate change embrace faunal shifts that affect freshwater and marine fish and shellfish biodiversity. These changes will be aggravated by unsustainable exploitation levels and environmental change (high confidence).

5.4.4. Human Settlements and Financial Services

The insurance industry faces potentially costly climate change impacts through the medium of property damage, but there is great scope for adaptive measures if initiatives are taken soon (high confidence). Transport, energy, and other industries will face changing demand and market opportunities. The concentration

Table TS-10: Estimates of flood exposure and incidence for Europe's coasts in 1990 and the 2080s. Estimates of flood incidence are highly sensitive to assumed protection standard and should be interpreted in indicative terms only (former Soviet Union excluded).

Region	1990 Exposed Population (millions)	Flood Incidence	
		1990 Average Number of People Experiencing Flooding (thousands yr ⁻¹)	2080s Increase due to Sea-Level Rise, Assuming No Adaptation (%)
Atlantic Coast	19.0	19	50 to 9,000
Baltic Coast	1.4	1	0 to 3,000
Mediterranean Coast	4.1	3	260 to 12,000

of industry on the coast exposes it to sea-level rise and extreme events, necessitating protection or removal (high confidence). [13.2.4]

Recreational preferences are likely to change with higher temperatures. Heat waves are likely to reduce the traditional peak summer demand at Mediterranean holiday destinations. Less-reliable snow conditions will impact adversely on winter tourism (medium confidence). [13.2.4.4]

The risk of flooding, erosion, and wetland loss in coastal areas will increase substantially, with implications for human settlement, industry, tourism, agriculture, and coastal natural habitats. Southern Europe appears to be more vulnerable to these changes, although the North Sea coast already has a high exposure to flooding (high confidence). Table TS-10 provides estimates of flood exposure and risk for Europe's coasts. [13.2.1.3]

5.4.5. Human Health

A range of risks is posed for human health through increased exposure to heat episodes (exacerbated by air pollution in urban areas), extension of some vector-borne diseases, and coastal and riverine flooding. Cold-related risks will be reduced (medium confidence; competing explanations). [13.2.5]

5.4.6. Adaptive Capacity

The adaptation potential of socioeconomic systems in Europe is relatively high because of economic conditions [high gross national product (GNP) and stable growth], a stable population (with the capacity to move within the region), and well-developed political, institutional, and technological support systems. However, the adaptation potential for natural systems generally is low (very high confidence). [13.3]

5.5. Latin America

There is ample evidence of climate variability at a wide range of time scales all over Latin America, from intraseasonal to long-term. In many subregions of Latin America, this variability

in climate normally is associated with phenomena that already produce impacts with important socioeconomic and environmental consequences that could be exacerbated by global warming and its associated weather and climate changes.

Variations in precipitation have a strong effect on runoff and streamflow, which are simultaneously affected by melting of glaciers and snow. Precipitation variations and their sign depend on the geographical subregion under consideration. Temperature in Latin America also varies among subregions. Although these variations might depend on the origin and quality of the source data as well as on the record periods used for studies and analyses, some of these variations could be attributed to a climate change condition (low confidence). [14.1.2.1]

ENSO is responsible for a large part of the climate variability at interannual scales in Latin America (high confidence). The region is vulnerable to El Niño, with impacts varying across the continent. For example, El Niño is associated with dry conditions in northeast Brazil, northern Amazonia, the Peruvian-Bolivian Altiplano, and the Pacific coast of Central America. The most severe droughts in Mexico in recent decades have occurred during El Niño years, whereas southern Brazil and northwestern Peru have exhibited anomalously wet conditions. La Niña is associated with heavy precipitation and flooding in Colombia and drought in southern Brazil. If El Niño or La Niña were to increase, Latin America would be exposed to these conditions more often. [14.1.2]

Some subregions of Latin America frequently experience extreme events, and these extraordinary combinations of hydrological and climatic conditions historically have produced disasters in Latin America. Tropical cyclones and associated heavy rain, flooding, and landslides are very common in Central America and southern Mexico. In northwestern South America and northeastern Brazil, many of the extremes that occur are strongly related to El Niño. [14.1.2]

5.5.1. Water Resources

It has been well established that glaciers in Latin America have receded in the past several decades. Warming in high mountain regions could lead to disappearance of significant

snow and ice surface (medium confidence), which could affect mountain sport and tourist activities. Because these areas contribute to river streamflow, this trend also would reduce water availability for irrigation, hydropower generation, and navigation. [14.2.4]

5.5.2. Ecosystems

It is well established that Latin America accounts for one of the Earth's largest concentrations of biodiversity, and the impacts of climate change can be expected to increase the risk of

biodiversity loss (high confidence). Observed population declines in frogs and small mammals in Central America can be related to regional climate change. The remaining Amazonian forest is threatened by the combination of human disturbance, increases in fire frequency and scale, and decreased precipitation from evapotranspiration loss, global warming, and El Niño. Neotropical seasonally dry forest should be considered severely threatened in Mesoamerica.

Tree mortality increases under dry conditions that prevail near newly formed edges in Amazonian forests. Edges, which affect an increasingly large portion of the forest because of increased

Table TS-11: Assessments of climate change impacts on annual crops in Latin America.

^dFor 2°C increase.

deforestation, would be especially susceptible to the effects of reduced rainfall. In Mexico, nearly 50% of the deciduous tropical forest would be affected. Heavy rain during the 1997–1998 ENSO event generated drastic changes in dry ecosystems of northern Peru's coastal zone. Global warming would expand the area suitable for tropical forests as equilibrium vegetation types. However, the forces driving deforestation make it unlikely that tropical forests will be permitted to occupy these increased areas. Land-use change interacts with climate through positive-feedback processes that accelerate loss of humid tropical forests. [14.2.1]

5.5.3. Sea-Level Rise

Sea-level rise will affect mangrove ecosystems by eliminating their present habitats and creating new tidally inundated areas to which some mangrove species may shift. This also would affect the region's fisheries because most commercial shellfish and finfish use mangroves for nurseries and refuge. Coastal inundation that stems from sea-level rise and riverine and flatland flooding would affect water availability and agricultural land, exacerbating socioeconomic and health problems in these areas. [14.2.3]

5.5.4. Agriculture

Studies in Argentina, Brazil, Chile, Mexico, and Uruguay—based on GCMs and crop models—project decreased yields for numerous crops (e.g., maize, wheat, barley, grapes) even when the direct effects of CO₂ fertilization and implementation of moderate adaptation measures at the farm level are considered (high confidence). Predicted increases in temperature will reduce crops yields in the region by shortening the crop cycle. Over the past 40 years, the contribution of agriculture to the GDP of Latin American countries has been on the order of 10%. Agriculture remains a key sector in the regional economy because it employs 30–40% of the economically active population. It also is very important for the food security of the poorest sectors of the population. Subsistence farming could be severely threatened in some parts of Latin America, including northeastern Brazil.

It is established but incomplete that climate change would reduce silvicultural yields because lack of water often limits growth during the dry season, which is expected to become longer and more intense in many parts of Latin America. Table TS-11 summarizes studies undertaken on the region for different crops and management conditions, all under rainfed conditions; most of these results predict negative impacts, particularly for maize. [14.2.2]

5.5.5. Human Health

The scale of health impacts from climate change in Latin America would depend primarily on the size, density, location,

and wealth of populations. Exposure to heat or cold waves has impacts on mortality rates in risk groups in the region (medium confidence).

Increases in temperature would affect human health in polluted cities such as Mexico City and Santiago, Chile. It is well established that ENSO causes changes in disease vector populations and in the incidence of water-borne diseases in Brazil, Peru, Bolivia, Argentina, and Venezuela. Studies in Peru and Cuba indicate that increases in temperature and precipitation would change the geographical distribution of infectious diseases such as cholera and meningitis (high confidence), although there is speculation about what the changes in patterns of diseases would be in different places. It is well established that extreme events tend to increase death and morbidity rates (injuries, infectious diseases, social problems, and damage to sanitary infrastructure), as shown in Central America with Hurricane Mitch in 1998, heavy rains in Mexico and Venezuela in 1999, and in Chile and Argentina in 2000. [14.2.5]

5.6. North America

North America will experience both positive and negative climate change impacts (high confidence). Varying impacts on ecosystems and human settlements will exacerbate subregional differences in climate-sensitive resource production and vulnerability to extreme events. Opportunities and challenges to adaptation will arise, frequently involving multiple stresses (Table TS-12). Some innovative adaptation strategies are being tested as a response to current climate-related challenges (e.g., water banks), but few cases have examined how these strategies could be implemented as regional climates continue to change. Shifting patterns in temperature, precipitation, disease vectors, and water availability will require adaptive responses—including, for example, investments in storm protection and water supply infrastructure, as well as community health services. [15.3.2, 15.4]

5.6.1. Communities and Urban Infrastructure

Potential changes in the frequency, severity, and duration of extreme events are among the most important risks associated with climate change in North America. Potential impacts of climate change on cities include fewer periods of extreme winter cold; increased frequency of extreme heat; rising sea levels and risk of storm surge; and changes in timing, frequency, and severity of flooding associated with storms and precipitation extremes. These events—particularly increased heat waves and changes in extreme events—will be accompanied by effects on health.

Communities can reduce their vulnerability to adverse impacts through investments in adaptive infrastructure, which can be expensive. Rural, poor, and indigenous communities may not be able to make such investments. Furthermore, infrastructure

Table TS-12: Climate change adaptation issues in North American subregions. Some unique issues for certain locations also are indicated.

North American Subregions	Development Context	Climate Change Adaptation Options and Challenges
Most or all subregions	<ul style="list-style-type: none"> – Changing commodity markets – Intensive water resources development over large areas—domestic and transboundary – Lengthy entitlement/land claim/treaty agreements—domestic and transboundary – Urban expansion – Transportation expansion 	<ul style="list-style-type: none"> – Role of water/environmental markets – Changing design and operations of water and energy systems – New technology/practices in agriculture and forestry – Protection of threatened ecosystems or adaptation to new landscapes – Increased role for summer (warm weather) tourism – Risks to water quality from extreme events – Managing community health for changing risk factors – Changing roles of public emergency assistance and private insurance
Arctic border	<ul style="list-style-type: none"> – Winter transport system – Indigenous lifestyles 	<ul style="list-style-type: none"> – Design for changing permafrost and ice conditions – Role of two economies and co-management bodies
Coastal regions	<ul style="list-style-type: none"> – Declines in some commercial marine resources (cod, salmon) – Intensive coastal zone development 	<ul style="list-style-type: none"> – Aquaculture, habitat protection, fleet reductions – Coastal zone planning in high demand areas
Great Lakes	<ul style="list-style-type: none"> – Sensitivity to lake level fluctuations 	<ul style="list-style-type: none"> – Managing for reduction in mean levels without increased shoreline encroachment

investment decisions are based on a variety of needs beyond climate change, including population growth and aging of existing systems. [15.2.5]

5.6.2. Water Resources and Aquatic Ecosystems

Uncertain changes in precipitation lead to little agreement regarding changes in total annual runoff across North America. Modeled impacts of increased temperatures on lake evaporation lead to consistent projections of reduced lake levels and outflows for the Great Lakes-St. Lawrence system under most scenarios (medium confidence). Increased incidence of heavy precipitation events will result in greater sediment and non-point-source pollutant loadings to watercourses (medium confidence). In addition, *in regions where seasonal snowmelt is an important aspect of the annual hydrologic regime (e.g., California, Columbia River Basin), warmer temperatures are likely to result in a seasonal shift in runoff, with a larger proportion of total runoff occurring in winter, together with possible reductions in summer flows (high confidence)*. This could adversely affect the availability and quality of water for instream and out-of-stream water uses during the summer (medium confidence). Figure TS-8 shows possible impacts. [15.2.1]

Adaptive responses to such seasonal runoff changes include altered management of artificial storage capacity, increased reliance on coordinated management of groundwater and surface water supplies, and voluntary water transfers between various water users. Such actions could reduce the impacts of reduced summer flows on water users, but it may be difficult or impossible to offset adverse impacts on many aquatic ecosystems, and it may not be possible to continue to provide current levels of reliability and quality for all water users. Some regions (e.g., the western United States) are likely to see increased market transfers of available water supplies from irrigated agriculture to urban and other relatively highly valued uses. Such reallocations raise social priority questions and entail adjustment costs that will depend on the institutions in place.

5.6.3. Marine Fisheries

Climate-related variations in marine/coastal environments are now recognized as playing an important role in determining the productivity of several North American fisheries in the Pacific, North Atlantic, Bering Sea, and Gulf of Mexico regions. There are complex links between climatic variations and changes in processes that influence the productivity and spatial distribution

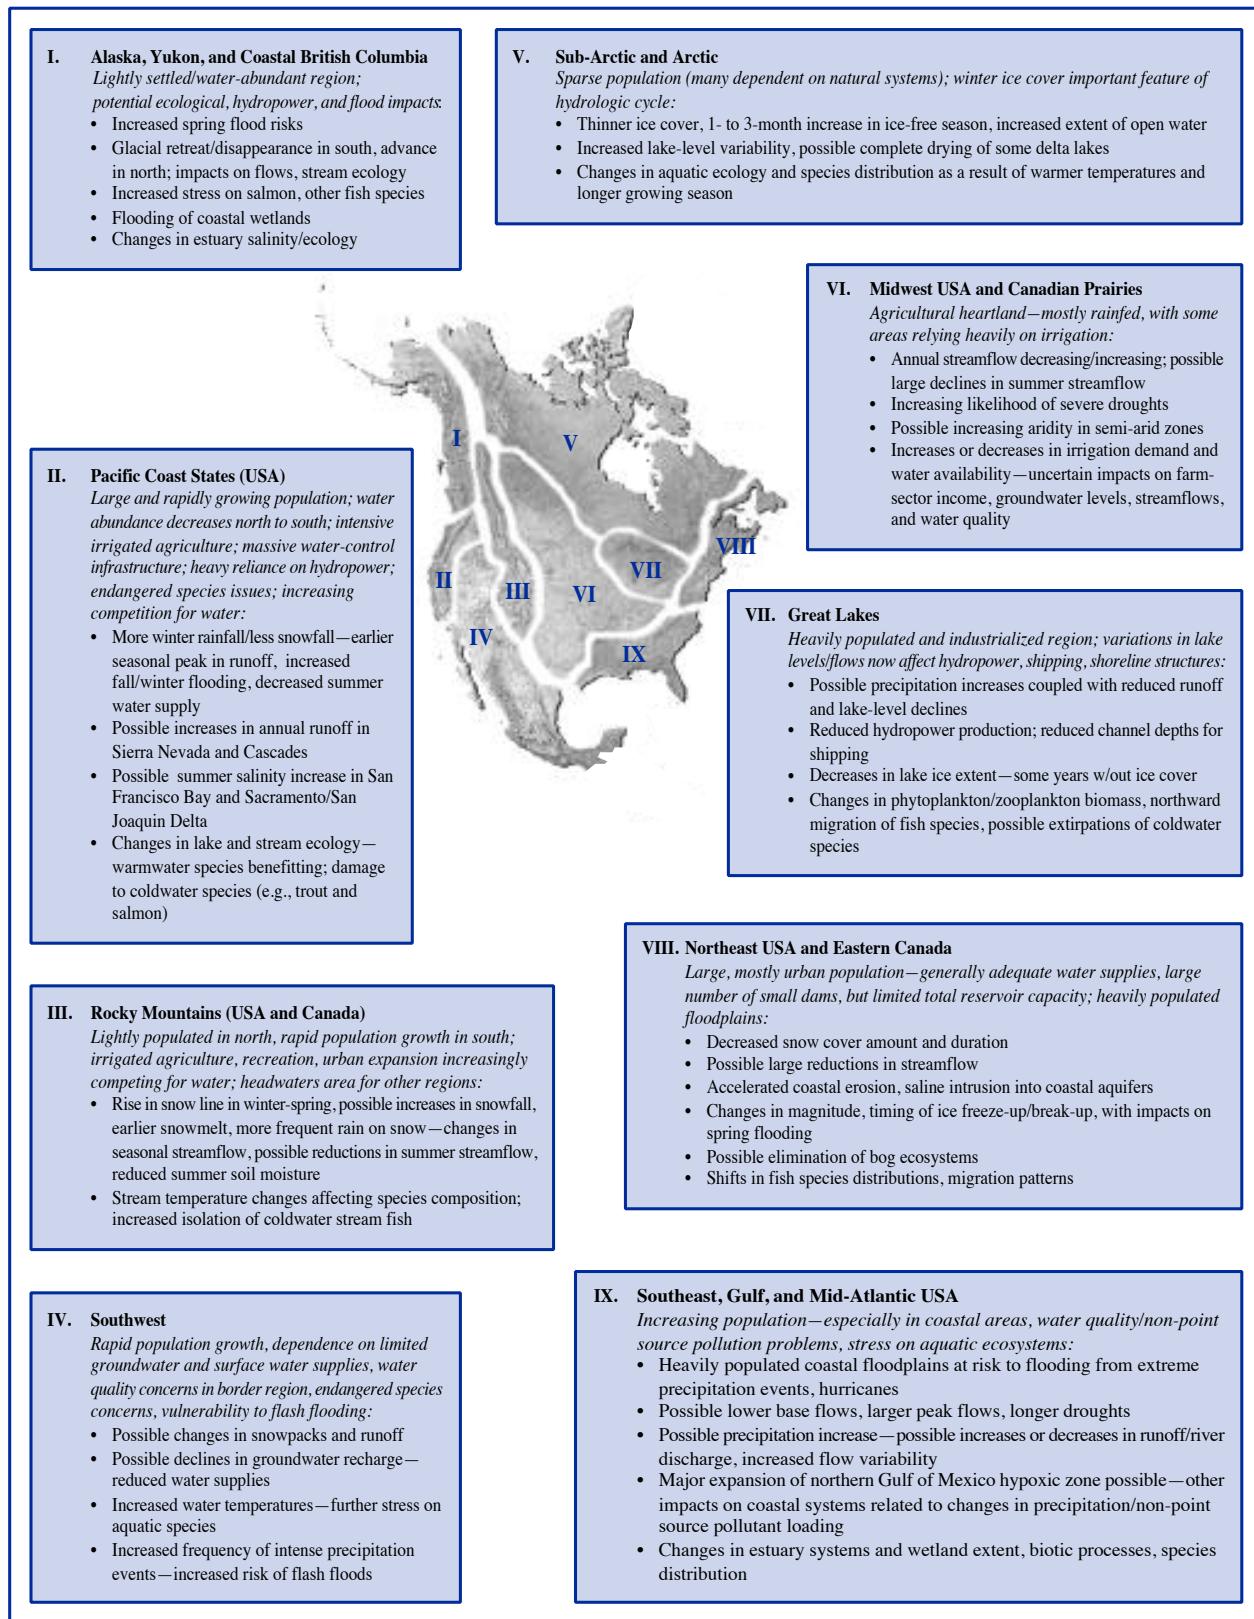

Figure TS-8: Possible water resources impacts in North America.

of marine fish populations (high confidence), as well as uncertainties linked to future commercial fishing patterns. Recent experience with Pacific salmon and Atlantic cod suggests that sustainable fisheries management will require timely and accurate scientific information on environmental conditions affecting fish stocks, as well as institutional and operational flexibility to respond quickly to such information. [15.2.3.3]

5.6.4. Agriculture

Small to moderate climate change will not imperil food and fiber production (high confidence). There will be strong regional production effects, with some areas suffering significant loss of comparative advantage to other regions (medium confidence). Overall, this results in a small net effect. The agricultural welfare of consumers and producers would increase with modest warming. However, the benefit would decline at an increasing rate—possibly becoming a net loss—with further warming. There is potential for increased drought in the U.S. Great Plains/Canadian Prairies and opportunities for a limited northward shift in production areas in Canada.

Increased production from direct physiological effects of CO₂, and farm- and agricultural market-level adjustments (e.g., behavioral, economic, and institutional) are projected to offset losses. Economic studies that include farm- and agricultural market-level adjustments indicate that the negative effects of climate change on agriculture probably have been overestimated by studies that do not account for these adjustments (medium confidence). However, the ability of farmers to adapt their input and output choices is difficult to forecast and will depend on market and institutional signals. [15.2.3.1]

5.6.5. Forests and Protected Areas

Climate change is expected to increase the areal extent and productivity of forests over the next 50–100 years (medium confidence). However, climate change is likely to cause changes in the nature and extent of several “disturbance factors” (e.g., fire, insect outbreaks) (medium confidence). Extreme or long-term climate change scenarios indicate the possibility of widespread forest decline (low confidence).

There is strong evidence that climate change can lead to the loss of specific ecosystem types—such as high alpine areas and specific coastal (e.g., salt marshes) and inland (e.g., prairie “potholes”) wetland types (high confidence). There is moderate potential for adaptation to prevent these losses by planning conservation programs to identify and protect particularly threatened ecosystems. Lands that are managed for timber production are likely to be less susceptible to climate change than unmanaged forests because of the potential for adaptive management. [15.2.2]

5.6.6. Human Health

Vector-borne diseases, including malaria and dengue fever, may expand their ranges in the United States and may develop in Canada. Tick-borne Lyme disease also may see its range expanded in Canada. However, socioeconomic factors such as public health measures will play a large role in determining the existence or extent of such infections. Diseases associated with water may increase with warming of air and water temperatures, combined with heavy runoff events from agricultural and urban surfaces. Increased frequency of convective storms could lead to more cases of thunderstorm-associated asthma. [15.2.4]

5.6.7. Public and Private Insurance Systems

Inflation-corrected catastrophe losses have increased eight-fold in North America over the past 3 decades (high confidence). The exposures and surpluses of private insurers (especially property insurers) and reinsurers have been growing, and weather-related profit losses and insolvencies have been observed. Insured losses in North America (59% of the global total) are increasing with affluence and as populations continue to move into vulnerable areas. Insurer vulnerability to these changes varies considerably by region.

Recent extreme events have led to several responses by insurers, including increased attention to building codes and disaster preparedness. Insurers’ practices traditionally have been based primarily on historic climatic experience; only recently have they begun to use models to predict future climate-related losses, so the potential for surprise is real. Governments play a key role as insurers or providers of disaster relief, especially in cases in which the private sector deems risks to be uninsurable. [15.2.7]

5.7. Polar Regions

Climate change in the polar region is expected to be among the greatest of any region on Earth. Twentieth century data for the Arctic show a warming trend of as much as 5°C over extensive land areas (very high confidence), while precipitation has increased (low confidence). There are some areas of cooling in eastern Canada. The extent of sea ice has decreased by 2.9% per decade, and it has thinned over the 1978–1996 period (high confidence). There has been a statistically significant decrease in spring snow extent over Eurasia since 1915 (high confidence). The area underlain by permafrost has been reduced and has warmed (very high confidence). The layer of seasonally thawed ground above permafrost has thickened in some areas, and new areas of extensive permafrost thawing have developed. *In the Antarctic, a marked warming trend is evident in the Antarctic Peninsula, with spectacular loss of ice shelves (high confidence).* The extent of higher terrestrial vegetation on the Antarctic Peninsula is increasing (very high confidence). Elsewhere, warming is less definitive. There has been no significant change in the Antarctic sea ice since 1973, although it apparently

retreated by more than 3° of latitude between the mid-1950s and the early 1970s (medium confidence). [16.1.3.2.]

The Arctic is extremely vulnerable to climate change, and major physical, ecological, and economic impacts are expected to appear rapidly. A variety of feedback mechanisms will cause an amplified response, with consequent impacts on other systems and people. There will be different species compositions on land and sea, poleward shifts in species assemblages, and severe disruptions for communities of people who lead traditional lifestyles. *In developed areas of the Arctic and where the permafrost is ice-rich, special attention will be required to mitigate the detrimental impacts of thawing, such as severe damage to buildings and transport infrastructure (very high confidence).* There also will be beneficial consequences of climatic warming, such as reduced demand for heating energy. Substantial loss of sea ice in the Arctic Ocean will be favorable for opening of Arctic sea routes and ecotourism, which may have large implications for trade and for local communities. [16.2.5.3, 16.2.7.1, 16.2.8.1, 16.2.8.2]

In the Antarctic, projected climate change will generate impacts that will be realized slowly (high confidence). Because the impacts will occur over a long period, however, they will continue long after GHG emissions have stabilized. For example, there will be slow but steady impacts on ice sheets and circulation patterns of the global ocean, which will be irreversible for many centuries into the future and will cause changes elsewhere in the world, including a rise of sea level. Further substantial loss of ice shelves is expected around the Antarctic Peninsula. Warmer temperatures and reduced sea-ice extent are likely to produce long-term changes in the physical oceanography and ecology of the Southern Ocean, with intensified biological activity and increased growth rates of fish. [16.2.3.4, 16.2.4.2]

Polar regions contain important drivers of climate change. The Southern Ocean's uptake of carbon is projected to reduce substantially as a result of complex physical and biological processes. GHG emissions from tundra caused by changes in water content, decomposition of exposed peat, and thawing of permafrost are expected to increase. Reductions in the extent of highly reflective snow and ice will magnify warming (very high confidence). Freshening of waters from increased Arctic runoff and increased rainfall, melt of Antarctic ice shelves, and reduced sea-ice formation will slow the thermohaline circulations of the North Atlantic and Southern Oceans and reduce the ventilation of deep ocean waters. [16.3.1]

Adaptation to climate change will occur in natural polar ecosystems, mainly through migration and changing mixes of species. Some species may become threatened (e.g., walrus, seals, and polar bears), whereas others may flourish (e.g., caribou and fish). Although such changes may be disruptive to many local ecological systems and particular species, the possibility remains that predicted climate change eventually may increase the overall productivity of natural systems in polar regions. [16.3.2]

For indigenous communities who follow traditional lifestyles, opportunities for adaptation to climate change are limited (very high confidence). Changes in sea ice, seasonality of snow, habitat, and diversity of food species will affect hunting and gathering practices and could threaten longstanding traditions and ways of life. Technologically developed communities are likely to adapt quite readily to climate change by adopting altered modes of transport and by increased investment to take advantage of new commercial and trade opportunities. [16.3.2]

5.8. Small Island States

Climate change and sea-level rise pose a serious threat to the small island states, which span the ocean regions of the Pacific, Indian, and Atlantic Oceans as well as the Caribbean and Mediterranean Seas. Characteristics of small island states that increase their vulnerability include their small physical size relative to large expanses of ocean; limited natural resources; relative isolation; extreme openness of small economies that are highly sensitive to external shocks and highly prone to natural disasters and other extreme events; rapidly growing populations with high densities; poorly developed infrastructure; and limited funds, human resources, and skills. These characteristics limit the capacity of small island states to mitigate and adapt to future climate change and sea-level rise. [17.1.2]

Many small island states already are experiencing the effects of current large interannual variations in oceanic and atmospheric conditions. As a result, the most significant and more immediate consequences for small island states are likely to be related to changes in rainfall regimes, soil moisture budgets, prevailing winds (speed and direction), short-term variations in regional and local sea levels, and patterns of wave action. These changes are manifest in past and present trends of climate and climate variability, with an upward trend in average temperature by as much as 0.1°C per decade and sea-level rise of 2 mm yr⁻¹ in the tropical ocean regions in which most of the small island states are located. Analysis of observational data from various regions indicates an increase in surface air temperature that has been greater than global rates of warming, particularly in the Pacific Ocean and Caribbean Sea. Much of the variability in the rainfall record of the Pacific and Caribbean islands appears to be closely related to the onset of ENSO. However, part of the variability also may be attributable to shifts in the Intertropical and South Pacific Convergence Zone, whose influence on rainfall variability patterns must be better understood. The interpretation of current sea-level trends also is constrained by limitations of observational records, particularly from geodetic-controlled tide gauges. [17.1.3]

5.8.1. Equity and Sustainable Development

Although the contribution of small island states to global emissions of GHG is insignificant, projected impacts of climate change and sea-level rise on these states are likely to be

Table TS-13: Importance of tourism for select small island states and territories.

^aData on tourist inflows and ratio to population pertain to 1997.

^bData for tourist receipts pertain to 1997 for the Bahamas, Cape Verde, Jamaica, the Maldives, Malta, Mauritius, Samoa, Seychelles, Singapore, and Solomon Islands; 1996 for Antigua and Barbuda, Cuba, Dominica, Dominican Republic, Fiji, Grenada, Haiti, Papua New Guinea, St. Lucia, and St. Vincent; 1995 for Barbados, Comoros, Cyprus, Trinidad and Tobago, and Vanuatu; and 1994 for St. Kitts and Nevis.

serious. The impacts will be felt for many generations because of small island states' low adaptive capacity, high sensitivity to external shocks, and high vulnerability to natural disasters. Adaptation to these changing conditions will be extremely difficult for most small island states to accomplish in a sustainable manner. [17.2.1]

5.8.2. Coastal Zone

Much of the coastal change currently experienced in small island states is attributed to human activities on the coast. Projected sea-level rise of 5 mm yr⁻¹ over the next 100 years, superimposed on further coastal development, will have negative impacts on the coasts (high confidence). This in turn will increase the vulnerability of coastal environments by reducing natural resilience and increasing the cost of adaptation. Given that severity will vary regionally, the most serious considerations for some small island states will be whether they will have adequate potential to adapt to sea-level rise within their own national boundaries. [17.2.2.1, 17.2.3]

5.8.3. Ecosystems and Biodiversity

Projected future climate change and sea-level rise will affect shifts in species composition and competition. It is estimated that one of every three known threatened plants are island endemics while 23% of bird species found on islands are threatened. [17.2.5]

Coral reefs, mangroves, and seagrass beds that often rely on stable environmental conditions will be adversely affected by rising air and sea temperature and sea levels (medium confidence). Episodic warming of the sea surface has resulted in greatly stressed coral populations that are subject to widespread coral bleaching. Mangroves, which are common on low-energy, nutrient/sediment-rich coasts and embayments in the tropics, have been altered by human activities. Changes in sea levels are likely to affect landward and alongshore migration of remnants of mangrove forests that provide protection for coasts and other resources. An increase in SST would adversely affect seagrass communities, which already are under stress from land-based pollution and runoff. Changes in these systems are

likely to negatively affect fishery populations that depend on them for habitat and breeding grounds. [17.2.4]

5.8.4. Water Resources, Agriculture, and Fisheries

Water resources and agriculture are of critical concern because most small island states possess limited arable land and water resources. Communities rely on rainwater from catchments and a limited freshwater lens. In addition, arable farming, especially on low islands and atolls, is concentrated at or near the coast. Changes in the height of the water table and soil salinization as a consequence of sea-level rise would be stressful for many staple crops, such as taro.

Although fishing is largely artisanal or small-scale commercial, it is an important activity on most small islands and makes a significant contribution to the protein intake of island inhabitants. Many breeding grounds and habitats for fish and shellfish—such as mangroves, coral reefs, seagrass beds, and salt ponds—will face increasing threats from likely impacts of projected climate change. Water resources, agriculture, and fisheries already are sensitive to currently observed variability in oceanic and atmospheric conditions in many small island states, and the impacts are likely to be exacerbated by future climate and sea-level change (high confidence). [17.2.6, 17.2.8.1]

5.8.5. Human Health, Settlement, Infrastructure and Tourism

Several human systems are likely to be affected by projected changes in climate and sea levels in many small island states. Human health is a major concern given that many tropical islands are experiencing high incidences of vector- and water-borne diseases that are attributable to changes in temperature and rainfall, which may be linked to the ENSO phenomenon, droughts, and floods. Climate extremes also create a huge burden on some areas of human welfare, and these burdens are likely to increase in the future. Almost all settlements, socioeconomic infrastructure, and activities such as tourism are located at or near coastal areas in small island states. Tourism provides a major source of revenue and employment for many small island states (Table TS-13). Changes in temperature and rainfall regimes, as well as loss of beaches, could devastate the economies of many small island states (high confidence). Because these areas are very vulnerable to future climate change and sea-level rise, it is important to protect and nourish beaches and sites by implementing programs that constitute wise use resources. Integrated coastal management has been identified as one approach that would be useful for many small island states for a sustainable tourism industry. [17.2.7, 17.2.9]

5.8.6. Sociocultural and Traditional Assets

Certain traditional island assets (good and services) also will be at risk from climate change and sea-level rise. These assets include subsistence and traditional technologies (skills and

knowledge) and cohesive community structures that, in the past, have helped to buttress the resilience of these islands to various forms of shock. Sea-level rise and climate changes, combined with other environmental stresses, already have destroyed unique cultural and spiritual sites, traditional heritage assets, and important coastal protected areas in many Pacific island states. [17.2.10]

6. Adaptation, Sustainable Development, and Equity

Adaptation to climate change has the potential to substantially reduce many of the adverse impacts of climate change and enhance beneficial impacts, though neither without cost nor without leaving residual damage. In natural systems, adaptation is reactive, whereas in human systems it also can be anticipatory. Figure TS-9 presents types and examples of adaptation to climate change. Experience with adaptation to climate variability and extremes shows that in the private and public sectors there are constraints to achieving the potential of adaptation. The adoption and effectiveness of private, or market-driven, adaptations in sectors and regions are limited by other forces, institutional conditions, and various sources of market failure. There is little evidence to suggest that private adaptations will be employed to offset climate change damages in natural environments. In some instances, adaptation measures may have inadvertent consequences, including environmental damage. The ecological, social, and economic costs of relying on reactive, autonomous adaptation to the cumulative effects of climate change are substantial. Many of these costs can be avoided through planned, anticipatory adaptation. Designed appropriately, many adaptation strategies could provide multiple benefits in the near and longer terms. However, there are limits on their implementation and effectiveness. Enhancement of adaptive capacity reduces the vulnerability of sectors and regions to climate change, including variability and extremes, and thereby promotes sustainable development and equity. [18.2.4, 18.3.4]

Planned anticipatory adaptation has the potential to reduce vulnerability and realize opportunities associated with climate change, regardless of autonomous adaptation. Adaptation facilitated

	Anticipatory	Reactive
Natural Systems		<ul style="list-style-type: none"> Changes in length of growing season Changes in ecosystem composition Wetland migration
Human Systems	<ul style="list-style-type: none"> Purchase of insurance Construction of houses on stilts Redesign of oil rigs 	<ul style="list-style-type: none"> Changes in farm practices Changes in insurance premiums Purchase of air-conditioning
Policy	<ul style="list-style-type: none"> Early-warning systems New building codes, design standards Incentives for relocation 	<ul style="list-style-type: none"> Compensatory payments, subsidies Enforcement of building codes Beach nourishment

Figure TS-9: Types of adaptation to climate change, including examples.

by public agencies is an important part of societal response to climate change. Implementation of adaptation policies, programs, and measures usually will have immediate and future benefits. Adaptations to current climate and climate-related risks (e.g., recurring droughts, storms, floods, and other extremes) generally are consistent with adaptation to changing and changed climatic conditions. Adaptation measures are likely to be implemented only if they are consistent with or integrated with decisions or programs that address nonclimatic stresses. Vulnerabilities associated with climate change are rarely experienced independently of nonclimatic conditions. Impacts of climatic stimuli are felt via economic or social stresses, and adaptations to climate (by individuals, communities, and governments) are evaluated and undertaken in light of these conditions. The costs of adaptation often are marginal to other management or development costs. To be effective, climate change adaptation must consider nonclimatic stresses and be consistent with existing policy criteria, development objectives, and management structures. [18.3.5, 18.4]

The key features of climate change for vulnerability and adaptation are related to variability and extremes, not simply changed average conditions (Figure TS-10). Societies and economies have been making adaptations to climate for centuries. Most sectors, regions, and communities are reasonably adaptable to changes in average conditions, particularly if the changes are gradual. However, losses from climatic variations and extremes are substantial and, in some sectors, increasing. These losses indicate that autonomous adaptation has not been sufficient to offset damages associated with temporal variations in climatic conditions. Communities therefore are more vulnerable and less adaptable to changes in the frequency and/or magnitude of conditions other than average, especially extremes, which are inherent in climate change. The degree to which future adaptations are successful in offsetting adverse impacts of climate change will be determined by success in adapting to climate change, variability, and extremes. [18.2.2]

6.1. Adaptive Capacity

The capacity to adapt varies considerably among regions, countries, and socioeconomic groups and will vary over time. Table TS-14 summarizes adaptation measures and capacities by sector, and Table TS-15 provides this information for each region covered by the TAR. The most vulnerable regions and communities are highly exposed to hazardous climate change effects and have limited adaptive capacity. The ability to adapt and cope with climate change impacts is a function of wealth, scientific and technical knowledge, information, skills, infrastructure, institutions, and equity. Countries with limited economic resources, low levels of technology, poor information and skills, poor infrastructure, unstable or weak institutions, and inequitable empowerment and access to resources have little capacity to adapt and are highly vulnerable. Groups and regions with adaptive capacity that is limited along any of these dimensions are more vulnerable to climate change damages, just as they are more vulnerable to other stresses. [18.5, 18.7]

6.2. Development, Sustainability, and Equity

Activities required for enhancement of adaptive capacity are essentially equivalent to those promoting sustainable development. Enhancement of adaptive capacity is a necessary condition for reducing vulnerability, particularly for the most vulnerable regions, nations, and socioeconomic groups. Many sectors and regions that are vulnerable to climate change also are under pressure from forces such as population growth and resource depletion. Climate adaptation and sustainability goals can be jointly advanced by changes in policies that lessen pressure on resources, improve management of environmental risks, and enhance adaptive capacity. Climate adaptation and equity goals can be jointly pursued through initiatives that promote the welfare of the poorest members of society—for example, by improving food security, facilitating access to safe water and health care, and providing shelter and access to other resources. Development decisions, activities, and programs play important roles in modifying the adaptive capacity of communities and regions, yet they tend not to take into account risks associated with climate variability and change. Inclusion of climatic risks

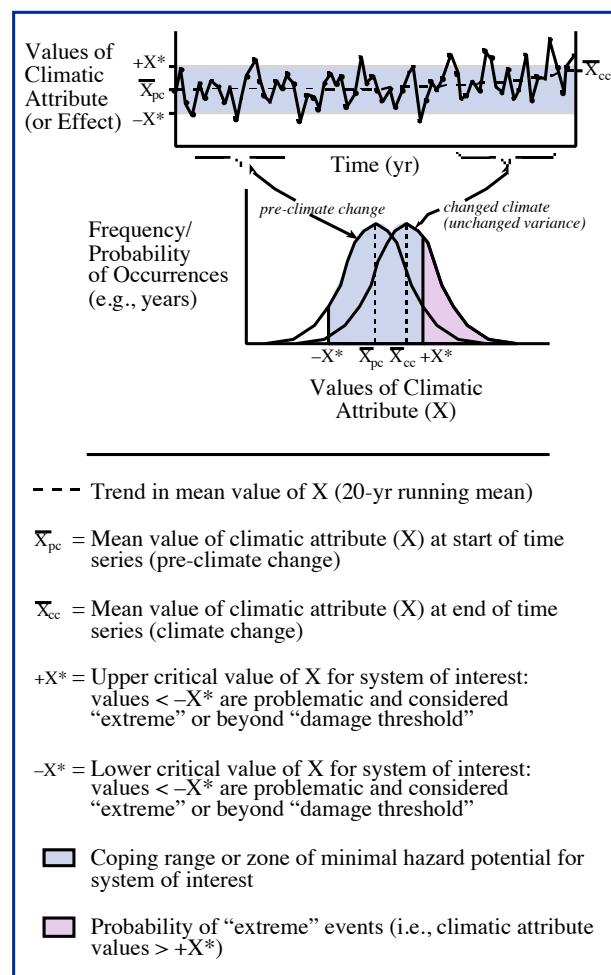

Figure TS-10: Climate change, variability, extremes, and coping range.

Table TS-14: Adaptation and adaptive capacity in sectors (key findings from Chapters 4 through 9).

Sector	Key Findings
Water Resources	<ul style="list-style-type: none"> – Water managers have experience with adapting to change. Many techniques exist to assess and implement adaptive options. However, the pervasiveness of climate change may preclude some traditional adaptive strategies, and available adaptations often are not used. – Adaptation can involve management on the supply side (e.g., altering infrastructure or institutional arrangements) and on the demand side (changing demand or risk reduction). Numerous no-regret policies exist, which will generate net social benefits regardless of climate change. – Climate change is just one of numerous pressures facing water managers. Nowhere are water management decisions taken solely to cope with climate change, although it is increasingly considered for future resource management. Some vulnerabilities are outside the conventional responsibility of water managers. – Estimates of the economic costs of climate change impacts on water resources depend strongly on assumptions made about adaptation. Economically optimum adaptation may be prevented by constraints associated with uncertainty, institutions, and equity. – Extreme events often are catalysts for change in water management, by exposing vulnerabilities and raising awareness of climate risks. Climate change modifies indicators of extremes and variability, complicating adaptation decisions. – Ability to adapt is affected by institutional capacity, wealth, management philosophy, planning time scale, organizational and legal framework, technology, and population mobility. – Water managers need research and management tools aimed at adapting to uncertainty and change, rather than improving climate scenarios.
Ecosystems and Their Services	<ul style="list-style-type: none"> – Adaptation to loss of some ecosystem services may be possible, especially in managed ecosystems. However, adaptation to losses in wild ecosystems and biodiversity may be difficult or impossible. – There is considerable capacity for adaptation in agriculture, including crop changes and resource substitutions, but adaptation to evolving climate change and interannual variability is uncertain. – Adaptations in agriculture are possible, but they will not happen without considerable transition costs and equilibrium (or residual) costs. – Greater adverse impacts are expected in areas where resource endowments are poorest and the ability of farmers to adapt is most limited. – In many countries where rangelands are important, lack of infrastructure and investment in resource management limit options for adaptation. – Commercial forestry is adaptable, reflecting a history of long-term management decisions under uncertainty. Adaptations are expected in land-use management (species-selection silviculture) and product management (processing-marketing). – Adaptation in developed countries will fare better, while developing countries and countries in transition, especially in the tropics and subtropics, will fare worse.
Coastal Zones	<ul style="list-style-type: none"> – Without adaptations, the consequences of global warming and sea-level rise would be disastrous. – Coastal adaptation entails more than just selecting one of the technical options to respond to sea-level rise (strategies can aim to protect, accommodate, or retreat). It is a complex and iterative process rather than a simple choice. – Adaptation options are more acceptable and effective when they are incorporated into coastal zone management, disaster mitigation programs, land-use planning, and sustainable development strategies. – Adaptation choices will be conditioned by existing policies and development objectives, requiring researchers and policymakers to work toward a commonly acceptable framework for adaptation. – The adaptive capacity of coastal systems to perturbations is related to coastal resilience, which has morphological, ecological, and socioeconomic components. Enhancing resilience—including the technical, institutional, economic, and cultural capability to cope with impacts—is a particularly appropriate adaptive strategy given future uncertainties and the desire to maintain development opportunities. – Coastal communities and marine-based economic sectors with low exposure or high adaptive capacity will be least affected. Communities with lower economic resources, poorer infrastructure, less-developed communications and transportation systems, and weak social support systems have less access to adaptation options and are more vulnerable.

Table TS-14 (continued)

Sector	Key Findings
<i>Human Settlements, Energy, and Industry</i>	<ul style="list-style-type: none"> – Larger and more costly impacts of climate change occur through changed probabilities of extreme weather events that overwhelm the design resiliency of human systems. – Many adaptation options are available to reduce the vulnerability of settlements. However, urban managers, especially in developing countries, have so little capacity to deal with current problems (housing, sanitation, water, and power) that dealing with climate change risks is beyond their means. – Lack of financial resources, weak institutions, and inadequate or inappropriate planning are major barriers to adaptation in human settlements. – Successful environmental adaptation cannot occur without locally based, technically competent, and politically supported leadership. – Uncertainty with respect to capacity and the will to respond hinder assessment of adaptation and vulnerability.
<i>Insurance and Other Financial Services</i>	<ul style="list-style-type: none"> – Adaptation in financial and insurance services in the short term is likely to be to changing frequencies and intensities of extreme weather events. – Increasing risk could lead to a greater volume of traditional business and development of new financial risk management products, but increased variability of loss events would heighten actuarial uncertainty. – Financial services firms have adaptability to external shocks, but there is little evidence that climate change is being incorporated into investment decisions. – The adaptive capacity of the financial sector is influenced by regulatory involvement, the ability of firms to withdraw from at-risk markets, and fiscal policy regarding catastrophe reserves. – Adaptation will involve changes in the roles of private and public insurance. Changes in the timing, intensity, frequency, and/or spatial distribution of climate-related losses will generate increased demand on already overburdened government insurance and disaster assistance programs. – Developing countries seeking to adapt in a timely manner face particular difficulties, including limited availability of capital, poor access to technology, and absence of government programs. – Insurers' adaptations include raising prices, non-renewal of policies, cessation of new policies, limiting maximum claims, and raising deductibles—actions that can seriously affect investment in developing countries. – Developed countries generally have greater adaptive capacity, including technology and economic means to bear costs.
<i>Human Health</i>	<ul style="list-style-type: none"> – Adaptation involves changes in society, institutions, technology, or behavior to reduce potential negative impacts or increase positive ones. There are numerous adaptation options, which may occur at the population, community, or personal levels. – The most important and cost-effective adaptation measure is to rebuild public health infrastructure—which, in much of the world, has declined in recent years. Many diseases and health problems that may be exacerbated by climate change can be effectively prevented with adequate financial and human public health resources, including training, surveillance and emergency response, and prevention and control programs. – Adaptation effectiveness will depend on timing. “Primary” prevention aims to reduce risks before cases occur, whereas “secondary” interventions are designed to prevent further cases. – Determinants of adaptive capacity to climate-related threats include level of material resources, effectiveness of governance and civil institutions, quality of public health infrastructure, and preexisting burden of disease. – Capacity to adapt also will depend on research to understand associations between climate, weather, extreme events, and vector-borne diseases.

in the design and implementation of development initiatives is necessary to reduce vulnerability and enhance sustainability. [18.6.1]

7. Global Issues and Synthesis

7.1. Detection of Climate Change Impacts

Observational evidence indicates that climate changes in the 20th century already have affected a diverse set of physical and

biological systems. Examples of observed changes with linkages to climate include shrinkage of glaciers; thawing of permafrost; shifts in ice freeze and break-up dates on rivers and lakes; increases in rainfall and rainfall intensity in most mid- and high latitudes of the Northern Hemisphere; lengthening of growing seasons; and earlier flowering dates of trees, emergence of insects, and egg-laying in birds. Statistically significant associations between changes in regional climate and observed changes in physical and biological systems have been documented in freshwater, terrestrial, and marine environments on all continents. [19.2]

Table TS-15: Adaptation and capacity in regions (key findings from Chapters 10 through 17).

Sector	Key Findings
Africa	<ul style="list-style-type: none"> – Adaptive measures would enhance flexibility and have net benefits in water resources (irrigation and water reuse, aquifer and groundwater management, desalination), agriculture (crop changes, technology, irrigation, husbandry), and forestry (regeneration of local species, energy-efficient cook stoves, sustainable community management). – Without adaptation, climate change will reduce the wildlife reserve network significantly by altering ecosystems and causing species' emigrations and extinctions. This represents an important ecological and economic vulnerability in Africa. – A risk-sharing approach between countries will strengthen adaptation strategies, including disaster management, risk communication, emergency evacuation, and cooperative water resource management. – Most countries in Africa are particularly vulnerable to climate change because of limited adaptive capacity as a result of widespread poverty, recurrent droughts, inequitable land distribution, and dependence on rainfed agriculture. – Enhancement of adaptive capacity requires local empowerment in decisionmaking and incorporation of climate adaptation within broader sustainable development strategies.
Asia	<ul style="list-style-type: none"> – Priority areas for adaptation are land and water resources, food productivity, and disaster preparedness and planning, particularly for poorer, resource-dependent countries. – Adaptations already are required to deal with vulnerabilities associated with climate variability, in human health, coastal settlements, infrastructure, and food security. Resilience of most sectors in Asia to climate change is very poor. Expansion of irrigation will be difficult and costly in many countries. – For many developing countries in Asia, climate change is only one of a host of problems to deal with, including nearer term needs such as hunger, water supply and pollution, and energy. Resources available for adaptation to climate are limited. Adaptation responses are closely linked to development activities, which should be considered in evaluating adaptation options. – Early signs of climate change already have been observed and may become more prominent over 1 or 2 decades. If this time is not used to design and implement adaptations, it may be too late to avoid upheavals. Long-term adaptation requires anticipatory actions. – A wide range of precautionary measures are available at the regional and national level to reduce economic and social impacts of disasters. These strategies include awareness-building and expansion of the insurance industry. – Development of effective adaptation strategies requires local involvement, inclusion of community perceptions, and recognition of multiple stresses on sustainable management of resources. – Adaptive capacities vary between countries, depending on social structure, culture, economic capacity, and level of environmental disruptions. Limiting factors include poor resource and infrastructure bases, poverty and disparities in income, weak institutions, and limited technology. – The challenge in Asia lies in identifying opportunities to facilitate sustainable development with strategies that make climate-sensitive sectors resilient to climate variability. – Adaptation strategies would benefit from taking a more systems-oriented approach, emphasizing multiple interactive stresses, with less dependence on climate scenarios.
Australia and New Zealand	<ul style="list-style-type: none"> – Adaptations are needed to manage risks from climatic variability and extremes. Pastoral economies and communities have considerable adaptability but are vulnerable to any increase in the frequency or duration of droughts. – Adaptation options include water management, land-use practices and policies, engineering standards for infrastructure, and health services. – Adaptations will be viable only if they are compatible with the broader ecological and socioeconomic environment, have net social and economic benefits, and are taken up by stakeholders. – Adaptation responses may be constrained by conflicting short- and long-term planning horizons. – Poorer communities, including many indigenous settlements, are particularly vulnerable to climate-related hazards and stresses on health because they often are in exposed areas and have less adequate housing, health care, and other resources for adaptation.

Table TS-15 (continued)

Sector	Key Findings
<i>Europe</i>	<ul style="list-style-type: none"> – Adaptation potential in socioeconomic systems is relatively high because strong economic conditions, stable population (with capacity to migrate), and well-developed political, institutional, and technological support systems. – The response of human activities and the natural environment to current weather perturbations provides a guide to critical sensitivities under future climate change. – Adaptation in forests requires long-term planning; it is unlikely that adaptation measures will be put in place in a timely manner. – Farm-level analyses show that if adaptation is fully implemented large reductions in adverse impacts are possible. – Adaptation for natural systems generally is low. – More marginal and less wealthy areas will be less able to adapt; thus, without appropriate policies of response, climate change may lead to greater inequities.
<i>Latin America</i>	<ul style="list-style-type: none"> – Adaptation measures have potential to reduce climate-related losses in agriculture and forestry. – There are opportunities for adapting to water shortages and flooding through water resource management. – Adaptation measures in the fishery sector include changing species captured and increasing prices to reduce losses.
<i>North America</i>	<ul style="list-style-type: none"> – Strain on social and economic systems from rapid climate and sea-level changes will increase the need for explicit adaptation strategies. In some cases, adaptation may yield net benefits, especially if climate change is slow. – Stakeholders in most sectors believe that technology is available to adapt, although at some social and economic cost. – Adaptation is expected to be more successful in agriculture and forestry. However, adaptations for water, health, food, energy, and cities are likely to require substantial institutional and infrastructure changes. – In the water sector, adaptations to seasonal runoff changes include storage, conjunctive supply management, and transfer. It may not be possible to continue current high levels of reliability of water supply, especially with transfers to high-valued uses. Adaptive measures such as “water markets” may lead to concerns about accessibility and conflicts over allocation priorities. – Adaptations such as levees and dams often are successful in managing most variations in weather but can increase vulnerability to the most extreme events. – There is moderate potential for adaptation through conservation programs that protect particularly threatened ecosystems, such as high alpines and wetlands. It may be difficult or impossible to offset adverse impacts on aquatic systems.

The presence of multiple causal factors (e.g., land-use change, pollution) makes attribution of many observed impacts to regional climate change a complex challenge. Nevertheless, studies of systems subjected to significant regional climate change—and with known sensitivities to that change—find changes that are consistent with well-established relationships between climate and physical or biological processes (e.g., shifts in the energy balance of glaciers, shifts in the ranges of animals and plants when temperatures exceed physiological thresholds) in about 80% of biological cases and about 99% of physical cases. Table TS-16 shows ~450 changes in processes or species that have been associated with regional temperature changes. Figure TS-11 illustrates locations at which studies have documented regional temperature change impacts. These consistencies enhance our confidence in the associations between changes in regional climate and observed changes in physical and biological systems. Based on observed changes, there is high confidence that 20th century climate changes have

had a discernible impact on many physical and biological systems. Changes in biota and physical systems observed in the 20th century indicate that these systems are sensitive to climatic changes that are small relative to changes that have been projected for the 21st century. High sensitivity of biological systems to long-term climatic change also is demonstrated by paleorecords. [19.2.2.]

Signals of regional climate change impacts are expected to be clearer in physical and biotic systems than in social and economic systems, which are simultaneously undergoing many complex non-climate-related stresses, such as population growth and urbanization. Preliminary indications suggest that some social and economic systems have been affected in part by 20th century regional climate changes (e.g., increased damages by floods and droughts in some locations, with apparent increases in insurance impacts). Coincident or alternative explanations for such observed regional impacts result in only low to medium

Table TS-15 (continued)

Sector	Key Findings
<i>Polar Regions</i>	<ul style="list-style-type: none"> – Adaptation will occur in natural polar ecosystems through migration and changing mixes of species. Species such as walrus, seals, and polar bears will be threatened; while others, such as fish, may flourish. – Potential for adaptation is limited in indigenous communities that follow traditional lifestyles. – Technologically developed communities are likely to adapt quite readily, although the high capital investment required may result in costs in maintaining lifestyles. – Adaptation depends on technological advances, institutional arrangements, availability of financing, and information exchange.
<i>Small Island States</i>	<ul style="list-style-type: none"> – The need for adaptation has become increasingly urgent, even if swift implementation of global agreements to reduce future emissions occurs. – Most adaptation will be carried out by people and communities that inhabit island countries; support from governments is essential for implementing adaptive measures. – Progress will require integration of appropriate risk-reduction strategies with other sectoral policy initiatives in areas such as sustainable development planning, disaster prevention and management, integrated coastal zone management, and health care planning. – Strategies for adaptation to sea-level rise are retreat, accommodate, and protect. Measures such as retreat to higher ground, raising of the land, and use of building set-backs appear to have little practical utility, especially when hindered by limited physical size. – Measures for reducing the severity of health threats include health education programs, health care facilities, sewerage and solid waste management, and disaster preparedness plans. – Islanders have developed some capacity to adapt by application of traditional knowledge, locally appropriate technology, and customary practice. Overall adaptive capacity is low, however, because of the physical size of nations, limited access to capital and technology, shortage of human resource skills, lack of tenure security, overcrowding, and limited access to resources for construction. – Many small islands require external financial, technical, and other assistance to adapt. Adaptive capacity may be enhanced by regional cooperation and pooling of limited resources.

confidence about determining whether climate change is affecting these systems. [19.2.2.4]

7.2. Five Reasons for Concern

Some of the current knowledge about climate change impacts, vulnerability, and adaptation is synthesized here along five reasons for concern: unique and threatened systems, global aggregate impacts, distribution of impacts, extreme weather events, and large-scale singular events. Consideration of these reasons for concern contribute to understanding of vulnerabilities and potential benefits associated with human-induced climate change that can aid deliberations by policymakers of what could constitute dangerous interference with the climate system in the context of Article 2 of the UNFCCC. No single dimension is paramount.

Figure TS-12 presents qualitative findings about climate change impacts related to the reasons for concern. At a small increase in global mean temperature,³ some of the reasons for concern show the potential for negative impacts, whereas others show little adverse impact or risk. At higher temperature increases, all lines of evidence show a potential for adverse impacts, with impacts in each reason for concern becoming more negative at increasing temperatures. There is high confidence

in this general relationship between impacts and temperature change, but confidence generally is low in estimates of temperature change thresholds at which different categories of impacts would happen. [19.8]

7.2.1. Unique and Threatened Systems

Small increases in global average temperature may cause significant and irreversible damage to some systems and species, including possible local, regional, or global loss. Some plant and animal species, natural systems, and human settlements are highly sensitive to climate and are likely to be adversely affected by climate changes associated with scenarios of <1°C mean global warming. Adverse impacts to species and systems

³Intervals of global mean temperature increase of 0–2, 2–3, and >3°C relative to 1990 are labeled small, moderate, and large, respectively. The relatively large range for the “small” designation results because the literature does adequately address a warming of 1–2°C. These magnitudes of change in global mean temperature should be taken as an approximate indicator of when impacts might occur; they are not intended to define absolute thresholds or to describe all relevant aspects of climate-change impacts, such as rate of change in climate and changes in precipitation, extreme climate events, or lagged (latent) effects such as rising sea levels.

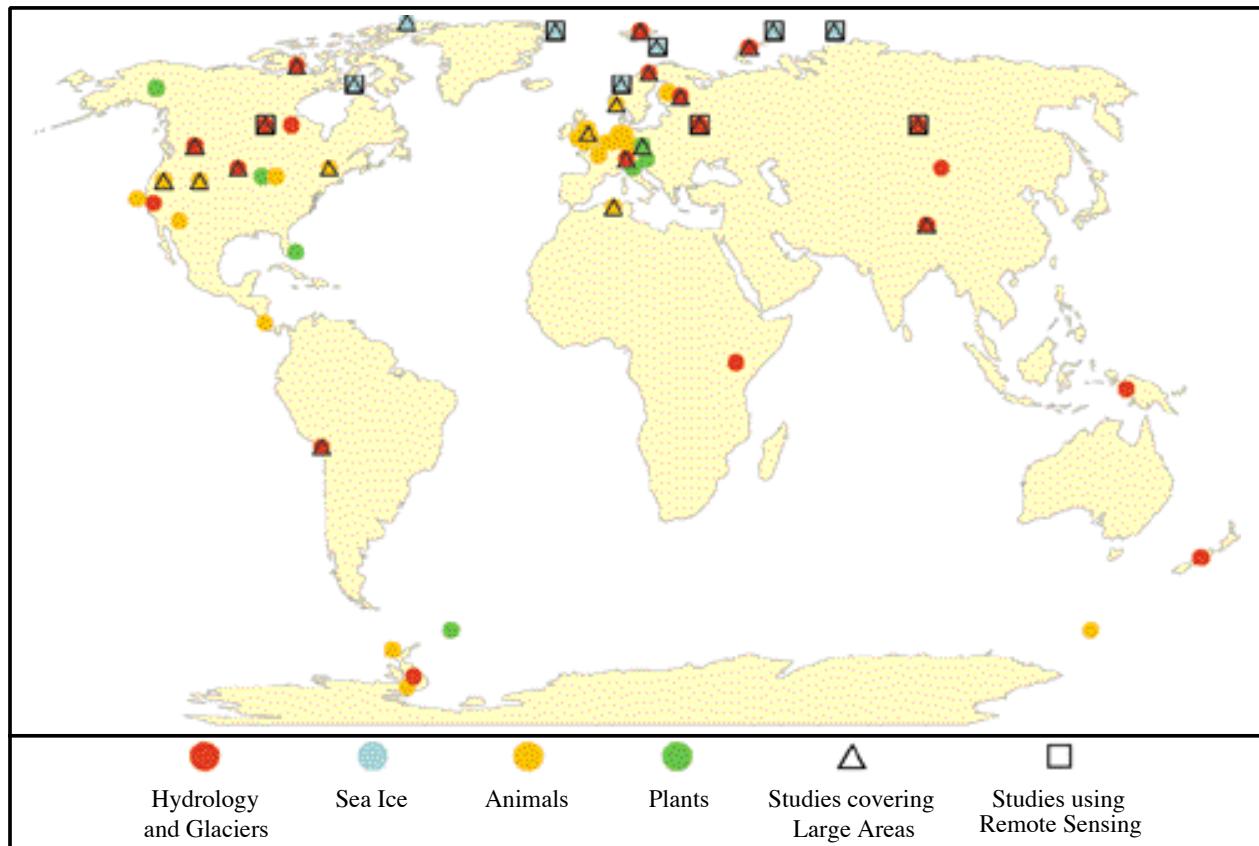

Figure TS-11: Locations at which systematic long-term studies meet stringent criteria documenting recent temperature-related regional climate change impacts on physical and biological systems. Hydrology, glacial retreat, and sea-ice data represent decadal to century trends. Terrestrial and marine ecosystem data represent trends of at least 2 decades. Remote-sensing studies cover large areas. Data are for single or multiple impacts that are consistent with known mechanisms of physical/biological system responses to observed regional temperature-related changes. For reported impacts spanning large areas, a representative location on the map was selected.

would become more numerous and more serious for climatic changes that would accompany a global mean warming of 1–2°C and are highly likely to become even more numerous and serious at higher temperatures. The greater the rate and magnitude of temperature and other climatic changes, the greater the likelihood that critical thresholds of systems would be surpassed. Many of these threatened systems are at risk from climate change because they face nonclimate pressures such as those related to human land use, land-use change, and pollution. [19.3]

Species that may be threatened with local or global extinction by changes in climate that may accompany a small mean global temperature increase include critically endangered species generally, species with small ranges and low population densities, species with restricted habitat requirements, and species for which suitable habitat is patchy in distribution, particularly if under pressure from human land-use and land-cover change. Examples of species that may be threatened by small changes include forest birds in Tanzania, the Resplendent Quetzal in

Central America, the mountain gorilla in Africa, amphibians that are endemic to cloud forests of the neotropics, the spectacled bear of the Andes, the Bengal tiger and other species that are endemic to the Sundarban wetlands, and rainfall-sensitive plant species that are endemic to the Cape Floral Kingdom of South Africa. Natural systems that may be threatened include coral reefs, mangroves, and other coastal wetlands; montane ecosystems that are restricted to the upper 200–300 m of mountainous areas; prairie wetlands; remnant native grasslands; coldwater and some coolwater fish habitat; ecosystems overlying permafrost; and ice edge ecosystems that provide habitat for polar bears and penguins. Human settlements that may be placed at serious risk by changes in climate and sea level that may be associated with medium to large mean warming include some settlements of low-lying coastal areas and islands, floodplains, and hillsides—particularly those of low socioeconomic status such as squatter and other informal settlements. Other potentially threatened settlements include traditional peoples that are highly dependent on natural resources that are sensitive to climate change. [19.3]

Table TS-16: Processes and species found in studies to be associated with regional temperature change.^a

Region	Glaciers, Snow Cover/ Melt, Lake/ Stream Ice ^b			Vegetation	Invertebrates	Amphibians and Reptiles	Birds	Mammals
Africa	1	0	—	—	—	—	—	—
Antarctica	3	2	2	0	—	—	2	0
Asia	14	0	—	—	—	—	—	—
Australia	1	0	—	—	—	—	—	—
Europe	29	4	13	1	46	1	7	0
North America	36	4	32	11	—	—	17	4
Latin America	3	0	—	—	—	22	0	15
Total	87	10	47	12	46	1	29	0
							292	96
							10	0

^a The columns represent the number of species and processes in each region that were found in each particular study to be associated with regional temperature change. For inclusion in the table, each study needed to show that the species or process was changing over time and that the regional temperature was changing over time; most studies also found a significant association between how the temperature and species or processes were changing. The first number indicates the number of species or processes changing in the manner predicted with global warming. The second number is the number of species or processes changing in a manner opposite to that predicted with a warming planet. Empty cells indicate that no studies were found for this region and category.

^b Sea ice not included.

7.2.2. Aggregate Impacts

With a small temperature increase, aggregate market-sector impacts could amount to plus or minus a few percent of world GDP (medium confidence); aggregate nonmarket impacts could be negative (low confidence). The small net impacts are mainly the result of the fact that developed economies, many of which could have positive impacts, contribute the majority of global production. Applying more weight to impacts in poorer countries to reflect equity concerns, however, can result in net aggregate impacts that are negative even at medium warming. It also is possible that a majority of people will be negatively affected by climate change scenarios in this range, even if the net aggregate monetary impact is positive. With medium to higher temperature increases, benefits tend to decrease and damages increase, so the net change in global economic welfare becomes negative—and increasingly negative with greater warming (medium confidence). Some sectors, such as coastal and water resources, could have negative impacts in developed and developing countries. Other sectors, such as agriculture and human health, could have net positive impacts in some countries and net negative impacts in other countries. [19.5]

Results are sensitive to assumptions about changes in regional climate, levels of development, adaptive capacity, rates of change, valuation of impacts, and methods used for aggregating losses and gains, including the choice of discount rate. In addition,

these studies do not consider potentially important factors such as changes in extreme events, advantageous and complementary responses to the threat of non-climate-driven extreme events, rapid change in regional climate (e.g., resulting from changes in ocean circulation), compounding effects of multiple stresses, or conflicting or complementary reaction to those stresses. Because these factors have yet to be accounted for in estimates of aggregate impacts and estimates do not include all possible categories of impacts, particularly nonmarket impacts, estimates of aggregate economic welfare impacts of climate change are considered to be incomplete. Given the uncertainties about aggregate estimates, the possibility of negative effects at a small increase in temperature cannot be excluded. [19.5]

7.2.3. Distribution of Impacts

Developing countries tend to be more vulnerable to climate change than developed countries (high confidence). Developing countries are expected to suffer more adverse impacts than developed countries (medium confidence). A small temperature increase would have net negative impacts on market sectors in many developing countries (medium confidence) and net positive impacts on market sectors in many developed countries (medium confidence). The different results are attributable partly to differences in exposures and sensitivities (e.g., present temperatures are below optimal in mid- and high latitudes for many crops but at or above optimal in low latitudes) and partly to lesser adaptive

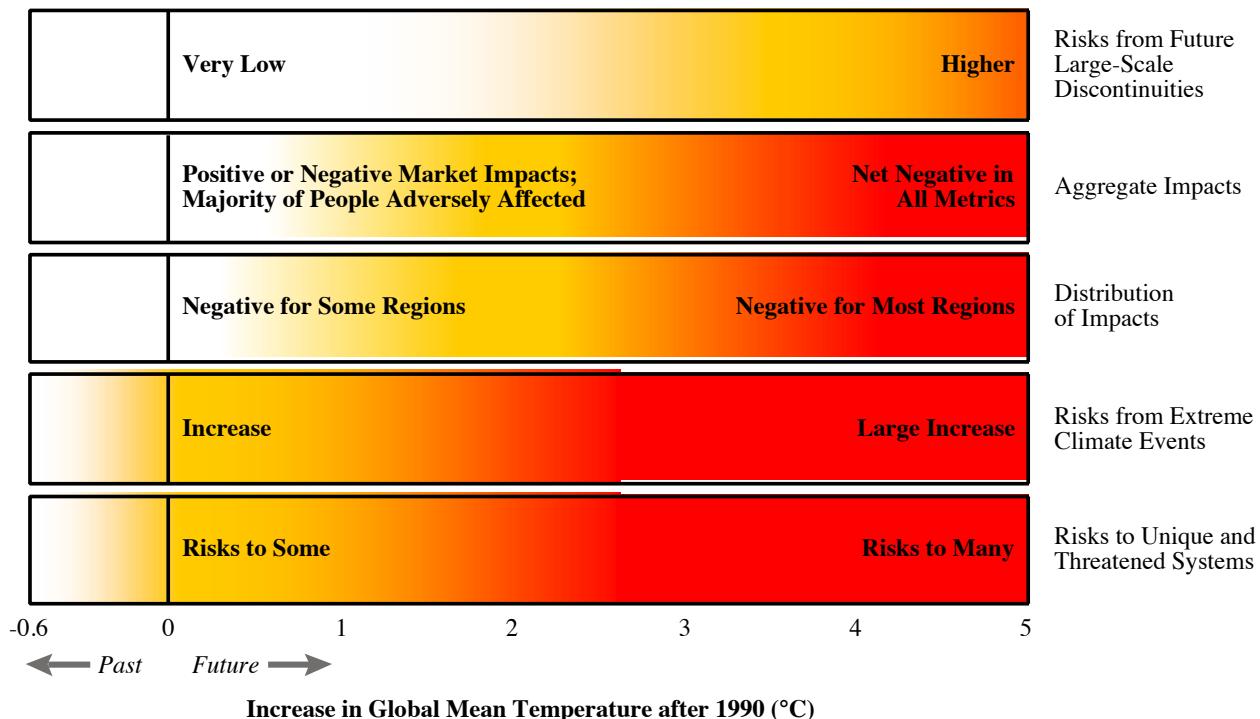

Figure TS-12: Impacts of or risks from climate change, by reason for concern. Each row corresponds to a reason for concern, and shades correspond to severity of impact or risk. White means no or virtually neutral impact or risk, yellow means somewhat negative impacts or low risks, and red means more negative impacts or higher risks. Global-averaged temperatures in the 20th century increased by 0.6°C and led to some impacts. Impacts are plotted against increases in global mean temperature after 1990. This figure addresses only how impacts or risks change as thresholds of increase in global mean temperature are crossed, not how impacts or risks change at different rates of change in climate. These temperatures should be taken as approximate indications of impacts, not as absolute thresholds.

capacity in developing countries relative to developed countries. At a medium temperature increase, net positive impacts would start to turn negative and negative impacts would be exacerbated (high confidence). The results of these studies do not fully take into account nonmarket impacts of climate change such as impacts on natural systems, which may be sensitive to small amounts of warming. Particularly vulnerable regions include deltaic regions, low-lying small island states, and many arid regions where droughts and water availability are problematic even without climate change. Within regions or countries, impacts are expected to fall most heavily, in relative terms, on impoverished persons. The poorest members of society can be inferred to be most vulnerable to climate change because of their lack of resources with which to cope and adapt to impacts, but few studies have explicitly examined the distribution of impacts on the poor relative to other segments of society. [19.4]

Impacts on unmanaged systems are likely to increase in severity with time, but impacts on managed systems could increase or decrease through the 21st century. The distribution of impacts over the 21st century is influenced by several factors. As GHG concentrations increase, the magnitude of exposure to change in climate stimuli also would increase. Nonclimate pressures on natural and social systems, which increase the vulnerability

of systems, also may grow through time as a result of population growth and increased demands for land, water, public infrastructure, and other resources. Increased population, incomes, and wealth also mean that more people and human-made resources potentially would be exposed to climate change, which would tend to increase market-sector damages in absolute dollar terms; this has been the case historically. Counteracting these tendencies are factors such as increased wealth and technology and improved institutions, which can raise adaptive capacity and reduce vulnerability to climate change. [8, 19.4]

Whether impacts and vulnerability increase or decrease with time is likely to depend in part on the rates of climate change and development and may differ for managed and unmanaged systems. The more rapid the rate of climate change, the greater would be future exposure to potentially adverse changes and the greater the potential for exceeding system thresholds. The more rapid the rate of development, the more resources would be exposed to climate change in the future—but so too would the adaptive capacity of future societies. The benefits of increased adaptive capacity are likely to be greater for intensively managed systems than for systems that presently are unmanaged or lightly managed. For this reason, and because of the possibility that nonclimate pressures on natural systems may increase in

the future, the vulnerability of natural systems is expected to increase with time (medium confidence). [19.4.2, 19.4.3]

Future development paths, sustainable or otherwise, will shape future vulnerability to climate change, and climate change impacts may affect prospects for sustainable development in different parts of the world. Climate change is one of many stresses that confront human and natural systems. The severity of many of these stresses will be determined in part by the development paths followed by human societies; paths that generate lesser stresses are expected to lessen the vulnerability of human and natural systems to climate change. Development also can influence future vulnerability by enhancing adaptive capacity through accumulation of wealth, technology, information, skills, and appropriate infrastructure; development of effective institutions; and advancement of equity. Climate change impacts could affect prospects for sustainable development by changing the capacity to produce food and fiber, the supply and quality of water, and human health and by diverting financial and human resources to adaptation. [18]

7.2.4. Extreme Weather Events

Many climatic impacts are related to extreme weather events, and the same will hold for the impacts of climate change. The large damage potential of extreme events arises from their severity, suddenness, and unpredictability, which makes them difficult to adapt to. Development patterns can increase vulnerability to extreme events. For example, large development along coastal regions increases exposure to storm surges and tropical cyclones, increasing vulnerability.

The frequency and magnitude of many extreme climate events increase even with a small temperature increase and will become greater at higher temperatures (high confidence). Extreme events include, for example, floods, soil moisture deficits, tropical cyclones, storms, high temperatures, and fires. The impacts of extreme events often are large locally and could strongly affect specific sectors and regions. Increases in extreme events can cause critical design or natural thresholds to be exceeded, beyond which the magnitude of impacts increases rapidly (high confidence). Multiple nonextreme consecutive events also can be problematic because they can lessen adaptive capacity by depleting reserves of insurance and reinsurance companies. [8, 19.6.3.1]

An increase in the frequency and magnitude of extreme events would have adverse effects throughout sectors and regions. Agriculture and water resources may be particularly vulnerable to changes in hydrological and temperature extremes. Coastal infrastructure and ecosystems may be adversely affected by changes in the occurrence of tropical cyclones and storm surges. Heat-related mortality is likely to increase with higher temperatures; cold-related mortality is likely to decrease. Floods may lead to the spread of water-related and vector-borne diseases, particularly in developing countries. Many of the monetary damages from extreme events will have

repercussions on a broad scale of financial institutions, from insurers and reinsurers to investors, banks, and disaster relief funds. Changes in the statistics of extreme events have implications for the design criteria of engineering applications (e.g., levee banks, bridges, building design, and zoning), which are based on estimates of return periods, and for assessment of the economic performance and viability of particular enterprises that are affected by weather. [19.6.3.1]

7.2.5. Large-Scale Singular Events

Human-induced climate change has the potential to trigger large-scale changes in Earth systems that could have severe consequences at regional or global scales. The probabilities of triggering such events are poorly understood but should not be ignored, given the severity of their consequences. Events of this type that might be triggered include complete or partial shutdown of the North Atlantic and Antarctic Deep Water formation, disintegration of the West Antarctic and Greenland Ice Sheets, and major perturbations of biosphere-regulated carbon dynamics. Determining the timing and probability of occurrence of large-scale discontinuities is difficult because these events are triggered by complex interactions between components of the climate system. The actual discontinuous impact could lag the trigger by decades to centuries. These triggers are sensitive to the magnitude and rate of climate change. Large temperature increases have the potential to lead to large-scale discontinuities in the climate system (medium confidence).

These discontinuities could cause severe impacts on the regional and even global scale, but indepth impact analyses are still lacking. Several climate model simulations show complete shutdown of the North Atlantic thermohaline circulation with high warming. Although complete shutdown may take several centuries to occur, regional shutdown of convection and significant weakening of the thermohaline circulation may take place within the next century. If this were to occur, it could lead to a rapid regional climate change in the North Atlantic region, with major societal and ecosystem impacts. Collapse of the West Antarctic Ice Sheet would lead to a global sea-level rise of several meters, which may be very difficult to adapt to. Although the disintegration might take many hundreds of years, this process could be triggered irreversibly in the next century. The relative magnitude of feedback processes involved in cycling of carbon through the oceans and the terrestrial biosphere is shown to be distorted by increasing temperatures. Saturation and decline of the net sink effect of the terrestrial biosphere—which is projected to occur over the next century—in step with similar processes, could lead to dominance of positive feedbacks over negative ones and strong amplification of the warming trend. [19.6.3.2]

8. Information Needs

Although progress has been made, considerable gaps in knowledge remain regarding exposure, sensitivity, adaptability, and

vulnerability of physical, ecological, and social systems to climate change. Advances in these areas are priorities for advancing understanding of potential consequences of climate change for human society and the natural world, as well as to support analyses of possible responses.

Exposure. Advances in methods for projecting exposures to climate stimuli and other nonclimate stresses at finer spatial scales are needed to improve understanding of potential consequences of climate change, including regional differences, and stimuli to which systems may need to adapt. Work in this area should draw on results from research on system sensitivity, adaptability, and vulnerability to identify the types of climate stimuli and nonclimate stresses that affect systems most. This research is particularly needed in developing countries, many of which lack historical data, adequate monitoring systems, and research and development capabilities. Developing local capacity in environmental assessment and management will increase investment effectiveness. Methods of investigating possible changes in the frequency and intensity of extreme climate events, climate variability, and large-scale, abrupt changes in the Earth system such as slowing or shutdown of thermohaline circulation of oceans are priorities. Work also is needed to advance understanding of how social and economic factors influence the exposures of different populations.

Sensitivity. Sensitivity to climate stimuli is still poorly quantified for many natural and human systems. Responses of systems to climate change are expected to include strong nonlinearities, discontinuous or abrupt responses, time-varying responses, and complex interactions with other systems. However, quantification of the curvature, thresholds, and interactions of system responses is poorly developed for many systems. Work is needed to develop and improve process-based, dynamic models of natural, social, and economic systems; to estimate model parameters of system responses to climate variables; and to validate model simulation results. This work should include use of observational evidence, paleo-observations where applicable, and long-term monitoring of systems and forces acting on them. Continued efforts to detect impacts of observed climate change is a priority for further investigation that can provide empirical information for understanding of system sensitivity to climate change

Adaptability. Progress has been made in the investigation of adaptive measures and adaptive capacity. However, work is needed to better understand the applicability of adaptation experiences with climate variability to climate change, to use this information to develop empirically based estimates of the effectiveness and costs of adaptation, and to develop predictive models of adaptive behavior that take into account decision making under uncertainty. Work also is needed to better understand the determinants of adaptive capacity and to use this information to advance understanding of differences in adaptive capacity across regions, nations, and socioeconomic groups, as well as how capacity may change through time. Advances in these areas are expected to be useful for identifying successful strategies for enhancing adaptation capacity in ways that can be complementary to climate change mitigation, sustainable development, and equity goals.

Vulnerability. Assessments of vulnerability to climate change are largely qualitative and address the sources and character of vulnerability. Further work is needed to integrate information about exposures, sensitivity, and adaptability to provide more detailed and quantitative information about the potential impacts of climate change and the relative degree of vulnerability of different regions, nations, and socioeconomic groups. Advances will require development and refinement of multiple measures or indices of vulnerability such as the number or percentage of persons, species, systems or land area negatively or positively affected; changes in productivity of systems; the monetary value of economic welfare change in absolute and relative terms; and measures of distributional inequities.

Uncertainty. Large gaps remain in refining and applying methods for treating uncertainties, particularly with respect to providing scientific information for decisionmaking. Improvements are required in ways of expressing the likelihood, confidence, and range of uncertainty for estimates of outcomes, as well as how such estimates fit into broader ranges of uncertainty. Methods for providing “traceable accounts” of how any aggregated estimate is made from disaggregated information must be refined. More effort is needed to translate judgments into probability distributions in integrated assessment models.

Overview of Impacts, Adaptation, and Vulnerability to Climate Change

1.1. Overview of the Assessment

The world community faces many risks from climate change. Clearly, it is important to understand the nature of those risks, where natural and human systems are likely to be most vulnerable, and what may be achieved by adaptive responses. To understand better the potential impacts and associated dangers of global climate change, Working Group II of the Intergovernmental Panel on Climate Change (IPCC) offers this Third Assessment Report (TAR) on the state of knowledge concerning the sensitivity, adaptability, and vulnerability of physical, ecological, and social systems to climate change. Building on the Second Assessment Report (SAR), this new report reexamines key findings of the earlier assessment and emphasizes new information and implications on the basis of more recent studies.

Human activities—primarily burning of fossil fuels and changes in land cover—are modifying the concentration of atmospheric constituents or properties of the Earth's surface that absorb or scatter radiant energy. In particular, increases in the concentrations of greenhouse gases (GHGs) and aerosols are strongly implicated as contributors to climatic changes observed during the 20th century and are expected to contribute to further changes in climate in the 21st century and beyond. These changes in atmospheric composition are likely to alter temperatures, precipitation patterns, sea level, extreme events, and other aspects of climate on which the natural environment and human systems depend.

One of several primary issues this report has been organized to address is a key question before the United Nations Framework Convention on Climate Change (UNFCCC): What are the potential impacts for societies and ecosystems of different atmospheric concentrations of GHGs and aerosols that absorb and scatter sunlight (United Nations, 1992)? Answering this question is a necessary step in assessing what constitutes “dangerous anthropogenic interference in the climate system.” This report does not make any judgments about what level of concentrations is “dangerous” because that is not a question of science *per se* but a value judgment about relative risks and tradeoffs. The task is to make the evidence about relative risks as clear as possible. This report therefore describes what is known about the distribution of impacts; how, why, and to what extent they differ from region to region or place to place; and how this relates to the distribution of vulnerability and capacity to adapt. However, it critically assesses the literature to help inform policymakers about effects associated with different concentration levels, so they may judge what levels of risk are acceptable. Assessment of what constitutes dangerous interference in the climate systems will require analysis of the interactions of climate change and social and economic conditions, which are inextricably linked. Understanding the role of socioeconomic factors, particularly adaptive responses and capacity, is critical.

Part of the justification for a TAR at this time is the abundance of new evidence that has come to the attention of the expert

community since publication of the SAR. The evidence is drawn predominantly from published, peer-reviewed scientific literature. Evidence also is drawn from published, non-peer-reviewed literature and unpublished sources such as industry journals; reports of government agencies, research institutions, and other organizations; proceedings of workshops; working papers; and unpublished data sets. The quality and validity of information from non-peer-reviewed and unpublished sources have been assessed by authors of this report prior to inclusion of information from these sources in the report. The procedures for the use of information from non-peer-reviewed and unpublished sources are described in IPCC (1999a) and discussed in Skodvin (2000).

Although this report builds on previous assessments, including the SAR and the IPCC's *Special Report on Regional Impacts of Climate Change* (IPCC, 1998), the TAR departs from them in important respects. In comparison to previous assessments, greater attention is given to climate change adaptation; multiple pressures on systems; links between climate change, sustainable development, and equity; and characterization of the state-of-the-science and confidence levels associated with key conclusions of the assessment (see Box 1-1). This overview chapter does not attempt to provide a comprehensive summary of the principal findings of the TAR, but it helps to illustrate basic concepts by selectively reporting on a few key conclusions, as well as providing a more comprehensive road map to the materials presented later in the report:

- Part I sets the stage for assessment of impacts, adaptation, and vulnerability by discussing the context of climate change, methods for research on impacts, and development of scenarios. These are important additions to what was emphasized in the SAR. Consideration of the context of change (in this chapter) draws attention to the relationship of climate change and sustainable development, including interactions of climate variability and change with other environmental changes and evolving demographic, social, and economic conditions that affect driving forces of change and resources available for adaptation. Assessment of methods (Chapter 2) and approaches for developing and applying scenarios (Chapter 3) cover scientific and technical aspects of research on impacts, providing a review of the science underlying the topics covered in other chapters of the report.
- Part II assesses recent advances in experimental work, observations, and modeling that contribute to the current state of knowledge of baseline trends, vulnerabilities, and adaptation options in six sectors or resource areas. This section of the report integrates material that had been covered in 18 chapters in the SAR, focusing to a greater extent on cross-sectoral issues. For example, Chapter 5, Ecosystems and their Goods and Services, integrates what had been separate chapters on forests, rangelands, deserts, mountain regions, wetlands, agriculture, food security, and other systems; it also adds assessment of climate change impacts on

wildlife—an issue not covered in the SAR. Integrating these issues into a single chapter provides an opportunity for improved assessment of interactions across these systems, the effects of change on landscapes, and the distribution of land use and cover. Information on the impacts of natural variability and the potential for nonlinear interactions also is included in the chapters in Part II.

- Chapters in Part III build on key findings of the IPCC's *Special Report on Regional Impacts of Climate Change*. Each chapter and subchapter in this part of the report explores what has been learned regarding the context of change, sensitivity, adaptation, and vulnerability of key sectors. A chapter is devoted to each of eight regions of the world: Africa, Asia, Australia and New Zealand, Europe, Latin America, North America, polar regions, and small island states (see Figure 1-1). These regions are chosen to correspond to continents or—in the case of polar regions and small island states—to bring together in one chapter areas that share important attributes related to climate change vulnerability. This regionalization of the world is convenient for organizing the report, but it must be recognized that there is a high

degree of heterogeneity within each of these regions in terms of climate, ecosystems, culture, and social, economic, and political systems. Consequently, climate change impacts, adaptive capacity, and vulnerability vary markedly within each of these regions. These chapters provide an opportunity to place vulnerability and adaptation in the context of multiple stresses and regional resources for adaptation. This is an extremely important development because it calls attention to the issues that regional and local decisionmakers in the private and public sectors will be facing in each of the regions.

Areas of important new findings include detection of impacts of observed climatic changes on environmental systems, transient scenarios, vulnerability to changes in climate variability, and vulnerability to strongly nonlinear, complex, and discontinuous responses to climate change. Another distinction from previous assessments is the recognition in the TAR that the many complexities of analysis logically lead to a focus on ranges of outcomes and characterizations, using subjective probabilities of events, rather than primary emphasis on "best guesses," point estimates, single "optimum," or aggregate conclusions.

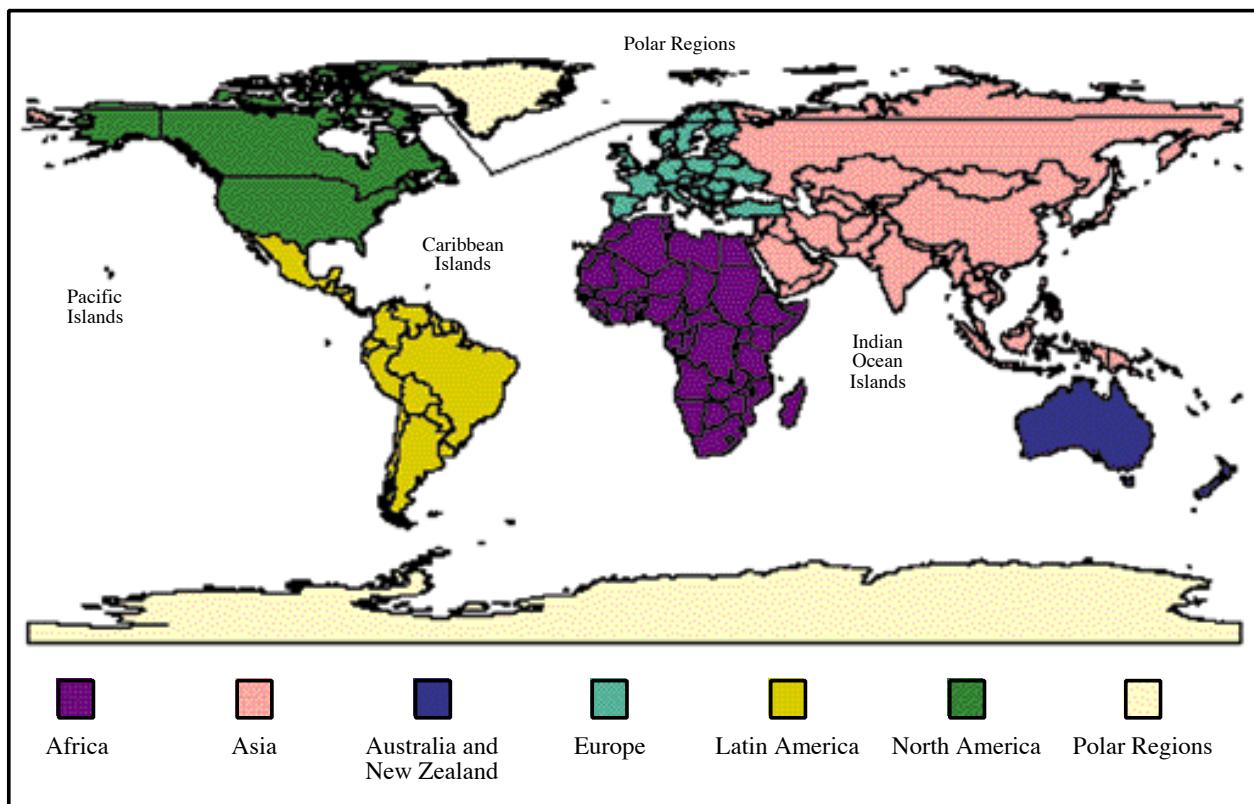

Figure 1-1: Regions for the IPCC Working Group II Third Assessment Report. Note that regions in which small island states are located include the Pacific, Indian, and Atlantic Oceans, and the Caribbean and Mediterranean Seas. The boundary between Europe and Asia runs along the eastern Ural Mountains, River Ural, and Caspian Sea. For the polar regions, the Arctic consists of the area north of the Arctic Circle, including Greenland; the Antarctic consists of the Antarctic continent, together with the Southern Ocean south of ~58°S.

Box 1-1 Uncertainties and Confidence Scale

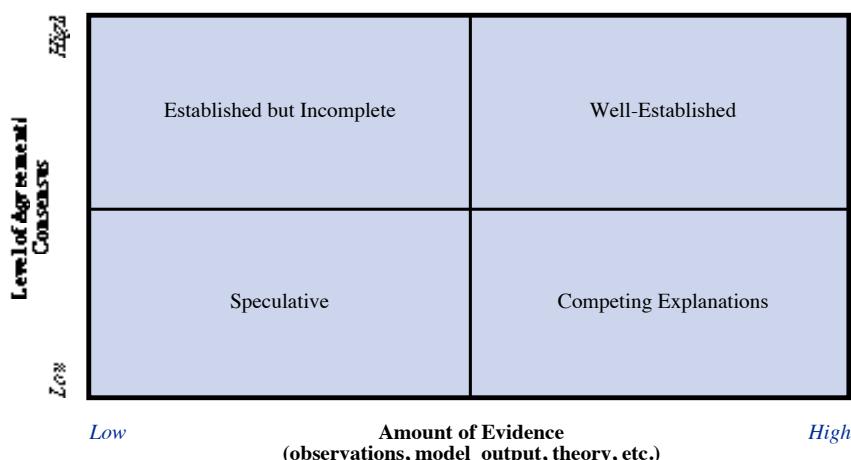

The many conclusions presented in this report are subject to varying degrees of uncertainty. The degree of uncertainty attached to conclusions in this report are assessed and reported in two different ways. One is to assess and report a confidence level for a conclusion, using a Bayesian probability framework. (Bayesian assessments of probability distributions would lead to the following interpretation of probability statements: The probability of an event is the degree of belief that exists among lead authors and reviewers that the event will occur, given observations, modeling results, and theory currently available.) The second is to assess and report the quality or level of scientific understanding that supports a conclusion.

The 5-point confidence scale below is used to assign confidence levels to selected conclusions. The confidence levels are stated as Bayesian probabilities, meaning that they represent the degree of belief among the authors of the report in the validity of a conclusion, based on their collective expert judgment of all observational evidence, modeling results, and theory currently available to them.

5-Point Quantitative Scale for Confidence Levels

95% or greater	Very High Confidence
67–95%	High Confidence
33–67%	Medium Confidence
5–33%	Low Confidence
5% or less	Very Low Confidence

For some conclusions, the 5-point quantitative scale is not appropriate as a characterization of associated uncertainty. In these instances, authors qualitatively evaluate the level of scientific understanding in support of a conclusion, based on the amount of supporting evidence and the level of agreement among experts about the interpretation of the evidence. The matrix below has been used to characterize the level of scientific understanding.

Key to Qualitative “State of Knowledge” Descriptors

- *Well-Established*: Models incorporate known processes; observations are consistent with models; or multiple lines of evidence support the finding.
- *Established but Incomplete*: Models incorporate most known processes, although some parameterizations may not be well tested; observations are somewhat consistent but incomplete; current empirical estimates are well founded, but the possibility of changes in governing processes over time is considerable; or only one or a few lines of evidence support the finding.
- *Competing Explanations*: Different model representations account for different aspects of observations or evidence or incorporate different aspects of key processes, leading to competing explanations.
- *Speculative*: Conceptually plausible ideas that haven’t received much attention in the literature or that are laced with difficult to reduce uncertainties.

Box 1-2. Cross-Cutting Issues Guidance Papers

Four cross-cutting guidance papers (Pachauri *et al.*, 2000) were available to all Lead Authors of all three IPCC working groups. Many of the concepts in these papers were previously unfamiliar to a large number of the Lead Authors. Significant efforts were made to incorporate the uncertainties guidance and at least consider the guidance in other papers by each working group. Future assessments will be increasingly able to benefit from the suggestions and frameworks in these four cross-cutting guidance papers.

Development, Sustainability, and Equity (DSE) (Munasinghe, 2000)

DSE is relevant to Working Group II with respect to three questions: How do development paths and equity conditions influence vulnerability to climate change and the capacity to adapt to or cope with climate change? How might climate change impacts and adaptation responses affect prospects for attaining sustainable development and equity goals? What types of policies are capable of reducing climate change vulnerability and promoting sustainable development and equity objectives?

DSE is a response to principles contained in UNFCCC Article 3.4 (to promote sustainable development). Article 3.2 takes into account the special needs and circumstances of developing countries. Article 4 deals, for example, with the responsibility of developed nations, competing priorities for developing nations, and “common, but differentiated responsibilities,” and Article 2 says to avoid “dangerous” interference with the climate system (United Nations, 1992). DSE is closely tied to sustainable development with respect to three underlying dimensions: economic, social, and environmental.

Development has been characterized as “qualitative improvement” (Ishida, 1998), including economic growth and social dimensions. Sustainability of a system refers to its durability or its capacity to withstand and recover from disturbances (WCED, 1987)—in other words, its resilience. Equity refers to procedural as well as distributional issues. Procedural issues relate to how decisions are made (e.g., internal equity and governance structures within nations could have significant effects on adaptive capacity). Distributional equity, on the other hand, relates to how the costs of impacts, mitigation, and adaptation are shared. Equity considerations are important in addressing global climate change for several reasons, including moral and ethical concerns; facilitating cooperation because equitable decisions carry greater legitimacy; the social dimension of sustainable development; and the UNFCCC itself, which considers equity as one of its basis principles (in Article 3.1).

Climate change could undermine social welfare, equity, and the sustainability of future development. In particular, it is generally believed that developing countries and disadvantaged groups within all countries are more vulnerable to the impacts of climate change (e.g., Chapter 18) as a result of limited resources and low adaptive capacity.

Uncertainty (Moss and Schneider, 2000)

Anticipating the imperfect nature of available information, UNFCCC Article 3.3 provides guidance to the effect that “where there are threats of serious or irreversible damage, lack of full scientific certainty should not be used as a reason for postponing measures to anticipate, prevent, or minimize the causes of climate change and mitigate its adverse effects” (United Nations, 1992). The uncertainties guidance paper develops a unified approach for assessing, characterizing, and reporting uncertainties in the TAR. The most important contribution of the uncertainties guidance paper is the construction of confidence schemes and qualitative terms to describe the state of science, which are reproduced in Box 1-1. The goal is to promote consistency in evaluating the judgments of scientific experts, to facilitate communication of these judgments to nonspecialists, and to provide peer-reviewed guidance for policymakers. Thus, a great deal of importance is attached to assessing the scientific merit of information in the literature and “explicitly distinguishing and communicating which findings are well understood, which are somewhat understood, and which are speculative” (Moss and Schneider, 1997). Section 2.6 discusses in more detail the differences between the well-calibrated ranges in the literature and the much larger, full range of uncertainty as well as the cascade of uncertainty that occurs when ranges in climate scenarios are cascaded with uncertainties in each successive step of assessment. In Chapters 4–19, selected findings are assigned levels of confidence, using either the scale for assessing confidence level quantitatively or the matrix for assessing the state of knowledge qualitatively.

Especially in the regional chapters, uncertainty about future climate is the dominant cause of uncertainty about the character and magnitude of impacts. In such cases, confidence estimates are evaluated conditionally on a specific climate change scenarios to avoid “cascades” (see Figure 2-2) in which confidence in the occurrence of an event does not include compounded uncertainties in each factor that contributes to the final outcome. Instead, the assessment evaluates each step in the cascade separately—what is called a “traceable account”—and is particularly appropriate for any aggregate conclusions.

Finally, the TAR has circulated cross-cutting “guidance papers” to all three working groups to try to achieve more consistency in dealing with four areas: development, sustainability, and equity; uncertainties; costing methodologies; and decision analytic frameworks (see Box 1-2).

The IPCC’s charge to Working Group II for the TAR implies that consideration of the impacts of climate change in the SAR is insufficient *per se* as a basis for decisionmaking. In general, the SAR was able to address the implications of climate change only for single economic sectors or environmental components. With this in mind, Chapters 4–19 consider the various decision analysis framework tools to improve upon the responses to the impacts of climate change provided in the SAR. In the current

exercise, not only are possible implications of climate change for the various economic sectors or environmental components assessed, options to alleviate identified impacts are investigated. In addition, direct and indirect costs of adaptation options are explored, and an extensive assessment of direct and indirect benefits is provided. Where monetary values can be assigned, CBA is employed to determine the optimal value of adaptation measures, including sensitivity analysis to critical parameters, and CEA is adopted to identify the least-cost solution to targeted mitigation objectives.

The concluding section of this report (Chapters 18 and 19) examines global issues and offers a synthesis. A significant addition to previous assessments is Chapter 18, which is devoted

Box 1-2. Cross-Cutting Issues Guidance Papers (continued)

Costing Methodologies (Markandya and Halsnaes, 2000)

This guidance paper discusses many issues related to assessing the impacts of climate change, including identifying the costs of mitigation and adaptation and benefits from avoiding climate damages (market versus nonmarket values; bottom-up versus top-down; willingness-to-pay versus willingness-to-accept-payment); recognizing value-laden assumptions associated with the dollar metric; addressing problems with aggregating costs and benefits that confound differentiated costs and benefits across groups; and determining how to account for ancillary (or co-)benefits and costs. Many of these issues are discussed more fully in the text of this chapter; see also Chapter 2. As noted in the uncertainties guidance paper, a “traceable account” of all aggregations is essential to maintain transparency of any conclusions.

“Cost” refers to any adverse consequence that humans would be willing to expend resources to avoid. “Benefit,” on the other hand, is defined as any advantageous consequence that humans would be willing to expend resources to secure. With respect to adaptation, costs are attached primarily to measures employed to alleviate the impacts of climate change. Real costs, however, are computed as the difference between total expenses on adaptation measures and the value of benefits generated in the process of alleviating impacts. Costs also are attached to damages that would be sustained in the event of no response or inadequate response.

Section 2.5 provides details about methods of costing and valuation used in the TAR. Elements of costing and valuation described include opportunity costs and discounting. Costing of market impacts, nonmarket impacts, and uncertainty are discussed and their applications in decision analyses, scenario analyses, and integrated assessments outlined. In Chapters 4–19, cost-benefit analysis is used to present and evaluate information about impacts and their consequences on ecosystems, socioeconomic sectors, and human health, convenience, and comfort. Where information is available, costs and benefits are quantified and given in monetary units. Often the magnitude of costs and benefits is linked explicitly to specific climate scenarios. As much as possible, the sensitivity of costs and benefits to different magnitudes and rates of climate change and the potential for nonlinear costs or benefits are assessed. For example, the sensitivity of costs and benefits to socioeconomic conditions and differences between developed and developing countries are assessed—with obvious implications for DSE. The contributions of costing and valuation to uncertainty levels in the major conclusions also are described.

Decision Analysis Frameworks (Toth, 2000)

Details on methods and tools of decision analysis frameworks that are applicable in the context of adaptation are provided in Section 2.7, which describes major decision analysis frameworks—including decision analysis (DA), cost-benefit analysis (CBA), cost-effectiveness analysis (CEA), and the policy exercise approach (PE). DA integrates utility theory, probability, and mathematical optimization in a procedure designed to select the best pathway. CBA involves valuing all costs and benefits of a proposed project over time on the basis of WTP and specifying a decision criterion to accept or turn down the project. CEA takes a predetermined objective and seeks ways to accomplish it as inexpensively as possible. PE synthesizes and assesses knowledge in several relevant fields of science for policy purposes in light of complex practical management problems. Application of these decision analysis frameworks cuts across the assignments of Working Groups II and III.

to assessment of opportunities for and barriers to adaptation. This chapter considers determinants of adaptive capacity; lessons from adaptation to present-day climate variability and extremes; the potential effectiveness of adaptation measures; and global-, national-, and local-scale options for strengthening adaptive capacity, especially for vulnerable populations, countries, or zones. Chapter 19, a synthesis, also is new to the TAR. It draws on the analyses of other chapters, synthesizing information that is important for interpretation of Article 2 of the UNFCCC and key provisions of international agreements to address climate change. Potential global impacts of different stabilization levels of atmospheric concentrations of GHGs are assessed. Chapter 19 assesses vulnerability within the framework of sustainable development and equity, acknowledging common but differentiated responsibilities.

The issue of what constitutes sustainable development was advanced in 1987 by the World Commission on Environment and Development (the so-called Brundtland Commission; WCED, 1987). The commission defined *sustainable development* as “development that meets the needs of the present without compromising the ability of future generations to meet their own needs” and notes that “even the narrow notion of physical sustainability implies a concern for social equity between generations, a concern that must logically be extended to equity within each generation.” The goal of sustainable development is a stable human environmental system in which available resources are sufficient to meet the needs of society in perpetuity. Questions have been asked about whether “needs,” as conceived in the Brundtland Commission report, should be limited to environment-dependent basic necessities of food, clothing, shelter, and health or should include more qualitative aspects such as comfort, convenience, or other “quality of life” measures. There is no consensus in the literature regarding what constitutes the limits of “needs” in this context.

Because available studies have not employed a common set of climate scenarios and methods and because of uncertainties regarding the sensitivities and adaptability of natural and human-dominated systems, assessment of regional vulnerabilities is necessarily qualitative. Whenever possible, quantitative estimates of the impacts of climate change are cited in this report. Field or experimental data often provide quantitative underpinnings for specific circumstances, but rarely are complex systems sufficiently described by the limited number of cases in which a large quantity of “hard data” is available. Thus, most quantitative estimates are still dependent on the specific assumptions employed regarding future changes in climate, as well as the particular methods and models applied in the analyses. On the other hand, issues in which there is a great deal of relevant field or lab data are likely to carry higher confidence in any such quantitative estimate. To interpret these estimates, it is important to bear in mind uncertainties regarding the character, magnitude, and rates of future climate change that will affect society’s degree of exposure. Of comparable importance are uncertainties associated with future states of the human condition—for example, the extent and quality of economic development throughout the world and the evolution of traditions

and institutions in societies—that will affect profoundly the capacity for coping and adaptation, hence level of vulnerability. These uncertainties impose limitations on the ability of the research community to project the impacts of climate change, particularly at regional and smaller scales.

This introductory chapter is organized to address a series of questions: What is potentially at stake as a result of changes in climate (Section 1.2)? How has society responded to the risks and potential opportunities (Section 1.3)? How are impacts, adaptation, and vulnerability assessed in the report (Section 1.4)? How do the complexities of analysis affect the assessment (Section 1.5)? How can this assessment be used to address policy-relevant questions (Section 1.6)?

1.2. What is Potentially at Stake?

The stakes surrounding anthropogenic climate change can be very high in terms of the vulnerabilities of some sectors and regions and in terms of the distributional consequences of actions taken to deal with these possibilities. The context is that humankind already is challenged today to provide the opportunity for this and future generations to achieve a more sustainable and equitable standard of living. Billions of people today live without adequate nourishment, access to clean water, modern energy services, and other basic human needs (see, e.g., UNDP, 1999). Providing for the increasing well-being of humans, especially the poor, in the context of sustainable and equitable development is one of the great challenges of the 21st century. Unabated climate change is likely to make meeting this challenge significantly more difficult. On the other hand, it also is argued (e.g., Grossman and Krueger, 1995) that increasing economic growth may lead to reductions in population growth and environmental degradation. Throughout the past century, however, per capita carbon dioxide (CO₂) emissions from combustion of fossil fuels have been driven primarily by growth in gross domestic product (GDP) per capita (although the growth rate in CO₂ emissions generally has not been as fast as the growth in GDP, owing to improvements in energy and carbon intensities of industrial economies (e.g., Hoffert *et al.*, 1998).

The impact (I) of a given population on the environment can be decomposed into the product of three factors: population size (P), affluence per capita (A), and unit impact per unit of affluence, which is related to technologies used (T) (Ehrlich and Holdren, 1971; Ehrlich and Ehrlich, 1990). Rising per capita consumption and a growing world population have resulted in unprecedented human resource use, which is altering global systems, including climate (Bartiaux and van Ypersele, 1993; Yang and Schneider, 1998). According to all of the scenarios considered in the IPCC’s *Special Report on Emissions Scenarios* (SRES) (IPCC, 2000), the human population will continue to grow until at least 2050, reaching a population that is 60–100% larger than it was in 1990. The SRES scenarios describe futures that generally are more affluent than today; many of the SRES scenarios assume a narrowing of income differences (in relative but not absolute terms) among world regions. This implies that

the third factor in the “I=PAT” identity, the unit impact per unit of affluence, will have a very important role in assessment of the global impact of human activities. Increasing population and affluence, if not accompanied by significant decreases in unit impact per unit of affluence, will make the challenge of promoting sustainable development even more difficult—particularly in developing countries, where most of the increase in population is projected to take place.

We have reached the point that the cumulative interaction of several factors related to human activities (e.g., land-use changes and emissions of GHGs, ozone-depleting substances, and local air pollutants) increases the risk of causing or aggravating potentially irreversible events, such as loss of species, forests, human settlements, glaciers, or heritage sites near coastlines and, in the long term, altered oceanic circulation regimes.

Although some regions may experience beneficial effects of climate change (e.g., increasing agricultural productivity at high latitudes), previous IPCC assessments have concluded that net negative climate impacts are more likely in most parts of the world (assessment of potential positive and negative impacts is one of the main purposes of this report; see Sections 2.5.6 and 2.6.4 and subsequent sections in this chapter for a discussion of uses of and problems with net monetary aggregation of impacts, and see Chapter 19 for a synthesis). These impacts will affect human welfare directly and indirectly, in many cases undercutting efforts to promote sustainable development that, in turn, serve as driving forces of environmental change.

Moreover, the time scales of change vary tremendously. For environmental systems, these time scales range from decades (for restoration of slightly disturbed ecosystems) to many centuries (for equilibration of the climate system and sea level), even with a stable level of atmospheric GHG concentrations. These environmental time scales imply that human activities in the short term will set in motion a chain of events with long-term consequences for the climate that cannot be reversed quickly, if at all.

For most human institutions, the time scales range from years for very short electoral cycles that determine the tenure of a government to a half-century or more for the useful lifetimes of buildings and major infrastructure such as irrigation projects, transportation networks, or energy supply systems. It may take a generation or more to effect significant changes to institutions. Because of these time scales, some decisions taken during the next few decades may limit the range of possible options in the future with respect to emissions reduction and adaptation, whereas other decisions may expand this range of options. During this period, many more insights into the effects and impacts of climatic changes will emerge. However, it is well established that uncertainties will remain, and efforts to manage risks in the face of considerable uncertainty will be a characteristic of climatic change assessments for decades more.

Working Group II’s contribution to the TAR focuses principally on the time horizon reaching from the present to the year

2100—which reflects the preponderance of studies on this time period in the literature and the high degree of uncertainty about the state of socioenvironmental systems beyond the 21st century. By 2100, most projections of human-induced climate change fall into ranges of about 1.4 to almost 5.8°C increase in annual global mean surface temperature (see Figure 5d in the TAR WGI Summary for Policymakers) compared to 1990 (although estimates that are outliers to both ends of even this large range can be found in the literature; Morgan and Keith, 1995) and about 10- to 90-cm rise in mean sea level (Figure 5e, TAR WGI Summary for Policymakers). By the time of doubling of CO₂-equivalent concentration, the global mean precipitation is projected to be about 1–5% higher than in 1990. These global numbers hide complex spatial patterns of changes (especially for temperature and precipitation), which are summarized in Chapter 3. In some regions, temperature increases are projected to be three times the global mean. In addition, high confidence is attached to “projected changes in extreme weather and climatic events” (e.g., see Table 1 in the TAR WGI Summary for Policymakers). Such changes, particularly at the higher ends of the ranges given, represent significant deviations from the climatic conditions of recent centuries. As noted above, warming of the climate and sea-level rise would continue for centuries beyond 2100, even if atmospheric concentrations of GHGs stabilize during the 21st century. For perspective, it should be noted that since the early Miocene (about 24 million years ago), atmospheric CO₂ concentrations appear to have remained below 500 ppmv (Pearson and Palmer, 2000). If human emissions of GHG until 2100 remain at or—as in many scenarios in the literature—increase well beyond current levels, CO₂ concentrations will be significantly above this value. It can therefore be remarked that climate changes in the 22nd century could exceed any experienced in more than 1 million years (see, e.g., Crowley, 1990; Crowley and North, 1991). Indeed, these authors estimate that global temperature was never significantly warmer than the present during the past 2 million years and that one would need to return to the early Pliocene (3–5 million years ago) or even the Miocene (5–25 million years ago) to find a climate that is warmer than today by more than 2°C. The potential impacts of these very large projected changes cannot be disregarded, even though it is difficult to imagine what human societies would look like in the 22nd century (see, e.g., Cline, 1992). However—reflecting the scarcity of studies of climatic impacts beyond 2100, despite their potential relevance to Article 2 of the UNFCCC—these impacts are not a major focus in the TAR (although Chapter 19 does focus on the possibilities of abrupt, nonlinear, and/or irreversible climatic changes in the centuries ahead).

1.2.1. Climatic Change Represents Opportunities and Risks for Human Development

Climate change is likely to present opportunities for some sectors and regions. For example, agriculture could expand into regions where it currently is limited by low temperatures, if adequate soils are present (see Chapter 5). Thinning of Arctic sea ice might allow surface navigation in areas that previously

were accessible only to submarines and icebreakers (see Chapter 16). The increase in winter temperature could decrease heating demand or mortality from cold spells (see Chapter 9). However, climate change also is likely to have numerous negative effects on human development and well-being. This is documented in Chapters 4–17 and reflected in the first sentence of the UNFCCC, which states that “changes in the Earth’s climate and its adverse effects are a common concern of humankind” (United Nations, 1992). The very existence of the UNFCCC demonstrates that the international community exhibits great concern for the risks that climatic change represents for human development and well-being, despite the potential opportunities it offers. Those risks are classified in Article 2 of the UNFCCC, which describes the Convention’s ultimate objective (preventing “dangerous anthropogenic interference with the climate system”). That article mentions the need “to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened, and to enable economic development to proceed in a sustainable manner.” Because a key function of the IPCC’s assessment reports is to help decisionmakers determine what constitutes “dangerous anthropogenic interference with the climate system” (as evidenced by approval at a 1999 IPCC Panel meeting of a series of Policy-Related Questions directed to the Synthesis Report authors; IPCC, 1999b), the discussion that follows is framed according to the aforementioned three categories of impacts.

1.2.1.1. Allow Ecosystems to Adapt Naturally to Climate Change

The speed and magnitude of climate change affect the success of species, population, and community adaptation. The rate of climatic warming may exceed the rate of shifts in certain species ranges; these species could be seriously affected or even disappear because they are unable to adapt (Chapter 5). Some plant and animal species (such as endangered species generally and species adapted to narrow niches for which habitat is discontinuous and barriers impede or block migration) and natural systems (such as coral reefs, mangroves, and other coastal wetlands; prairie wetlands; remnant native grasslands; montane ecosystems near ridges and mountaintops; and ecosystems overlying permafrost) could be adversely affected by regional climatic variations that correspond to a less than 1°C mean global warming by 2100. With mean warming of 1–2°C by 2100, some regional changes would be significant enough so that adverse impacts to some of these highly sensitive species and systems would become more severe and increase the risk of irreversible damage or loss, and additional species and systems would begin to be adversely impacted. Warming beyond 2°C would further compound the risks (note discussions and citations in Chapters 5 and 19).

1.2.1.2. Ensure that Food Production is not Threatened

Human production factors notwithstanding, food production is influenced mostly by the availability of water and nutrients, as

well as by temperature. Increases in temperature could open new areas to cultivation, but they also could increase the risk of heat or drought stress in other areas. Livestock (e.g., cattle, swine, and poultry) are all susceptible to heat stress and drought (Gates, 1993). The effects of climatic changes—even smooth trends—will not be uniform in space or time. For smoothly evolving climatic scenarios, recent literature (see Chapter 5) tends to project that high latitudes may experience increases in productivity for global warming up to a 1°C increase, depending on crop type, growing season, changes in temperature regimes, and seasonality of precipitation. In the tropics and subtropics—where some crops already are near their maximum temperature tolerance and where dryland, non-irrigated agriculture predominates—the literature suggests that yields will tend to decrease with even nominal amounts of climate change (IPCC, 1998; Chapter 5). Moreover, the adaptive capacity of less-developed countries in the tropics is limited by financial and technological constraints that are not equally applicable to more temperate, developed countries. This would increase the disparity in food production between developed and developing countries. For global warming greater than 2.5°C, Chapter 5 reports that most studies agree that world food prices—a key indicator of overall agricultural vulnerability—would increase. Much of the literature suggests that productivity increases in middle to high latitudes will diminish, and yield decreases in the tropics and subtropics are expected to be more severe (Chapters 5 and 19). These projections are likely to be underestimates, and our confidence in them cannot be high because they are based on scenarios in which significant changes in extreme events such as droughts and floods are not fully considered or for which rapid nonlinear climatic changes have not been assumed (Section 2.3.4 notes that vulnerability to extreme events generally is higher than vulnerability to changing mean conditions).

Water availability can be regarded as another component of food security. Water quantity and distribution depends to a large extent on rainfall and evaporation, which are both affected in a changing climate. Typically, estimated patterns of changes for 2100 under SRES scenarios include rainfall increases in high latitudes and some equatorial regions and decreases in many mid-latitude, subtropical, and semi-arid regions—which would increase water stress (the ratio between water usage and renewable flow) in the latter regions and decrease it in the former. As noted in Chapter 4, negative trends in water availability have the potential to induce conflict between different users (e.g., Kennedy *et al.*, 1998). For perspective, it should be remembered that the capability of current water supply systems and their ability to respond to changes in water demand determine to a large extent the severity of possible climate change impacts on water supply. Currently, 1.3 billion people do not have access to adequate supplies of safe water, and 2 billion people do not have access to adequate sanitation (Gleick, 1998; UNDP, 1999). In addition to changes in average water supply, climate extremes such as droughts and floods often are projected to become a larger problem in many temperate and humid regions (IPCC, 1998; Table SPM-1, WGII TAR Summary for Policymakers).

1.2.1.3. Enable Economic Development to Proceed in a Sustainable Manner

Sustainable development, as noted earlier, implies “meeting the needs of the present without compromising the ability of future generations to meet their own needs” (WCED, 1987). Besides food and water, essential needs include a space to live, good health, respite from extreme events, peace and basic freedom, energy and natural resources that allow development, and so forth. Each of these factors could be affected by climatic change. For example, if there were no significant adaptive responses, a 1-m sea-level rise would decrease the area of Bangladesh by 17.5% or that of the Majuro Atoll in the Marshall Islands by 80%. Human health impacts of global climatic change include changes in the geographic range and seasonality of various infectious diseases (with positive and negative impacts), increases in mortality and morbidity associated with heat waves, and effects on malnutrition and starvation in some regions as a result of redistribution of food and water resources (Chapter 9). The possibility of improved conditions in other regions remains, but, as noted in Chapter 5, the literature tends to project that positive effects in agriculture would be concentrated in high latitudes and negative effects in lower latitudes—precisely where problems of hunger already exist. The frequency and severity of extreme events such as heat waves, high rainfall intensity events, summer droughts, tropical cyclones, windstorms, storm surges, and possibly El Niño-like conditions are likely to increase in a warmer world (Table SPM-1, WGII TAR Summary for Policymakers), which would have a range of adverse impacts and would affect the conditions of development. Migration of populations affected by extreme events or average changes in the distribution of resources might increase the risks of political instabilities and conflicts (e.g., Myers, 1993; Kennedy *et al.*, 1998; Rahman, 1999). For each of these potential impacts, the relative vulnerability of different regions to adverse impacts of climatic change is largely determined by their access to resources, information, and technology and by the stability and effectiveness of their institutions. This means that possibilities to promote sustainable development will be affected more negatively by climatic change in developing countries and among less-privileged populations. Thus, climatic change could make satisfying the essential needs of these populations more difficult, in the short term and in the long term. In that sense, climatic change is likely to increase world and country-scale inequity, within the present generation and between present and future generations, particularly in developing countries. Given this potential vulnerability, steps to strengthen adaptive and mitigative (see TAR WGIII Chapter 1) capacity and to lessen nonclimatic stressors could well enhance sustainable development.

1.2.2. Human-Environment Systems: Implications for Development, Equity, and Sustainability

The TAR attempts to place the issue of climate change more centrally within the evolving socioeconomic context. This context is critical to evaluation of the vulnerability of sectors or regions

to climatic changes and thus must be borne in mind by anyone who attempts such assessments, as well as policymakers who will need to consider the wide range of implications of technological or organizational choices on the resilience of natural and social systems to climatic changes.

Development of social institutions and technological innovations over the past 10,000 years (the era of civilization after the glacial age when ice largely disappeared) has led to rapid advancement in material well-being but also, very importantly, population growth and resource pressures (e.g., Cohen, 1995; Meyer, 1996). This development process has accelerated and become much larger in scale in recent decades. Globally, growth in annual per capita income has been estimated to have risen from about 0.6% in the 19th-century period of industrial expansion to more than 2% yr⁻¹ in the post-World War II era of high technological innovation and global economic cooperation (Cooper, 2000). Some analysts attribute this boom to the combination of stabilization of national economies by governmental management and liberalization of trade allowed by international organizations. Indeed, in this vision—which has been labeled the “cornucopian world view” (Ehrlich and Ehrlich, 1996)—a competitive system that fosters and rewards innovation has led to a prolonged period of development and growth that will increasingly embrace currently less-developed nations as well. Furthermore, according to Kates (1996), it is possible to achieve a world without famine, with little seasonal or chronic undernutrition and virtually no nutrient deficiencies or nutrition-related illnesses. In the area of energy and natural resources, according to von Weizsäcker *et al.* (1998), it is possible to increase resource productivity by a factor of four: The world would then enjoy twice the wealth that is currently available, simultaneously halving the stress placed on our natural environment.

However, this level of development continues to be an elusive goal for a large fraction of the world’s population. There is a noticeable disparity between the levels of development that have been achieved in various societies. These differences are obscured by globally averaged income growth data such as those reported by Cooper (2000). For example, gaps between the rich and the poor are widening between developed and developing countries and within tropical African, Asian, and Latin American countries (UNDP, 1999). Although there have been notable successes, many countries in these regions have experienced increases in economic instability, social insecurity, environmental degradation, and endemic poverty. Despite spectacular gains in the means of development—such as advances in science, technology, and medicine during the past century—development planning at national and global levels has not always alleviated poverty and inequity (see Box 1-2; Munasinghe, 2000).

Global food security clearly has improved in recent years as the focus of famine has shifted from large, heavily populated countries to sparsely populated and small nations, but the number of people at risk of hunger still is very high, even in parts of heavily populated nations. Chen and Kates (1996) estimate that the population at risk of outright starvation could

be as high as 35 million; FAO (1999) estimates that about 800 million people in developing countries and 34 million people in developed countries suffer from undernourishment. Achieving global food security is complicated by growth in human population and political instability that disrupts food delivery systems. Projections vary widely, ranging from stabilization of population at near-present levels sometime in the 21st century to a greater than three-fold increase by the end of the century (e.g., Fischer *et al.*, 1996; Lutz, 1996; IPCC, 2000). At current population growth rates, world food production must double within the next 40 years to feed this population; such a doubling of food production may require expansion of agricultural land into forests and areas that presently are considered marginal for agriculture (but not necessarily marginal in other respects). On the other hand, some authors (e.g., Waggoner *et al.*, 1996) have argued it is possible to increase the dietary standard of all humans up to a doubling of current populations and at the same time to "spare land for nature" (Ausubel, 1996). This expansive vision follows from the belief that resources can be made available for the extension of current intensive agricultural practices to currently low-technology regions. The extent to which such practices can be extended is debated, on social and environmental grounds, by those who hold an opposing worldview, which has been called "limits to growth" (e.g., Ehrlich *et al.*, 1995). Moreover, even if such agricultural intensification were to occur, there is no guarantee that extensive land use for economic development activities other than growing food would not simultaneously occur. Thus, the hope of "sparing land for nature" via intensification likewise is a controversial vision.

The need to improve productivity per unit area has led to more intensive methods in developing countries—which, together with low or negative economic support for agricultural products, often has driven smallholders off their land and led to emigration to urban centers (WCED, 1987). The influx of poor, unskilled, and often unemployable people has led to explosive and difficult-to-manage growth in these centers (O'Meara, 1999). This sets the stage for the gestation of a new set of environmental problems, including substandard housing, squatter settlements, solid waste buildups, unsatisfactory sewage disposal, urban floods, and urban water pollution, as well as the characteristic problems of large cities such as crime and social insecurity.

In opposition to the aforementioned expansive visions, others (e.g., Daily, 1997) express concern that services provided by ecosystems to society may be undermined by a combination of unsustainable population growth, destruction of natural habitats, and pollution of air, soils, and waters. Three decades ago, debate raged about whether indefinite economic expansion would be limited by environmental and other resource constraints. Meadows *et al.* (1972) postulated in a controversial work that environmental protection and economic growth are not compatible; there are "limits to growth." For those holding this worldview, current development patterns will not allow continued improvement of the human condition for much longer; instead, such development will ensure continuing degradation of natural assets such as biodiversity (e.g., Pimm, 1991). Thus, it is feared that the environment may be losing part

of its capacity to support life and therefore may be imposing another set of constraints on the development process—disturbances to air, waters, soils, and species distributions brought about by human activities—that will require responses to reduce additional risks. Several sharp critiques appeared (e.g., Cole *et al.*, 1973), noting that the "limits" paradigm ignored enhanced productivity brought about by innovation and that although limits eventually might become a problem, increased knowledge generated by economic expansion could create substitutes for resources that were being used nonrenewably, and much less energy and materials would be needed to produce economic growth as technology blossomed (e.g., Grossman and Krueger, 1995; but see Myers and Simon, 1994). Moreover, it has been argued that enhanced wealth and knowledge also can reduce vulnerability to environmental stresses such as climatic change.

Subsequently, a modified view that considered both the "cornucopian" and "limits" paradigms emerged: the strategy of sustainable development. It is designed to promote conservation of resources and protection of the environment while sustaining a healthy society whose needs are securely provided. In response to requests from governments participating in the IPCC process, the TAR is attentive to the concept of sustainable development.

Technology and organization clearly have reduced the vulnerability of humans in some countries to a variety of hazards. In the context of the IPCC process, this would include, for example, flood control engineering projects that have reduced lives lost in catastrophic flooding. However, pioneering analyses in the natural hazards literature (e.g., Burton *et al.*, 1993) note that large-scale dependence of massive populations on the functioning of giant engineering projects or social institutions often has simply transformed our risks from the predevelopment state of high-frequency, low-amplitude risk (many localized threats to small numbers of people in each instance) to the present state of low-frequency, high-amplitude vulnerability (where a rare levee failure or the simultaneous occurrence of drought in several major exporting granaries poses the risk of infrequent but very catastrophic losses). Moreover, the consequences of these risks are unlikely to be equitably distributed within and across income groups and nations, which requires assessment of the distributional implications of developmental risks and benefits (e.g., Box 1-2). In many developing regions, population pressures and poverty have led to occupation of hazardous lands (e.g., steep slopes, valley bottoms) and has greatly increased vulnerability to climate extremes. Of course, many factors other than those mentioned above can contribute to vulnerability (e.g., Etkin, 1999).

In addition to this huge list of challenges, potential threats to the global environment are connected to the development process. The TAR identifies scientific and policy linkages among key global environmental issues, one of which is climate change. Other global environmental issues include loss of biological diversity, stratospheric ozone depletion, marine environment and resource degradation, and persistent organic

pollutants (Watson *et al.*, 1998). Other contemporary issues are evident in many places across the globe—though each instance is not global in scale (e.g., Turner *et al.*, 1990)—such as freshwater degradation, desertification, land degradation, deforestation, and unsustainable use of forest resources. None of these threats implies that the *net* effects of human developments are necessarily negative, only that embedded in many development activities are a host of negative aspects that many analysts and policymakers believe must be considered in development planning. Strategies to modify the amount and/or kinds of development activities to account for these threats are considered more comprehensively in the report of Working Group III. The TAR also focuses on linkages between climate change on one hand and local and regional environmental issues—for example, urban air pollution and regional acid deposition—on the other. (Strategies to deal with these issues that also help with adaptive or mitigative capacity for climate change often are called co-benefits.) Among the new areas of emphasis in the TAR are linkages between global environmental issues and the challenges of meeting key human needs such as adequate food, clean water, clean air, and adequate and affordable energy services.

1.3. How has Society Responded?

1.3.1. International Responses

A primary response to concerns about climate change has been *international* action to address the issue, particularly through the UNFCCC. International action to date has focused mainly on mitigation, although adaptation is mentioned in UNFCCC Article 4.1 (e) and in funding by the Global Environment Facility (GEF) of adaptation studies (e.g., the Caribbean Planning for Adaptation to Climate Change program). Multinational action is required because no single country or small group of countries can reduce emissions sufficiently to stop GHG concentrations from continuing to grow and because wherever emissions originate, they affect climate globally. Because the extent and urgency of action required to mitigate emissions depends on our vulnerability, a key question is the degree to which human society and the natural environment are vulnerable to the potential effects of climate change.

At the first meeting of the Conference of Parties to the UNFCCC in 1995, governments reviewed the adequacy of existing international commitments to achieve this goal and decided that additional commitments were required. They established the Ad Hoc Group on the Berlin Mandate (AGBM, 1995) to identify appropriate actions for the period beyond 2000, including strengthening of commitments through adoption of a protocol or another legal instrument. The AGBM process culminated in adoption of the Kyoto Protocol in December 1997 (United Nations, 1997). In the Kyoto Protocol, industrialized countries (Annex I Parties to the UNFCCC) agreed to reduce their overall emissions of six GHGs by an average of 5% below 1990 levels between 2008 and 2012. The Protocol also allowed the Parties to account for the removal of GHGs by sinks resulting from direct, human-induced land-use change and forestry activities,

emissions trading, “joint implementation” (JI) between developed countries, and a “clean development mechanism” (CDM) to encourage joint emissions reduction projects between developed and developing countries and a commitment to provide assistance in meeting the costs of adaptation for countries deemed most vulnerable to the adverse effects of climate change using the proceeds of the CDM (Article 12). To date, the Kyoto Protocol has not entered into force. The UNFCCC also established national reporting requirements for all Parties regarding their emissions and their potential vulnerabilities/adaptation options. These reporting obligations are being fulfilled through preparation of National Communications to the UNFCCC.

The foundation for any policy to address the climate change problem is information on GHG emissions, the climate system and how it may change, likely impacts on human activities and the environment, and the costs and co-benefits (e.g., protecting primary forests not only retains stored carbon in the trees but also confers the “co-benefit” of biodiversity protection; Kremen *et al.*, 2000) of taking steps to reduce GHG emissions or to change land use. To provide the best available scientific information for policymakers and the public, governments established the IPCC to periodically assess and summarize the state of knowledge in the literature related to climate change. The IPCC completed comprehensive assessments in 1990 and 1995 of the effects of human activities on the climate system, potential consequences of climate for natural and human systems, and the effectiveness and costs of response options (IPCC, 1990, 1996a,b,c). In addition, the IPCC has prepared numerous special reports, technical papers, and methodologies on topics ranging from radiative forcing of climate to technologies, policies, and measures for emissions mitigation. As knowledge has progressed, IPCC assessments have added a regional focus by assessing regional climate modeling and regional sensitivities and adaptive capacity.

Other international bodies also are taking up the challenge of climate change. These organizations include the World Bank, the United Nations Environment Programme (UNEP), the UN Development Programme (UNDP), and the GEF, as well as a variety of regional institutions. Although a primary audience for this report is those who are involved in negotiating and implementing the UNFCCC and, to some extent, other international agreements on global environmental problems, the report also contains information that is useful to other international institutions. The report has been designed to be useful in assessing potential projects and opportunities for investment that will be robust to potential negative effects and to emerging opportunities from climate change.

1.3.2. National and Local Governmental Responses

Governments have initiated a spectrum of responses, ranging from international assessments of climate science, impacts, and abatement strategies (the United States, for example) to implementation of a legally binding mitigation policy (Sweden, for example, has implemented a domestic carbon tax on direct

fuel use and on fuel use in the transportation sector; see also OECD, 1999). Governments also have produced country studies, vulnerability assessments of sea-level rise, and national communications; carried out GHG reductions in other countries; and created research opportunities and fora for exchanges of ideas and data. Such management of climate-related research and educational activities has accelerated in the wake of climatic assessment that suggested a discernible human influence on climate (IPCC, 1996a). Similarly, many countries have implemented policies for reasons unrelated to climate change that nevertheless have led to reductions of GHG emissions (e.g., the ethanol program in Brazil, support to renewable energy and energy efficiency in a large number of countries). With regard to adaptation, the first National Communications to UNFCCC from most countries contained analyses of vulnerability and adaptation options.

At the local level, dozens of cities—mainly in industrialized countries—have adopted GHG emission reduction targets and have taken measures to implement them, mostly in the energy and transport sector. In many cases, these policies have been defined by coupling climate protection objectives with other, more local objectives: co-benefits such as reducing air pollution, traffic congestion, or waste production. Some measures, such as water conservation, are adaptive (more resilient to drought) and reduce emissions (less energy for pumping). The use of “social” policy instruments such as public awareness campaigns, information, and technical assistance is commonplace (OECD, 1999). With regard to adaptation, for example, the Federation of Canadian Municipalities is promoting adaptation as well as mitigation measures.

Many countries have developed national climate strategies that are based on a diverse range of policy instruments such as economic instruments, regulation, research and development, and public awareness and information. Energy efficiency, fuel switching, public transportation, and renewable energies typically are promoted. The government sector itself is an increasingly common target for GHG mitigation, and “greening” of government purchasing policies has started to take place in some countries (OECD, 1999).

Overall, these policies and measures to date have had limited effect on emissions, probably because of their lack of integration in a truly global, long-term framework, as well as continued economic growth around the world (AGBM, 1995).

1.3.3. *Organizational Responses*

Numerous private businesses have developed plans to facilitate trading of permits for carbon emissions or have set up schemes to help manage CDM transactions if the Kyoto Protocol is ratified or some other instrument of carbon policy is put in place by some nations. Moreover, large multinational corporations such as Shell International and BP Amoco have declared that they will voluntarily observe elements of the Kyoto Protocol (van der Veer, 1999; Browne, 2000).

International scientific organizations have responded to the prospect of climate changes for more than 2 decades, from the second objective of the Global Atmospheric Research Program (GARP) to a series of World Climate Conferences sponsored by the World Meteorological Organization and UNEP. The International Council of Scientific Unions and dozens of national scientific societies have responded by creating journals to publish the results of climatic assessments, organizing many meetings and symposia to further our understanding of climate-related scientific issues, and creating committees to help steer research in promising directions.

Similarly, environmental nongovernmental organizations (NGOs) around the world have initiated climate campaigns with the aim of convincing citizens and governments to strengthen the Kyoto Protocol. Meanwhile, direct advertisements have appeared in the media—primarily sponsored by organizations that are attempting to influence public opinion to oppose the Kyoto Protocol.

1.3.4. *Adaptive Responses*

Natural and human systems have adapted to spatial differences in climate. There also are examples of adaptation (with varying degrees of success) to temporal variations—notably, deviations from annual average conditions. Many social and economic systems—including agriculture, forestry, settlements, industry, transportation, human health, and water resource management—have evolved to accommodate some deviations from “normal” conditions, but rarely the extremes.

Adaptations come in a huge variety of forms. Autonomous adaptations invariably take place in reactive response (after initial impacts are manifest) to climatic stimuli as a matter of course, without directed intervention by a public agency. The extent to which society can rely on autonomous, private, or market adaptation to reduce the costs of climate change impacts to an acceptable or nondangerous level is an issue of great interest. There is little evidence to date that efficient and effective adaptations to climate change risks will be undertaken autonomously (see Chapter 18).

Planned adaptations can be reactive or anticipatory (undertaken before impacts are apparent). Potential adaptations include sharing losses, modifying threats, preventing or decreasing effects, changing use, and changing location. There are many lists of adaptation measures, initiatives, or strategies that have potential to moderate impacts, if they were implemented. Such lists indicate the range of strategies and measures that represent possible adaptations to climate change risks in particular sectors and regions. Only in a few cases have such lists of potential adaptations considered who might undertake them, under what conditions might they be implemented, and how effective might they be.

Knowledge of processes by which individuals or communities actually adapt to changes in conditions over time comes largely

from analog and other empirical analyses. These studies indicate that autonomous adaptations tend to be incremental and ad hoc, take multiple forms, occur in response to multiple stimuli (usually involving a particular catalyst, rarely climate alone), and are constrained by economic, social, technological, institutional, and political conditions.

Although an impressive variety of adaptation initiatives have been undertaken across sectors and regions, responses are not universally or equally available. Adaptation options generally occur in socioeconomic sectors and systems in which turnover of capital investment and operating costs is shorter, and less often where long-term investment is required. Examples include purchase of more efficient irrigation equipment by individual farmers in anticipation of increased evapotranspiration in a warmer climate, design of bridges or dams to account for an expected increase in sea level or extremes of drought and flood, purchase of insurance, abandonment of insurance coverage to people living in high-risk areas such as coastlines, and creation of migration corridors for species expected to be forced to migrate with climate change.

Often more than one adaptation option is available. People rarely seem to choose the best responses—those among available options that would most effectively reduce losses—often because of an established preference for, or aversion to, certain options. In some cases, there is limited knowledge of risks or alternative adaptation strategies. In other cases, adoption of adaptive measures is constrained by other priorities, limited resources, or economic or institutional barriers. Recurrent vulnerabilities, in many cases with increasing damages, illustrate less than perfect adaptation of systems to climatic variations and risks. Chapter 18 describes some evidence that the costs of adaptations to climate conditions are growing.

Current adaptation strategies with clear applications to climate change in agriculture include moisture-conserving practices, hybrid selection, and crop substitution. In the water resources sector, current management practices often represent useful adaptive strategies for climate change. Some analysts go further to point out that certain adaptations to climate change not only address current hazards but may be additionally beneficial for other reasons. Such evaluations are further complicated by the existence of secondary impacts, related to the adaptation itself. For example, water development projects (adaptations to water supply risks) can have significant effects on local transmission of parasitic diseases. Improved water supply in some rural areas of Asia has resulted in a dramatic increase in Aedes mosquito breeding sites and, consequently, outbreaks of dengue (Section 18.4.4).

1.4. How are Impacts, Adaptation, and Vulnerability Assessed in this Report?

An important new category of issues on climatic impacts pertains to methodological advances; Chapter 2 provides more details. These advances include methods for assessing impacts and

vulnerability, methods for detecting biotic response to climate change in natural ecological systems by using indicator species, and detection and attribution of observed changes in environmental systems to climatic changes, as distinct from other possible causal factors (Chapter 5). Other new methods relate to costing and valuation, decision analytic techniques and frameworks, uncertainties assessment, and consistent characterization of levels of confidence that could be attached to observations or conclusions (see Box 1-2 and Chapter 2). All of these developments extend methodological considerations beyond those typically employed in the SAR. Development and application of regional-scale scenarios to climate change impacts, adaptations, and vulnerability (as described in Chapter 3) represent a new emphasis of a technique that was limited in the SAR to the science of climate change. The directive in the IPCC's charge to Working Group II to emphasize regional issues is reflected in the eight regional chapters (Chapters 10–17). This directive calls for utilization of new advances in knowledge, including integrated methods, to assess the most cost-effective approaches to adapt to changes in climate at the regional level. This section elaborates briefly on several issues that are related to assessment of impacts, vulnerability, and adaptation and illustrates several of the foregoing methodological considerations.

1.4.1. Sensitivity, Adaptability, and Vulnerability

This report assesses recent advances in our understanding of the vulnerability of major sectors, systems, and regions to climate change. Consistent with common usage and definitions in the SAR, *vulnerability* is defined as the extent to which a natural or social system is susceptible to sustaining damage from climate change. Vulnerability is a function of the *sensitivity* of a system to changes in climate (the degree to which a system will respond to a given change in climate, including beneficial and harmful effects), *adaptive capacity* (the degree to which adjustments in practices, processes, or structures can moderate or offset the potential for damage or take advantage of opportunities created by a given change in climate), and the degree of *exposure* of the system to climatic hazards (Figure 1-2). Under this framework, a highly vulnerable system would be a system that is very sensitive to modest changes in climate, where the sensitivity includes the potential for substantial harmful effects, and for which the ability to adapt is severely constrained. *Resilience* is the flip side of vulnerability—a resilient system or population is not sensitive to climate variability and change and has the capacity to adapt.

Adaptation is recognized as a crucial response because even if current agreements to limit emissions are implemented, they will not stabilize atmospheric concentrations of GHG emissions and climate (Wigley, 1998). Hence, adaptation is considered here, along with mitigation—the more widely considered response to climate change—as a key component of an integrated and balanced response to climate variability and change (MacIver, 1998). Adaptations, which can be autonomous or policy-driven, are adjustments in practices, processes, or structures to take

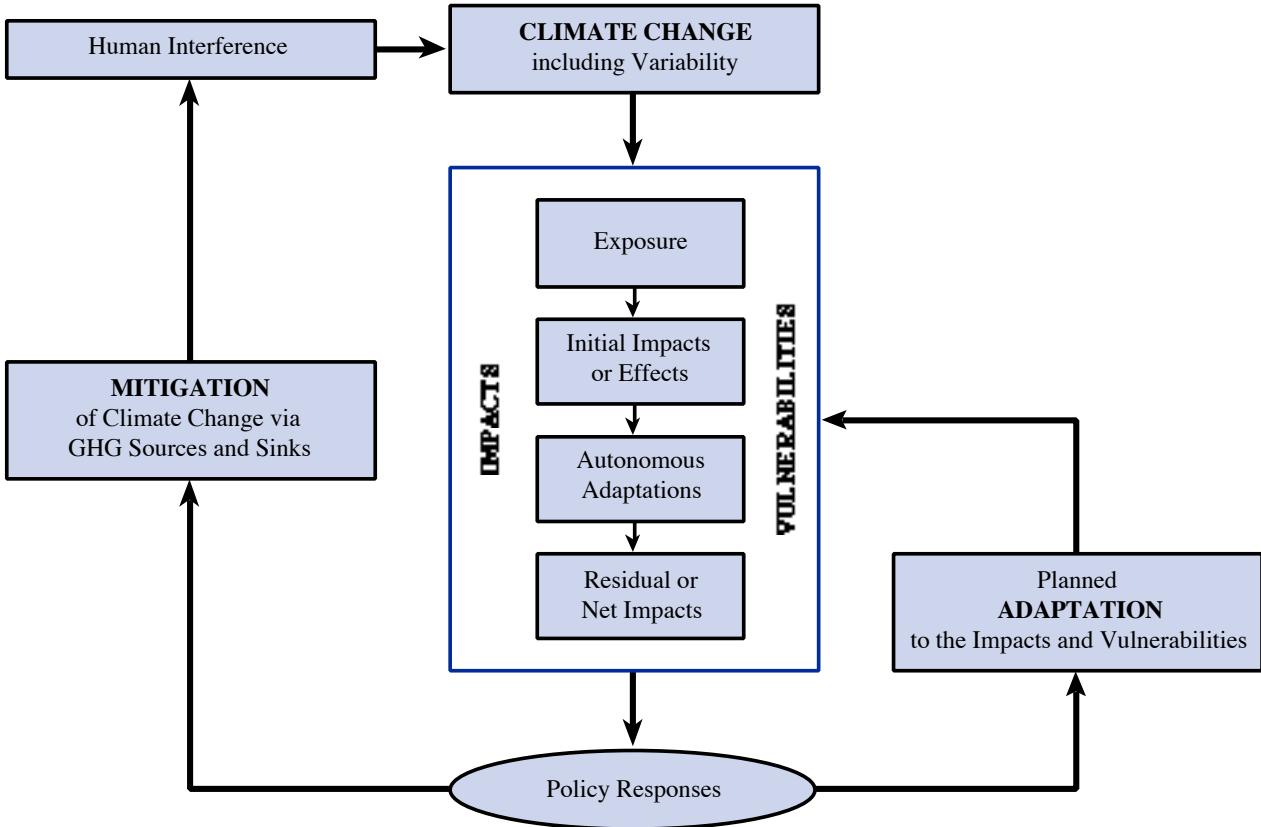

Figure 1-2: Places of adaptation in the climate change issue (Smit *et al.*, 1999).

account of changing climate conditions. Impacts, however, sometimes are difficult to identify, let alone quantify, in part because of the nonlinear nature of climate change itself. Impacts can be subtle but nonetheless significant, and their consequences can differ for different members of the same community—as when some individuals or groups perceive an opportunity with change and others experience a loss, thereby changing community dynamics and complicating decisions about how to adapt and the apportionment of costs of adaptation. Negative impacts often are observed as chance occurrences (surprises) beyond critical values (thresholds) of accustomed weather parameters. They can be conceived as risks or the “probability of occurrence of a damaging event,” such as flood, drought, strong winds, heat wave, subfreezing temperatures, or forest or bush fire. “The extent to which natural ecosystems, global food supplies and sustainable development are in danger depends partly on the nature of climate change and partly on the ability of the impacted systems to adapt” to these events (Smit *et al.*, 1999).

The capacity of a sector or region to adapt to climatic changes depends on several factors (see Figure 1-2 and Chapter 18). The literature emphasizes that studies that neglect adaptive potential are likely to overestimate the costs of climatic impacts (e.g., Reilly *et al.*, 1996). However, more recent literature also notes that maladaptations are possible—particularly when

information about future climatic and other conditions is much less than perfect—as a response to an incorrect perception of such changes, often driven by a masking of slowly evolving trends by large natural variability or extreme events (West and Dowlatabadi, 1999; Schneider *et al.*, 2000a; West *et al.*, 2001). Maladaptations can increase the costs of impacts relative to those when adaptive agents have perfect foresight or when adaptive responses are absent. On the other hand, appropriate adaptations can reduce negative impacts or take advantage of new opportunities presented by changing climate conditions. The SAR assessed technical options for adaptation but did not evaluate the feasibility of these options for different regions and circumstances because little information was available in the literature. The *Special Report on Regional Impacts of Climate Change* focuses to a greater extent on the regional dimensions of adaptation; because the report is based largely on the SAR, as well as early and preliminary results from country studies and national communications to the UNFCCC, however, many questions about the capacities required to implement theoretically promising adaptation options remain. Hence, in this report, greater attention has been focused on societal determinants of adaptive capacity and vulnerability. To the extent possible, the report seeks to examine information in the literature on the interaction of these factors to develop options for bolstering adaptive capacity.

Previous IPCC assessments conclude that most systems are sensitive to the magnitude and the rate of climate change. Sensitive systems include, for example, aspects of food and fiber production, water resources, ecosystems of all types, coastal systems, human settlements, and human health. This sensitivity includes adverse effects in many regions, as well as potentially beneficial effects in some regions and sectors (high confidence). Social systems generally are more resilient than natural systems because of the potential for deliberate adaptation (high confidence). However, confidence in most specific aggregate estimates of impacts remains low because of uncertainties and complexities of analysis (as detailed further in succeeding sections).

For systems that already are exposed to increasing resource demands, unsustainable management, and pollution, exposure to climate change is an important additional pressure. Systems that are exposed to multiple pressures (synergistic effects) usually are more vulnerable to climate change than systems that are not (high confidence).

1.4.2. Detection and Attribution of Impacts to Climate Change

Many observed changes in ecosystems, animal (e.g., butterfly and bird patterns) and plant (e.g., timing of flowering) species, and physical systems (e.g., glaciers or river runoff) have been associated with observed changes in climate (not necessarily anthropogenic changes) in recent decades (high confidence). Moreover, as described in Chapters 5 and 19, such observed changes often are in the directions expected as a response to climate stimuli, based on understandings expressed in the literature about biophysical processes that govern responses to climate (e.g., Root and Schneider, 2001; Root *et al.*, 2001). This consistency has led the authors of such studies to conclude that surface temperature trends of recent decades are likely to be discernible at regional scales through observed changes in biological and physical entities for several systems (varying confidence, depending on which specific system is considered; see, e.g., Chapters 5 and 19). From these observed responses to the relatively small climate changes observed to date (as compared to changes projected for the next century), it is concluded that many environmental systems can be highly sensitive to climate change. However, determination of a potential causal relationship between the response of a physical or biological system to observed recent climatic changes does not imply that regional climate changes were a direct result of anthropogenic global climatic trends, although the latter are likely to have had significant influence on many regional trends. Working Group II does not focus on evaluating the likelihood that regional observed climatic variations are caused by anthropogenic climate changes; detection and attribution assessment of climatic changes is primarily a Working Group I activity. As noted, however, Working Group II does address attribution of observed changes to environmental systems to observed climate changes, even if the connection to possible anthropogenic climate changes is not specifically addressed here.

1.4.3. Key Determinants of Impacts

1.4.3.1. Magnitude of Change

Early studies concentrated on impacts caused by changes in global mean temperature. Often these studies were carried out at a few elevated temperatures—typically, 2°C and 4°C (corresponding to the bulk of the range of IPCC Working Group I SAR equilibrium temperature rise expected for a doubling of CO₂ concentration above pre-industrial levels). Global mean temperature still is a significant variable, serving as a modulus of change against which to compare climate sensitivities and impacts. In addition to mean quantities, however, other characteristics of climate measures, such as climate variability or runs of unusually warm weather, have become important variables for analysis (e.g., Mearns *et al.*, 1984; Colombo *et al.*, 1999), as has specification of changes in regional temperatures, sea level, and precipitation. These expanded measures of climatic change are routinely included in recent impact studies (e.g., IPCC, 1998). Less often considered are changes in extreme events (but see Table SPM-1, WGII TAR Summary for Policymakers), despite their potential importance.

1.4.3.2. Rate of Change

It is essentially undisputed that a sustained 2°C temperature change occurring in a decade would have a more profound impact than one occurring over a century. The effect of rates of change on impacts is still under active investigation (see Chapter 19). Early results have suggested that rates of change exceeding the ability of ecosystems to migrate would be particularly damaging (see Chapter 5). Adaptation of coastal dwellers to rapid climatic changes or a high background “noise level” of natural variability would be more difficult relative to slowly occurring changes or smoothly varying climates (e.g., West *et al.*, 2001). Finally, as noted by IPCC Working Group I (1996a, p. 7), “nonlinear systems, when rapidly forced, are particularly subject to unexpected behavior.” In other words, the adaptability of various decision agents would be reduced if any change is unexpected; thus, a rapid rate of change is more likely to generate “surprises” that inhibit effective adaptation by natural and managed systems. Table 1-1 describes several extreme events that can substantially influence the vulnerability of sectors or regions to climatic changes (see also Table SPM-1, WGII TAR Summary for Policymakers).

Economists also have suggested that the transient stage of moving from one equilibrium climate to another could cause the greatest economic impacts, even if the static impacts of the new equilibrium climate were small (Nordhaus and Boyer, 2000).

1.4.3.3. Transient Scenarios

Climate sensitivity—the globally averaged response of the surface temperature to a fixed doubling of CO₂—is based on static or equilibrium calculations in which the climatic model

Table 1-1: Typology of climate extremes.

Type	Description	Examples of Events	Typical Method of Characterization ^a
Simple extremes	Individual local weather variables exceeding critical level on a continuous scale	Heavy rainfall, high/low temperature, high wind speed	Frequency/return period, sequence and/or duration of variable exceeding a critical level
Complex extremes	Severe weather associated with particular climatic phenomena, often requiring a critical combination of variables	Tropical cyclones, droughts, ice storms, ENSO-related events	Frequency/return period, magnitude, duration of variable(s) exceeding a critical level, severity of impacts
Unique or singular phenomena	A plausible future climatic state with potentially extreme large-scale or global outcomes	Collapse of major ice sheets, cessation of thermohaline circulation, major circulation changes	Probability of occurrence and magnitude of impact

^a Stakeholders also can be engaged to define extreme circumstances via thresholds that mark a critical level of impact for the purposes of risk assessment. Such critical levels often are locally specific, so they may differ between regions.

is allowed to reach a steady state after the CO₂ increase is applied. The real Earth, on the other hand, is being forced by a time-evolving forcing of GHGs and other global change forcings; this, combined with the time-evolving response of the climate system to any forcing, means that the amount of global climatic warming, as well as the time-evolving patterns of climatic changes, are likely to be different during the transient phase of climatic change than in equilibrium. Recent studies of climate change impacts have made use of transient or time-dependent scenarios of climate change that are derived from fully coupled, ocean-atmosphere general circulation models (AOGCMs). These studies indicate that many systems would be notably affected (see Chapter 19)—some adversely and some beneficially—by changes in climate within the next 2 to 3 decades (high confidence). Farther into the 21st century, as radiative forcing on the climate builds, the magnitude of adverse impacts would increase, the number and scale of many beneficial effects would decrease (Chapter 19), and the probability that adverse impacts would predominate would increase (high confidence). Transient scenarios are just entering the climate impacts literature, which unfortunately tends to lag the climate effects literature by several years; thus, much of the impacts literature still is based on equilibrium climate change scenarios. To the extent possible, Working Group II has assessed literature that uses transient scenarios. It is important to use transient scenarios as much as possible because the climate effects literature suggests that static calculations (typically, CO₂ held fixed at double pre-industrial concentrations) do not produce the same time-evolving regional patterns of climatic changes as do transients—and because, of course, the actual Earth is undergoing a transient response to anthropogenic forcings.

1.4.3.4. Climate Variability and Extreme Events

Most studies of climate change impacts have focused on changes in mean climate conditions. However, global climate change is

likely to bring changes in climate variability and extreme events as well. This is relevant here because decisionmakers often consider hedging strategies to be prepared for the possibility of low-probability but high-consequence events—a risk management framework. Features of projected changes in extreme weather and climate events in the 21st century include more frequent heat waves, less frequent cold spells (barring so-called singular events), greater intensity of heavy rainfall events, more frequent midcontinental summer drought, greater intensity of tropical cyclones, and more intense El Niño-Southern Oscillation (ENSO) events (Table SPM-1, WGII TAR Summary for Policymakers).

A small number of studies have investigated the potential impacts of hypothesized changes in climate variability and/or extreme events. Results of these studies, coupled with observations of impacts from historical events (e.g., Chapter 8), suggest that changes in climate variability and extremes are likely to be at least as important as changes in mean climate conditions in determining climate change impacts and vulnerability (high confidence). The literature suggests that omission of changes in extreme events and/or climate variability will yield underestimates of climate change impacts and vulnerability. In its assessment of potential vulnerabilities and adaptation options, Working Group II has focused on the interactions of natural climate variability and anthropogenic change and the potential for “win-win” adaptation options that would increase resilience to both phenomena.

1.4.3.5. Thresholds

In many environmental fields, there are thought to be thresholds below which only minor effects occur. Critical levels in acid rain are one example (Brodin and Kuylenstierna, 1992). These kinds of thresholds also are possible in climate change and are incorporated into some models as “tolerable” levels that must

be exceeded before significant impacts occur (Hope *et al.*, 1993).

However, in climate change, thresholds have been proposed that are much more complicated. Below the threshold, there may be some impacts, but they will be smoothly varying with the change in climate. Some positive effects might even be observed in some regions or sectors for a small global warming, giving the impression that there is little impact. Above the threshold, however, potentially damaging events may occur. For example, most models show (by 2100) a weakening of thermohaline circulation that transports warmer water to the North Atlantic (see TAR WGI Summary for Policymakers) but only very low confidence that there will be full collapse of the thermohaline circulation by 2100—although some rapid greenhouse buildup scenarios suggest that emissions during the 21st century could trigger a collapse in the following century (e.g., Rahmstorf, 1999; Schneider and Thompson, 2000). Likewise, only very low confidence is given to the prospect of substantial collapse by 2100 of the West Antarctic Ice Sheet (TAR WGI Summary for Policymakers). Other examples of potential threshold phenomena can be found in the literature for regional situations. For example, Wang and Eltahir (2000) demonstrate that rainfall in the Sahel region of Africa can have several equilibrium values, depending on the level of disturbance to vegetation cover. For vegetation removal of less than a threshold value, the system recovers within a few years. For vegetation removal above a threshold, however, there is a new steady-state rainfall regime that is much reduced from “normal” conditions. These thresholds may be, as characterized previously, a result of rapid transient forcing of the climate system, in terms of altered radiative properties of the atmosphere or characteristics of the land surface. Although such threshold events remain somewhat speculative, their impacts clearly would be more severe than smoothly varying (and thus more adaptable) events. Some thresholds in impacts, however, are much less speculative, such as hospital admissions for heat conditions above a threshold temperature—and these threshold temperatures vary regionally as there is some acclimatization to heat stress (Chapter 9)—or species living near mountaintops that would be forced out of existence, even by smooth climatic warming, because they reached the threshold of having no place to move up into (e.g., Still *et al.*, 1999).

Sometimes the expression “threshold” is used as an approximation when the response actually is more likely to be smooth but strongly nonlinear. The release of methane from gas hydrates trapped in deep sediments and the health impacts of thermal stress would be examples of this category. Working Group II assesses potential thresholds for ecological and human systems.

1.4.3.6. Surprises

By definition, it is difficult to give examples of the surprises that might be created under a changed climate. Such surprises, however, can make even the most careful calculation of impacts extremely inaccurate, as noted previously. Surprises have been

classified by many authors in many contexts (see Schneider *et al.*, 1998, for a review of the literature and many citations). In particular, low-probability events—or those whose probability is difficult to assess—often are labeled rhetorically as “surprises,” even though the event has been classified or identified as known. Strictly speaking, such events are more accurately called “imaginable surprises;” true surprises are wholly unexpected events. Another useful category is “imaginable conditions for surprise” (Schneider *et al.*, 1998), where the specific event in question is unexpected but a set of conditions that increases the likelihood of surprises can be assessed; increasing the rate of forcing of the climatic system is one example, as noted in Section 1.4.3.2.

1.4.3.7. Nonlinear, Complex, and Discontinuous Responses

Investigations into climate change and its potential consequences have begun to highlight the importance of strongly nonlinear, complex, and discontinuous responses. These types of responses, called singularities, can occur at all temporal and spatial scales of systems influenced by climate change (high confidence can be given to the likelihood that some such singularities will occur, but low confidence usually is assigned to any specific example of a possible abrupt event; see Chapter 19). Strongly nonlinear responses are characterized by thresholds—which, if exceeded by a stimulus, result in substantially greater sensitivity to further stimulus or dramatic change, explosive growth, or collapse. Complex responses involve interactions of many intricate elements that yield outcomes that are not easily predicted. Examples of these types of responses include coral bleaching, collapse of fish stocks, disease outbreaks, changes in fire and other disturbance regimes in vegetation systems, crop failure, malnutrition and hunger, and collapse of pastoral communities. Advances in our understanding of these types of responses are largely qualitative, but they are important in understanding the character of dangers posed by climate change. Omission of potential nonlinear and complex responses from climate change impact assessments is expected (well-established, but incomplete) to yield underestimates of impacts (see Chapters 5 and 19). Because of the magnitude of their potential consequences, large-scale discontinuous responses warrant careful consideration in evaluations of climate change dangers. Working Group II points to the potential for such occurrences and their potential consequences for human and natural systems, but it is unable to provide detailed assessments of potential effects, given the paucity of information in the literature.

1.4.4. Synergies and Tradeoffs

1.4.4.1. Synergies and Tradeoffs between Climate Change and Other Environmental Issues

Climate change is only one issue among many. The early stages of economic development typically lead to an increase in many pollutants, and actions taken to reduce one can have ancillary benefits caused by simultaneous reduction of

others. Assessments that neglect these synergies can seriously underestimate the justification for cutbacks. On the other hand, impacts from climate change can depend on the levels of other pollutants. For example, forests weakened by acid rain are likely to be more vulnerable to changes in rainfall brought on by climate change or warming, and lake acidification can have a synergy with ultraviolet radiation penetration into the water (e.g., Schindler *et al.*, 1996). While maintaining its primary focus on decadal to centennial-scale climate change, Working Group II has examined linkages among climate change and other environmental issues, including climate variability, loss of biodiversity, deforestation, and desertification.

1.4.4.2. Synergies and Tradeoffs between Adaptation and Mitigation

It is often argued in the literature that there is a tradeoff between adaptation and mitigation in that resources committed to one are not available for the other. This is debatable in practice because the people who bear emission reduction costs or benefits often are different from those who pay for and benefit from adaptation measures. Arguments are given on both sides of this issue. On one hand, in a straight comparison, several factors point to the wisdom of initially committing resources to adaptation. Insofar as no level of mitigation will completely prevent some climate change, some adaptation will be necessary. The benefits from adaptation are received in the country that incurs the costs, so there is no “free-rider” problem; climate change from GHG emissions that already have occurred means that adaptation will be required even if quite stringent mitigation also is agreed on; many adaptation options, such as switching agricultural crops and strengthening seawalls, are relatively cheap options for some (but not all—e.g., for small island states), and there may be ancillary benefits of the adaptation action even if climatic change effects turn out to be small (e.g., “no regrets” policies such as improving the efficiency of irrigation equipment).

On the other hand, it has been argued that climatic changes today still are relatively small, thus there is little need for adaptation, although there is considerable need for mitigation to avoid more severe future damages. By this logic, it is more prudent to invest the bulk of the resources for climate policy in mitigation, rather than adaptation.

It is reasonable to assume that many adaptation options will be pursued. This means that the baseline against which mitigation options should be assessed is one with adaptation also occurring. If the adaptations were effective in reducing the costs of climatic impacts, this can significantly reduce the benefits that otherwise would have been attributable to mitigation. On the other hand, as Section 1.4.1 notes, lack of perfect foresight about future climatic or other relevant social trends can lead to maladaptations. This situation would then argue for more emphasis on mitigation because maladaptations in the future would increase the costs of climatic impacts thus justify stronger abatement efforts. Furthermore, it has been argued

that early steps toward mitigation can lower long-term costs of carbon abatement by reducing the rate at which the energy-intensive capital stock has to be turned over, by inducing research and development, and/or by enhancing learning by doing (Grubb *et al.*, 1994; Azar, 1998; Goulder and Schneider, 1999). Others have argued that delayed abatement is more cost-effective because the bulk of the climate damages are likely to occur in the future, whereas the costs of immediate abatement occur in the nearer term; thus, discounting reduces the present value of the benefits of avoided climate damage versus less discounted abatement costs (e.g., Wigley *et al.*, 1996). Working Group III explores these issues in more depth, but in the context of the Working Group II mandate it must be recognized that many factors that still contain considerable uncertainty enter the debate about tradeoffs between timing and magnitudes of adaptation and mitigation efforts.

1.4.5. Integrated Assessment

Given the multi-sectoral, multi-regional, multidisciplinary, and multi-institutional nature of the integration of climatic change assessments of effects, impacts, and policy options, methods to perform “end-to-end” analyses have been developed and often are labeled “integrated assessments” (see, e.g., Weyant *et al.*, 1996; Morgan and Dowlatabadi, 1996, and references therein). Integrated assessment models (IAMs) have been developed to provide the logical consequences of a variety of explicit assumptions that undergird any formal assessment technique. IAMs seek to combine knowledge from several disciplines that is relevant to climate change in mathematical representations of the determinants of GHG emissions, responses of the climate system and feedbacks to emissions, effects on socioeconomic activities and ecosystems, and potential policies and responses (Parson and Fisher-Vanden, 1997). To date, IAMs have relied primarily on highly aggregated representations that directly link monetized measures of projected impacts to mean climate variables—principally, annual global mean temperature. Over time, these sorts of estimates have been extended by introducing variation between regions, by separating market and nonmarket damages, or by introducing other climate variables such as precipitation (Parson and Fisher-Vanden, 1997). A few IAMs adopt a process-based, geographically explicit approach to modeling, thus have more detailed representation of impacts, often including changes in physical units (e.g., crop yields) as measures of impact. These models do not translate impacts into a common metric, such as money. This makes comparing the level of impacts depicted in the two different modeling approaches very difficult (Tol and Fankhauser, 1998).

IAMs have evolved from a variety of disciplinary tools that often were developed for purposes other than assessments of climatic changes. IAMs have been classified into a hierarchy of five levels (Schneider, 1997). This classification scheme does not imply that each successive level of modeling along the hierarchy (see Section 2.3.8) incorporates all of the elements at lower levels or that incorporation of additional levels of comprehensiveness or complexity provides more fidelity in the

model's simulation skills; that depends on the validity of the underlying assumptions and the accuracy of methods used to formally solve the equations that represent those assumptions. Finally, difficulties are encountered in aggregating costs or benefits across the many categories of impacts or opportunities, and a traceable account of any aggregations must be paramount to maintain transparency of any analytic methods such as IAMs (see Sections 1.5.6 and 2.6.4).

Despite these complexities, IAMs are a principal tool for studying systematic sets of interactions that are believed to be important in explaining systems behavior or simulating the consequences of various policies on the magnitude and distribution of risks and benefits of climatic changes or policies to enhance adaptation or encourage mitigation. The goal of IAMs has been to provide insights about the possible interactions of many factors in a complex socionatural system, rather than "answers" to specific scientific or policy questions.

1.5. How do the Complexities of Analysis Affect the Assessment?

The threat posed by climate change must be considered in the context of efforts by countries around the world to achieve sustainable development (see Section 1.1). Improved analysis of impacts of and adaptation to climate change is important for the development of appropriate policy measures. However, the chain of events from human behaviors that give rise to disturbances to the climatic system; to atmospheric changes; to impacts on humans, societies, other species, ecosystems, and their adaptive responses is very complex (as noted in Chapters 2 and 19). Uncertainty is a common feature in the discussion of complexity, and it is compounded by the complex interactions of many subsystems that constitute the socionatural system, each of which has its own inherent uncertainties (see Box 1-2). This section summarizes some of the complexities that make it difficult to provide very many highly confident projections about climatic impacts—assessments that are directly relevant to the oft-asked policy question: "What should we do about climate change?" (see Chapter 2 and references therein for more complete treatment).

1.5.1. Regional Climate Uncertainties

At the regional level, there is a wide range of projected changes in temperature and precipitation simulated from a doubling of CO₂ concentrations because of large model-to-model differences. Annex B of the *Special Report on Regional Impacts of Climate Change* (IPCC, 1998) provides the following conclusion regarding the confidence that can be placed in regional climate projections:

"Analysis of surface air temperature and precipitation results from regional climate change experiments carried out with AOGCMs indicates that the biases in present-day simulations of regional climate change and the inter-model

variability in the simulated regional changes are still too large to yield a high level of confidence in simulated change scenarios. The limited number of experiments available with statistical downscaling techniques and nested regional models has shown that complex topographical features, large lake systems, and narrow land masses not resolved at the resolution of current GCMs significantly affect the simulated regional and local change scenarios, both for precipitation and (to a lesser extent) temperature (IPCC, 1996a). This adds a further degree of uncertainty in the use of GCM-produced scenarios for impact assessments. In addition, most climate change experiments have not accounted for human-induced landscape changes and only recently has the effect of aerosols been vigorously investigated. Both these factors can further affect projections of regional climate change."

The wide range of projected changes in temperature and precipitation would affect the degree of exposure of systems and populations to climatic stimuli and hence their vulnerability to climate change. This range suggests that high confidence will not often be assigned to any regional impact assessments that are based on GCM results. Difficulty in obtaining many highly confident outcomes is why the term "climate scenarios" has been adopted in most impact assessments. Such scenarios should be regarded as internally consistent patterns of plausible future climates, not predictions carrying assessed probabilities (see Section 2.6 and Chapter 3). Decisionmakers need to be aware of the large range of plausible climate projections when they formulate strategies to cope with the risks of climate change. However, in the absence of some explicit estimation of the likelihood of various scenarios by those who produce them, users of the many decision frameworks in the literature (see Box 1-2 and Section 2.7) often have to impute likelihood to various scenarios to apply many of these methods.

The review chapters in this report summarize impact studies that are based on a range of climate scenarios, when available. As noted earlier, transient scenarios are particularly valuable because the Earth currently is undergoing a transient response to global change disturbances. Great care is required in interpreting and comparing results from research or assessments that use different climate scenarios, particularly when some conclusions follow from static scenarios and others from transient scenarios. Unfortunately, such mixed use of scenarios is still a problem in the literature and in assessments of it.

1.5.2. Socioeconomic Uncertainties

An often overlooked source of uncertainty in assessments of impacts and vulnerability is the wide difference in assumptions (often not even stated) in the initial conditions and trends of environmental systems and socioeconomic conditions. These assumptions include information on population and related variables (e.g., population density), economic trends (e.g., income levels, sectoral composition of GDP, or levels of trade), other social indicators (e.g., education levels, private- and

public-sector institutions), culture, land cover and use, and availability and use of other resources such as water. They are important not only for determining the forces driving global changes but also for understanding the general capabilities available to societies for adaptation. Projections of these factors for time periods such as the middle of the 21st century are at least as uncertain as projections of future climate; hence, it is probably most advisable to use such information as scenarios of change, or conditioning assumptions (IPCC, 1998). Moreover, culture exerts important influences on socioeconomic processes, problemsolving methods, and the like. The formation of coalitions, social movements, and educational programs directed toward changing institutional norms that might influence people's behavior concerning climatic change is culturally determined, like other complex social and psychological processes. Cultural processes and economic behavior, for example, can be modeled to capture some of the complexity of the social processes, structures, and cognitive behavior involving culture (e.g., Rotmans and van Asselt, 1996; Koizumi and Lundstedt, 1998). Thus, it is simply impossible to predict with high confidence how societies and economies will develop in the future—hence the extent to which they will have the capacity needed for adaptation. The use of scenarios to assess driving forces and adaptive capacity is one way to explicitly acknowledge these kinds of structural uncertainties (e.g., IPCC, 2000). Socioeconomic scenarios, as already noted, are not predictions of future states of the world but consistent and plausible sets of assumptions about issues such as population growth, economic development, values, and institutions.

Although the emphasis on adaptation to reduce vulnerability and take advantage of emerging opportunities is increasing in impact assessment, many uncertainties remain regarding the effectiveness of different options, the relationship between adaptation to short-term climate fluctuations and long-term climate change, and constraints and opportunities that will be imposed by factors such as existing institutional structures, economic and financial limitations, and cultural resistance (IPCC, 1998).

1.5.3. Risk and Uncertainty

Uncertainties are pervasive throughout climate change impact assessment. For some sectors, such as agriculture, uncertainty is large enough to prevent a highly confident assessment of even the sign of the impacts. Until a few years ago, uncertainties in assessments were so great that few researchers were willing to carry their analysis through to numerical estimates of monetary impacts. Even today, as the applicability of subjective probabilities is becoming more accepted, impact estimates with explicit confidence intervals are the exception rather than the rule (a few exceptions are Peck and Teisberg, 1992; Hope *et al.*, 1993; Nordhaus, 1994a; Manne and Richels, 1995; Morgan and Dowlatabadi, 1996; Titus and Narayanan, 1996; Roughgarden and Schneider, 1999). Figure 2-2 (Moss and Schneider, 2000) graphically depicts how uncertainties in emissions scenarios feed into uncertainties in carbon cycle response, climate sensitivity,

regional climate responses, and ranges of impacts in an “explosion” or “cascade” of widening uncertainty bounds. However, despite this daunting expansion of uncertainty, methods to classify and formally treat such uncertainties via subjective probability distributions are available in the literature (see Box 1-2 and Section 2.6) and can help to clarify which subcomponents of the overall human-environment system are most critical to integrated assessments of the costs and benefits of climatic changes or climate policies.

1.5.4. Low-Probability Catastrophic Events

Efforts to deal with low-probability, potentially catastrophic events in integrated assessments of climate change are not well-represented in the literature. One possibility would be to treat these risks like any hazard and use methods from risk analysis: The value of the risk is the probability of occurrence multiplied by the consequences of the event. For rare and catastrophic possibilities, there is very little frequency data; thus, probabilities assessed are based largely on subjective methods (e.g., Nordhaus, 1994b; Roughgarden and Schneider, 1999). Equally important, under these conditions the expected cost estimate would be very sensitive to the analyst’s (subjective) assumptions about the costs of catastrophic events. Subjective probabilities can vary widely from analyst to analyst under such conditions. This partly explains why most analysts have been reluctant to include low-probability but potentially catastrophic events in integrated assessments (for a recent exception, see Mastrandrea and Schneider, 2001). However, absence of analysis does not necessarily imply absence of risk, and many risk management decisions in the private and public sectors are based on strategic hedging against low-probability but highly costly possibilities, such as insurance and deterrence (see Chapter 8). However, the expected cost approach would imply a risk neutrality—an uncomfortable position for those holding risk averse values in the face of possibilities such as collapse of the “conveyor belt” circulation in the North Atlantic Ocean (e.g., Broecker, 1997; Rahmstorf, 1999; Chapter 19) or melting of the West Antarctic Ice Sheet (e.g., Oppenheimer, 1998). Risk-averse individuals often worry about the possibility that a forecast for a high-consequence event is either accurate or an underestimate—the “type 2 error.” Such individuals have argued that a better way to treat the possibility of catastrophe is to ensure that all possible efforts are taken to avoid it—the “precautionary principle” (see, e.g., Wiener, 1995). However, spending valuable, limited resources to hedge against possible catastrophic outcomes with a low probability of occurring is infeasible in practice; scarce resources could have been used more productively elsewhere, including dealing with more probable climatic threats. People who are concerned about “squandering” resources on what they perceive to be unlikely threats or even an erroneous forecast—the “type 1 error”—often are engaged in contentious debates with those more concerned with type 2 errors—a situation that is well-known in risk management disciplines. Thus, it is difficult to apply the precautionary principle unambiguously to justify a hedging strategy against a potential catastrophic climatic event without

also applying it to the possibility of negative outcomes from the hedging strategy itself, then weighing the relative risks of type 1 versus type 2 errors (Wiener, 1995).

1.5.5. Valuation Methods—Monetary Measures or Multiple Numeraires

Although much progress on valuation techniques is being made, as noted in Box 1-2, uncertainties are still large, and many impact estimates are “highly speculative” (Nordhaus and Boyer, 2000). Impacts can be divided into market and nonmarket impacts.

Market impacts occur in sectors or activities such as agriculture, forestry, provision of water, insurance against extreme events, transportation, tourism, and activities that use low-lying coastal land. Where these activities produce marketed goods, a monetary estimate of impacts (in units of dollars per °C, for example) sometimes can be made with fairly straightforward techniques, at least under present-day conditions; this has been the most common approach in impact studies to date (e.g., Mendelsohn *et al.*, 2000). Market prices, adjusted to correct for market distortions (e.g., externalities), are the appropriate measure for unit impacts. Although the techniques are well established, the numbers obtained still are approximate as a result of all the uncertainties that surround impact assessments. Working out how the impacts will unfold in the distant future is much less straightforward. Impacts could increase as the intensity and scale of the activity increases (e.g., loss of coastal property) or decrease as more modern and robust systems replace existing ones (e.g., new crop strains are introduced with more climatic adaptability). Also, as noted in Box 1-2, impacts expressed in economic terms embed the values people attribute to the impacts across several numeraires, as well as the values of future generations (see Section 2.5.6 for further elaborations).

For example, the use of highly aggregated decision analysis frameworks (see Box 1-2 and Chapter 2) can be controversial because aggregation of positive and negative costs of even a limited number of market category sectors involves the arithmetic sum of many subelements that contain large uncertainties and are related to different regions. Furthermore, important market costs could be incurred by political instability (e.g., Kennedy *et al.*, 1998), migration of displaced persons (e.g., Myers, 1993), diminished capacity of damaged ecosystems to provide accustomed services (e.g., Daily, 1997), or loss of heritage sites from sea-level rise (e.g., Schneider *et al.*, 2000b). Moreover, losses in nonmonetary categories (i.e., other numeraires such as biodiversity lost, lives lost, quality of life degraded, or inequity generated—all per °C) are very controversial (e.g., Goulder and Kennedy, 1997, discuss attempts to estimate the intrinsic value of species). Any aggregation over such numeraires into a common metric—usually the dollar—cannot be accomplished transparently unless a variety of assumptions are explicitly given for the valuation of each of these numeraires before aggregation hides the underlying assumptions of how valuation was accomplished.

1.5.6. Damage Aggregation and Distributional Effects

Aggregation of various damages into a single estimate sometimes is appropriate to provide policymakers with information about the magnitude of damages that can be expected on a global scale. However, as noted in Box 1-2, Section 1.5.5, and Section 2.6.4, there also is the risk that such aggregation conceals rather than highlights some of the critical issues and value-laden assumptions that are at stake.

As a hypothetical but concrete example, assume that climatic change would cause destruction of lives, ecosystems, and property in Bangladesh, corresponding to a loss of 80% of its GDP. This loss to Bangladesh would amount to roughly 0.1% of global GDP. If the global economy grows at 2% yr⁻¹, this assumed impact on Bangladesh would correspond to a delay in global income growth of less than 3 weeks. It is debatable whether adding, say, the possible benefits for temperate agriculture to the losses of lives resulting from sea-level rise in Bangladesh helps to assess the severity of climate change impacts because the “winner” does not compensate the “loser” (i.e., benefits for temperate agriculture offer little relief to those who have been affected by sea-level rise in other regions). Authors in the literature have expressed concern about trading the costs of emission reduction in some countries (e.g., more efficient end-use energy technologies) with large-scale losses of lives and human health in others (e.g., Munasinghe, 2000). Still, this is implicitly done in most conventional cost-benefit analyses of climate change available in the literature. As noted above and in Section 2.6.4, this points to the necessity of using appropriately disaggregated cost and benefit data to make the analysis more transparent. Possible ways of incorporating equity concerns include use of distributional weights in cost-benefit analysis (e.g., Azar and Sterner, 1996; Fankhauser *et al.*, 1997; Azar, 1999).

Owing to the complexities of valuation and aggregation analyses described above and in the preceding subsection, the TAR authors are cautious about the applicability of single “optimal” answers. Instead, they attempt to examine ranges of outcomes calculated under a variety of assumptions available in the literature, for which alternative valuation methods can be applied to different categories across various numeraires.

1.5.7. Discounting

Comparing impact, mitigation, and adaptation costs that occur at different points in time requires them to be discounted. There is longstanding debate about the appropriate rate of discount to use (e.g., Arrow *et al.*, 1996; Portney and Weyant, 1999). Uncertainty regarding the discount rate relates not to calculation of its effects, which is mathematically precise, but to a value judgment about the appropriateness of the present generation valuing various services for future generations (see Section 2.3.1 for elaboration).

Two different approaches to discounting are presented in the SAR (Arrow *et al.*, 1996). The *descriptive* approach focuses on

intertemporal cost-efficiency, and the discount rate is based on observed market interest rates. The *prescriptive* approach emphasizes that normative issues are involved in valuing the future. One important problem for both approaches is the fact that we cannot observe future market interest rates or know the level of income that will prevail in the future (at least for time horizons involved in the climate change debate). Most analysts have resolved this dilemma by using constant discount rates over the entire horizon, despite the fact that they are likely to change. Others have suggested or used non-fixed discount rates that apply strong short-term discounting but entail little further discounting for the very long-term future (e.g., Azar and Sterner, 1996; Heal, 1997). That would cause events a decade or two hence to be significantly discounted but would not cause events a century hence to be reduced in value by powers of 10, as is the occurrence with conventional exponential (compound interest) discounting. Because the largest costs from climate change usually are believed to occur many decades in the future, conventional discounting renders the present value of such future damages very small, whereas non-fixed discount rates (e.g., “hyperbolic discounting”) would cause present generations to take serious notice of very large potential damages, even a century hence. Because both the value of the discount rate and the choice of discounting approach involve value judgments about the ethics of intergenerational transfers, it is important for all assessments to be clear about what discounting formulations have been used and the sensitivity of the conclusions to alternative formulations.

1.5.8. “Safe Emission Levels,” Cost-Effectiveness Analysis, and the Timing of Emission Abatement

Several issues raised in this section are discussed primarily in the report of Working Group III. However, because this chapter is intended to provide a context for impact, adaptation, and vulnerability issues, this section briefly reviews several emissions abatement complexities that have a bearing on the adaptation/mitigation tradeoff issues (see Section 1.4.4.2 and Chapter 2). Because estimates of the monetary costs of impacts span a wide range of values given the many uncertainties and often are value laden, some analysts have argued that climate change targets should be based on physical or social, rather than economic, indicators—for example, past fluctuations in temperature or expected climate-related deaths or some general reference to sustainability or the precautionary principle (see Section 1.5.4). This precautionary approach is used in European negotiations on emissions of acidifying substances and is acknowledged in Article 3, paragraph 3, of the UNFCCC, which states as a principle that “The Parties should take precautionary measures to anticipate, prevent or minimize the causes of climate change and mitigate its adverse effects. Where there are threats of serious or irreversible damage, lack of full scientific certainty should not be used as a reason for postponing such measures....” Such threshold levels (see Section 1.4.3.5) also have been used as upper ceilings on the amount of warming considered “tolerable” in the academic sphere (see Alcamo and Kreileman, 1996; Azar and Rodhe, 1997) and the political sphere (for instance, the

European Union has adopted a maximum of 2°C temperature change above pre-industrial levels or a maximum of 550 ppm CO₂ concentration target). Implicit in this approach is the assumption of the possibility of very nonlinear damage functions. One drawback with this approach is that necessary tradeoffs between climate damage avoidance and the opportunity costs of resources used to mitigate that climate change often are not made explicit.

Even if the precautionary approach were taken, cost-efficiency analysis would be used to identify the lowest cost of meeting the predefined target. Several studies have made an argument that “where” and “when” flexibility in emissions reductions can greatly reduce its costs (Wigley *et al.*, 1996). Ha-Duong *et al.* (1997) and Goulder and Schneider (1999) show that preexisting market failures in the energy sector could reduce the costs of immediate climate policies substantially or that neglect of inducing technological changes by delaying incentives associated with immediate climate policies could reverse the conclusions that delayed abatement is more cost-effective. Unfortunately, there is very little literature on how climate policies might induce technological change (see WGIII TAR). Another reason for the controversy in the literature about abatement timing is a misreading of Wigley *et al.* (1996) that they do not endorse efforts over the next 30 years to make abatement cheaper in the future. Azar (1998) argues, however, that if stabilization targets would be at or below 450 ppm CO₂, early abatement (not just efforts to make future abatement cheaper) would be cost-efficient, even in the Wigley *et al.* (1996) model.

Furthermore, the problem of valuing impacts in monetary terms cannot be avoided entirely even under the cost-efficiency approach. Different trajectories toward the stabilization target have different impacts and costs associated with them. How does delaying mitigation affect the impacts, including distributive consequences? The answer to this question is unclear, partly because of large remaining uncertainties about the extent to which rapid forcing of the climate system could trigger threshold events (e.g., Tol, 1995). Moreover, the difference in impacts between early and delayed mitigation responses appears to be sensitive to assumptions about sulfate aerosol cooling and whether small transient temperature differences can have significant effects.

1.5.9. Validation

Validation of models and assessments that deal with projections over many decades is a serious issue. Often it is not helpful in the context of sustainable development to suggest postponing policy responses until model predictions can be directly compared against reality because that would require experiencing the consequences without amelioration. Instead, models and assessments are subjected to varying levels of quality control, intercomparison with standard assumptions, comparisons with experiments, and extensive peer review. Some authors have argued (e.g., Oreskes *et al.*, 1994) that it is impossible in principle to “validate” models for future events when the processes that

determine the model projections contain structural uncertainties (see Boxes 1-1-and 2-1). Although the impossibility of direct before-the-fact validation is strictly true, this does not mean that models cannot be rigorously tested. Several stages are involved. First, how well known are the data used to construct model parameters? Second, have the individual processes been tested against lab experiments, field data, or other more comprehensive models? Third, has the overall simulation skill of the model been tested against known events? Fourth, has the model been tested for sensitivity to known shocks (e.g., an oil price hike in an economic model or a paleoclimatic abrupt change in a climate model)? For example, crop yield models are tested against actual yield variation data (Chapter 5), and sea-level increase models are tested for their ability to reproduce observed changes in the 20th century. The ability of a model to reproduce past conditions is a necessary, but not necessarily sufficient, condition for a highly confident forecast of future conditions, unless the underlying processes that gave rise to the phenomena observed in the past will be fully operative in the future and the model captures the influence of such phenomena. Finally, has the comparison between model and data been done at commensurate scales, so that small-scale data are first aggregated to the scale of the lowest resolved element of the model before attempting evaluation (e.g., Root and Schneider, 1995)? When such validation protocols are performed and a model performs “well,” subjective confidence that assessment teams can assign to various projections based on such models increases considerably (see Section 2.6), even if “definitive proof” of a specific forecast before the fact is impossible in principle.

All of these considerations demonstrate how the complexities of analysis have led Working Group II TAR authors to emphasize risk management approaches to climate change and policy assessment, rather than just an optimizing framework (e.g., see Section 2.7). These complexities of analysis are not problematic only for the assessment of impacts, vulnerabilities, and adaptability; they also carry forward to questions of tradeoffs between investments in adaptation and mitigation strategies and make a connection between the purviews of Working Groups II and III.

1.6. How can this Assessment be Used to Address Policy-Relevant Questions? A Users’Guide

1.6.1. United Nations Framework Convention on Climate Change

An important audience for this report is the UNFCCC Conference of Parties and Subsidiary Bodies, through which implementation of the provisions of the Convention (United Nations, 1992) and associated protocols will be negotiated. The major issue is contained in Article 2 of the UNFCCC and relates to identifying the level for stabilization of GHG concentrations. As stated in that Article, the level for stabilization is set in terms of impacts of climate change. Hence, the focus of this report is on identifying impacts potentially associated

with different rates and levels of climate change. It is important to reiterate that readers will not find any magnitude or rate of climate change defined as “dangerous” by this report. As noted earlier, this is because such a designation is necessarily political for two important reasons. First, the impacts associated with any given concentration target or emissions trajectory will be unevenly distributed across countries, ecosystems, and socioeconomic sectors. Thus, some sectors or regions may receive some benefit from a particular pattern of climate change, whereas others will be harmed. It is not the role of the scientific community to determine whether a particular pattern of impacts constitutes “dangerous” interference; that is a political judgment to be negotiated among participating governments and institutions. Second, there are scientific uncertainties associated with climate change scenarios and our knowledge of impacts that may result. Thus, it is not possible to state in absolute terms that particular impacts will be associated with a given concentration target or stabilization pathway. Instead, information about impacts will be conditional and is best considered in a risk management framework—that is, different stabilization targets or pathways pose different risks to food production, ecosystems, and economic development, and such risks are likely to vary by region and over time. There is no way to determine scientifically what level of risk is acceptable under the UNFCCC. This, too, will be a matter for negotiation by governments. However, information on the state of the science presented in IPCC assessments is widely believed to help put such decisionmaking exercises on a firmer factual basis (see discussion of guidelines for practitioners from an international social science assessment of human choice and climate change in Rayner and Malone, 1998).

The TAR focuses on the vulnerability of different systems and regions to various rates and magnitudes of climate change. Assessment of vulnerability and adaptation is relevant not only to identifying impacts associated with different targets but also to identifying “developing country Parties that are particularly vulnerable to the adverse effects of climate change” (Article 12; United Nations, 1997); these countries are to be compensated from the proceeds of the CDM to help meet the costs of adaptation.

1.6.2. Links to Biodiversity Loss, Desertification, Deforestation and Unsustainable Use of Forests, Stratospheric Ozone Depletion, and Other Global Environmental Issues

Climate change is not an isolated issue; it is intimately connected to other recognized natural hazards and global environmental problems. Separate international conventions and processes exist to address these issues; in several cases, these include successful scientific assessment mechanisms. This report contains information of relevance to these bodies and processes, although it is not the intention of the report to supersede or contradict information developed in those assessments. The purpose of incorporating information of relevance to these issues is to highlight scientific and policy links among them, so that unnecessary tradeoffs can be avoided and potential multiple

benefits can be realized (e.g., Orlando and Smeardon, 1999; Kremen *et al.*, 2000). For example, several international conventions and agreements call for sustainable management and use of land and water resources, with varying goals (such as enhancing GHG sinks and reservoirs, protecting biological diversity, safeguarding aquatic ecosystems, managing forests to meet human needs, and halting desertification). To the extent that these objectives are potentially affected by climate change, and to the extent that options to adapt to changing climate conditions can be structured to help attain additional environmental or socioeconomic objectives associated with these other agreements (i.e., co-benefits), this is highlighted in the relevant sections of the TAR.

1.6.3. Resource Planners, Managers in National and Regional Institutions, and Actors in Specialized International Agencies

Although the primary audiences of this report are involved in negotiating and implementing the UNFCCC (United Nations, 1992) and, to some extent, other international agreements on global environmental problems, the report also contains information that is useful to resource managers in national governments; regional institutions such as regional development or lending agencies; and specialized international agencies such as the World Bank, UNEP, UNDP, or the GEF. In the chapters that focus on sectors or systems of climate change (e.g., Chapters 4–9, which cover advances in our understanding of impacts and adaptation options in water resources, agriculture, health, ecosystems, and so forth), planners and managers in national ministries or regional planning authorities will find information on how their mandates—such as encouraging agriculture, providing freshwater, protecting endangered species, or increasing energy production—could be affected by climate change. To the extent provided in the literature, these chapters also include detailed technical and cost information on adaptation options and factors that will influence their implementation. In chapters that focus on regional analyses, managers and planners at regional and international agencies will find information on baselines and trends (climate, socioeconomic, and other environmental); each chapter also highlights particular vulnerabilities and opportunities for adaptation that may occur in each region. It is hoped that this information will be useful in assessing potential projects and opportunities for investment, so that these can be structured to be more robust to potential negative effects of climate change or to take advantage of emerging opportunities. In addition, this report will be useful in the education of the media and the general public about climate, the environment, and development issues.

EXECUTIVE SUMMARY

The purpose of this chapter is to address several overarching methodological issues that transcend individual sectoral and regional concerns. In so doing, this chapter focuses on five related questions: How can current effects of climate change be detected? How can future effects of climate change be anticipated, estimated, and integrated? How can impacts and adaptations be valued and costed? How can uncertainties be expressed and characterized? What frameworks are available for decisionmaking? In addressing these questions, each section of Chapter 2 seeks to identify methodological developments since the Second Assessment Report (SAR) and to identify gaps and needs for further development of methods and tools.

Detection of Response to Climate Change by Using Indicator Species or Systems

Assessment of the impacts on human and natural systems that already have occurred as a result of recent climate change is an important complement to model projections of future impacts. Such detection is impeded by multiple, often inter-correlated, nonclimatic forces that are concurrently affecting those systems. Attempts to overcome this problem have involved the use of indicator species to detect responses to climate change and to infer more general impacts of climate change on natural systems. An important component of the detection process is the search for systematic patterns of change across many studies that are consistent with expectations, based on observed or predicted changes in climate. Confidence in attribution of these observed changes to climate change increases as studies are replicated across diverse systems and geographic regions.

Since the SAR, approaches to analysing and synthesizing existing data sets from abiotic and biotic systems have been developed and applied to detection of present impacts of 20th-century climate change. Even though studies now number in the hundreds, some regions and systems are underrepresented. However, there is a substantial amount of existing data that could fill these gaps. Organized efforts are needed to identify, analyze, and synthesize those data sets.

Anticipating the Effects of Climate Change

A wide range of methods and tools are now used and available for studies of local, regional, and global impacts. Since the SAR, improvements have included greater emphasis on the use of process-oriented models and transient climate change scenarios, refined socioeconomic baselines, and higher resolution assessments. Country studies and regional assessments in every

continent have tested models and tools in a variety of contexts. First-order impact models have been linked to global systems models. Adaptation has been included in many assessments, often for the first time.

Methodological gaps remain concerning scales, data, validation, and integration. Procedures for assessing regional and local vulnerability and long-term adaptation strategies require high-resolution assessments, methodologies to link scales, and dynamic modeling that uses corresponding and new data sets. Validation at different scales often is lacking. Regional integration across sectors is required to place vulnerability in the context of local and regional development. Methods and tools to assess vulnerability to extreme events have improved but are constrained by low confidence in climate change scenarios and the sensitivity of impact models to major climatic anomalies. Understanding and integrating higher order economic effects and other human dimensions of global change are required. Adaptation models and vulnerability indices to prioritize adaptation options are at early stages of development in many fields. Methods to enable stakeholder participation in assessments need improvement.

Integrated Assessment

Integrated assessment is an interdisciplinary process that combines, interprets, and communicates knowledge from diverse scientific disciplines in an effort to investigate and understand causal relationships within and between complicated systems. Methodological approaches employed in such assessments include computer-aided modeling, scenario analyses, simulation gaming and participatory integrated assessment, and qualitative assessments that are based on existing experience and expertise.

Since the SAR, significant progress has been made in developing and applying these approaches to integrated assessment, globally and regionally. However, the emphasis in such integrated assessments, particularly in integrated modeling, has been on mitigation; few existing studies have focused on adaptation and/or determinants of adaptive capacity. Methods designed to include adaptation and adaptive capacity explicitly in specific applications need to be developed.

Costing and Valuation

Methods of economic costing and valuation rely on the notion of opportunity cost of resources used, degraded, or saved. Opportunity cost depends on whether the market is competitive

or monopolistic and whether any externalities are present. It also depends on the rate at which future costs are discounted, which can vary across countries, over time, and over generations. The impact of uncertainty also can be valued if the probabilities of different possible outcomes are known. Public and nonmarket goods and services can be valued through willingness to pay for them or willingness to accept compensation for lack of them. Impacts on different groups, societies, nations, and species need to be assessed. Comparison of alternative distributions of welfare across individuals and groups within a country can be justified if they are made according to internally consistent norms. Comparisons across nations with different societal, ethical, and governmental structures cannot yet be made meaningfully.

No new fundamental developments in costing and valuation methodology have taken place since the SAR. Many new applications of existing methods to a widening range of climate change issues, however, have demonstrated the strengths and limitations of some of these methods. For example, many contingent valuation studies have raised questions about the reliability of such evaluations. Similarly, more attention is now paid to the limitations of methods that underlie efforts to reduce all impacts to one monetary value and/or to compare welfare across countries and cultures. Multi-objective assessments are preferred, but means by which their underlying metrics might more accurately reflect diverse social, political, economic, and cultural contexts need to be developed. In addition, methods for integrating across these multiple metrics are still missing from the methodological repertoire.

Treatment of Uncertainties

The Earth's linked climate and social-natural systems are very complex; thus, there are many unresolved uncertainties in nearly all aspects of the assessment of climatic impacts, vulnerabilities, and adaptation. Subjective judgments are inevitable in most estimates of such complex systems. Since the SAR, more

consistent treatment of uncertainties and assessment of biases in judgments have been attempted. Progress also has been made in developing methods for expressing confidence levels for estimates, outcomes, and conclusions, based on more consistent quantitative scales or consistently defined sets of terms to describe the state of the science. Notable attempts to provide "traceable accounts" of how disaggregated information has been incorporated into aggregated estimates have been made, but more work is needed. Greater attention to eliminating inconsistent use of confidence terms or including a full range of uncertainty for key results is still needed in future assessments. Whereas significant progress on issues of uncertainty has been achieved in the context of impacts and vulnerability, a major challenge now lies in addressing uncertainties associated with adaptability.

Decision Analytic Frameworks

Policymakers who are responsible for devising and implementing adaptive policies should be able to rely on results from one or more of a diverse set of decision analytical frameworks. Commonly used methods include cost-benefit and -effectiveness analyses, various types of decision analysis (including multi-objective studies), and participatory techniques such as policy exercises, but there are many other possible approaches. Among the large number of assessments of climate change impacts reviewed in this volume, only a small fraction include comprehensive and quantitative estimates of adaptation options and their costs, benefits, and uncertainty characteristics. This information is necessary for meaningful applications of any decision analytical method. Very few cases in which decision analytic frameworks have been used in evaluating adaptation options have been reported. Greater use of methods in support of adaptation decisions is needed to establish their efficacy and identify directions for necessary research in the context of vulnerability and adaptation to climate change.

2.1. Introduction

In assessing impacts, vulnerability, and adaptation to climate change, a large array of methods and tools pertain to specific sectors, scales of analysis, and environmental and socioeconomic contexts. In this chapter, the term *methods* refers to the overall process of assessment, including tool selection and application; the term *tools* refers to the formulated means of assessment. It is not the intent of this chapter to comprehensively canvas this full array of methods and tools; clearly, such appraisal falls more properly within the purview of the individual chapters in this volume. The purpose of this chapter is to address several overarching methodological questions that transcend individual sectoral and regional concerns. In so doing, this chapter focuses on five related questions:

- *How can the current effects of climate change be detected?* Is climate change already having a discernible effect? One of the key methodological problems is how to unequivocally identify a climate change signal in indicators of change in biotic and abiotic systems. This problem is exemplified in Section 2.2 by focusing on biological indicators and methodological advances that have been made since the Second Assessment Report (SAR).
- *How can the future effects of climate change be anticipated, estimated, and integrated?* Since the SAR, an explosion of climate change vulnerability and adaptation studies has occurred around the world, stimulated in large part by the United Nations Framework Convention on Climate Change (UNFCCC) and its national reporting requirements, as well as the availability of international donor support to non-Annex I countries. Section 2.3 reflects on methodological developments and needs for such vulnerability and adaptation studies, and Section 2.4 focuses on methods for regional and cross-sectoral integration.
- *How can impacts and adaptations be valued and costed?* Ultimately, decisions to avoid or reduce the adverse effects of climate change (or enhance the benefits) require some means of appraisal (monetary or otherwise) of projected impacts and alternative adaptation options. Section 2.5 reviews various methods for valuing and costing, including issues of nonmarket effects, equity, integration, and uncertainty.
- *How can uncertainties be expressed and characterized?* From the science of climate change to assessments of its impacts, uncertainties compound, resulting in a “cascade of uncertainty” that perplexes decisionmaking. Section 2.6 canvasses the problems of, and methods for, incorporating uncertainty into policy-relevant assessments.
- *What frameworks are available for decisionmaking?* Once adaptations have been valued, the choice of adaptation requires methods of weighing and balancing options. Section 2.7 summarizes the main decision analytic frameworks (DAFs) that can be used in this context.

In addressing these questions, the following sections seek to furnish a brief description of the state of methods at hand, methodological developments that have occurred since the SAR, and needs and directions for applications and methods development for the future. Section 2.8 contains concluding remarks.

2.2. Detection of Response to Climate Change by Using Indicator Species or Systems

Climate change may cause responses in many human and natural systems, influencing human health (disease outbreaks, heat/cold stress), agriculture (yield, pest outbreaks, crop timing), physical systems (glaciers, icepack, streamflow), and biological systems (distributions/abundances of species, timing of events). In intensely human-managed systems, the direct effects of climate change may be either buffered or so completely confounded with other factors that they become impossible to detect. Conversely, in systems with little human manipulation, the effects of climate change are most transparent. Systems for which we have a good process-based understanding of the effects of climate and weather events, and have had minimal human intervention, may act as indicators for the more general effects of climate change in systems and sectors where they are less readily studied.

2.2.1. Detection in Natural Systems

2.2.1.1. Predicted Physical Responses to Climatic Warming Trends

The cryosphere is very sensitive to climate change because of its proximity to melting. Consequently, the size, extent, and position of margins of various elements of the cryosphere (sea ice, river and lake ice, snow cover, glaciers, ice cores, permafrost) are frequently used to indicate past climates and can serve as indicators of current climate change (Bradley and Jones, 1992; Fitzharris, 1996; Everett and Fitzharris, 1998). In particular, former glacier extent is indicative of past glacials and the Little Ice Age. At high latitudes and high altitudes, ice cores have provided high-resolution annual (and, in some cases, seasonal) records of past precipitation, temperatures, and atmospheric composition. These records stretch back for many hundreds of years, well before the instrumental period, so they have proven to be very valuable in documenting past climates. Borehole measurements provide data on permafrost warming. Later freeze-up and earlier breakup of river and lake ice is measurable at high latitudes.

Interpretation of climate change resulting from changes in the cryosphere is seldom simple. For example, in the case of glaciers, glacier dynamics and extent are influenced by numerous factors other than climate. Different response times are observed for the same climate forcing, so some glaciers can be in retreat while others are advancing. Changes in glacier size can be caused by changes in temperature or in precipitation—or even

a nonlinear combination of both. Similarly, changes in sea ice can be a result of changes in ice dynamics (winds, currents) as much as thermodynamics (temperature). Thus, attribution of the exact nature of climate change from changes in the cryosphere is quite complicated.

With many measures of the cryosphere, there frequently is large interannual variability. This makes determination of possible anthropogenic climate trends difficult to distinguish from the natural noise of the data. Another problem is that high-resolution records usually are not available, except from polar or high-altitude ice cores. Changes in the extent of sea ice and seasonal snow are best observed with satellites, but such records are relatively short (from about 1970), so long-term climate change is difficult to distinguish from short-term, natural variability. The first records of cryospheric extent and changes often come from documentary sources such as old diaries, logbooks of ships, company records, and chronicles (Bradley and Jones, 1992). Although these sources are fraught with difficulty of interpretation, they clearly demonstrate climate changes such as the medieval warm period and the Little Ice Age (see Section 5.7, Chapter 16, and Section 19.2).

2.2.1.2. Predicted Biological Responses to Climatic Warming Trends

All organisms are influenced by climate and weather events. Physiological and ecological thresholds shape species distributions (i.e., where species can survive and reproduce) and the timing of their life cycles (i.e., periods of growth, reproduction, and dormancy) (Uvarov, 1931; MacArthur, 1972; Precht *et al.*, 1973; Weiser, 1973; Brown *et al.*, 1996; Hoffman and Parsons, 1997; Saether, 1997) In the face of a local environmental change, such as a systematic change in the climate, wild species have three possible responses:

- Change geographical distribution to track environmental changes
- Remain in the same place but change to match the new environment, through either a plastic or genetic response [a plastic response is a reversible change within an individual, such as a shift in phenology (timing of growth, budburst, breeding, etc.); a genetic response is an evolutionary change within a population over several generations, such as an increase in the proportion of heat-tolerant individuals]
- Extinction.

In many individual studies, careful experimental design or direct tests of other possible driving factors make attribution of response to climate change possible with medium to high confidence. These studies address three questions (see Sections 5.4 and 19.2):

- Are changes observed in natural systems during the 20th century in accord with predictions from known effects of climate and from bioclimatic theory?

- Given that species, communities, and ecosystems are responding to a complex function of factors, do statistical analyses identify climatic components that statistically explain most of the observed change?
- If so, how can these results guide future predictive models of biotic response to climate change?

Studies of responses to past large-scale climatic changes during the Pleistocene ice ages and the early Holocene provide a good basis for predicting biotic responses to current climate change. Overwhelmingly, the most common response was for a species to track the climatic change such that it maintained, more or less, a species-specific climatic envelope in which it lived or bred. Typically, a species' range or migratory destination shifted several hundreds of kilometers with each 1°C change in mean annual temperature, moving poleward and upward in altitude during warming trends (Barnosky, 1986; Woodward, 1987; Goodfriend and Mitterer, 1988; Davis and Zabinski, 1992; Graham, 1992; Baroni and Orombelli, 1994; Coope, 1995; Ashworth, 1996; Brandon-Jones, 1996). Extinctions of entire species, as well as observable evolutionary shifts, were rare. Phenological shifts may have occurred but cannot be detected with Pleistocene data.

For very mobile or migratory animals—such as many birds, large mammals, pelagic fish, and some insects—shifts of species range occur when individuals move or migration destinations change. Thus, these movements actually track yearly climatic fluctuations. In contrast, most wild species, especially plants, are sedentary, living their lives in a single spot because they have limited mobility or because they lack behavioral mechanisms that would cause them to disperse from their site of birth. Rather than occurring by individual movements, range changes in sedentary species operate by the much slower process of population extinctions and colonizations. Intertidal organisms represent a mix of these two extremes: Adults frequently are completely sedentary, but many species have free-floating planktonic larvae. The dispersal of this early life-history phase is heavily governed by ocean currents. As a result, changes in distribution are driven by a combination of changes in strength and pathways of currents as well as general changes in sea temperature.

2.2.1.3. Bioclimatic Models

A variety of modeling techniques have been used to determine the strength of association between suites of biotic and abiotic variables and species distributions. These associations can then be used to predict responses to environmental change, including climatic change. Bioclimatic models encompass a wide range of complexity. The simplest model is described as a "climate envelope." It is designed to describe static associations between a species' distribution and a single set of climatic variables (Grinnell, 1924, 1928). Modern statistical analyses and improved computer power have facilitated determination of complex suites of climatic and nonclimatic variables that correlate with the range boundaries for a given species (e.g.,

software such as BIOCLIM and GARP) (Stockwell and Noble, 1991). These models incorporate biological realism, such as local adaptation and differences in the nature of range limitations at different edges. Modern biogeographic models have demonstrated a high level of predictive power in cross-validation tests (Peterson and Cohoon, 1999).

2.2.1.4. Strengths and Limitations of Data

In assessing the strengths of studies as indicators of response to climate change, it is helpful to consider where they lie along axes of time, space, and replication (numbers of populations, numbers of species, etc.). To assess changes in species distributions, data over large geographic areas are important, especially for areas that represent the boundaries of a species' range or migratory destination. To assess trends through time, frequent (yearly is ideal) observations over many decades are most informative. And to assess the generality of the result, good replication is necessary, with many populations/census sites per species to indicate distributional changes within species or many species per community to indicate community shifts.

2.2.1.5. Data and Response Types

Ranges of migratory or mobile species can be very sensitive to climate when individuals show an immediate response in their migratory destinations. As with climatic data itself, one then needs long time series to distinguish year-to-year variation (noise) from long-term trends. Distributions of sedentary species have an inherent lag time stemming from limited dispersal abilities. Neither the numbers of populations nor the geographic location of the range limit may fluctuate strongly between adjacent years, and detectable shifts in species ranges may take decades or even centuries. In such cases, data often are not continuous through time, although data for a single year can be taken as representative of the state of the species during the surrounding multi-year period.

In addition to these shifts in species distributions, a suite of more subtle “plastic” responses allow organisms to adjust seasonally to natural variations of climate. Phenological changes—that is, shifts in the timing of events—can be assessed. These events include dates of budburst, flowering, seed set, fruit ripening, hibernation, breeding, and migration (Yoshino and Ono, 1996; Bradley *et al.*, 1999; Menzel and Fabian, 1999). Changes in phenologies can be detected in a wide variety of organisms, but this requires studies conducted over several years, in which weekly or daily observations should be made before and during the target event (e.g., flowering). Remote-sensing data have the advantage that they can be analyzed for such effects years after the events, but they are limited to very general, community-wide questions such as dates when the ground begins to turn “green” from spring growth. They indicate trends only for the past 30 years because satellites with suitable detection equipment have been in place only since the early 1970s (Myneni *et al.*, 1997). There are very long-term records (i.e., centuries) in a

few unusual cases (Lauscher, 1978; Hameed, 1994; Sparks and Carey, 1995), but most monitoring data also are in the realm of the past 30 years (see Sections 5.4 and 19.2).

A different type of rapid response—probably nongenetic—is exemplified by changes in body size of small mammals and lizards (Sullivan and Best, 1997; Smith *et al.*, 1998). Body size becomes smaller with general warming and larger with either cooling or increased variability of climate. This source of information has been studied with reference to historical climate (Morgan *et al.*, 1995; Hadly, 1997; Badgley, 1998); it has been unexplored with respect to current trends and should be given greater attention.

Attribution of an observed biological trend to effects of climate change rests on several grounds (Easterling *et al.*, 2000; Parmesan *et al.*, 2000), namely:

- Known fundamental mechanistic links between thermal/precipitation tolerances and species in the studies
- A large body of theory that links known regional climate changes to observed biotic changes
- Direct observations of climate effects in some studies.

2.2.2. Interpretation of Causation from Correlative Data

2.2.2.1. Lines of Evidence

Attribution of observed changes in natural systems to the effects of climate change is analogous to attribution of anthropogenic greenhouse gases (GHGs) as causal factors of recent climate trends. Within the climate realm, the lines of evidence are as follows:

- 1) Knowledge of fundamental processes of atmospheric forcing by different gases and radiative features
- 2) Geological evidence that shows changes in particular atmospheric gases associated with changes in global climate
- 3) General circulation models (GCMs) that accurately “predict” climatic trends of the 20th century, based on fundamental principles of atmospheric forcing
- 4) Analyses of global mean temperature and precipitation records that indicate large variances within and among station data as a result of genuine climate variance, as well as errors and biases resulting from instrument change, location changes, or local urbanization. There are large differences in the length of records because stations have been added over the century. Total record length may vary widely. This necessitates large-scale analyses that average the effects over many hundreds or thousands of stations so that the true climate signal can emerge.

Analogs in the biological realm are as follows:

- 1) Knowledge of fundamental responses of organisms to climate and extreme events. This knowledge is based

on experimental work in the laboratory on physiological thresholds and metabolic costs of different thermal/water regimes, as well as experimental work in the field on ecological thresholds and fitness costs of different temperature/water treatments. In addition to these controlled, manipulated experiments, there are onsite observations of individuals and populations before and after particular weather events (e.g., documentation of population evolution of body size in birds caused by a single winter storm or a single extreme drought, or population extinctions of butterflies caused by a single midseason freeze or a single extreme drought year). The biological community generally accepts the assertion that climate is a major influence on the abundances and distributions of species.

- 2) Geological evidence that shows changes in global mean temperature associated with changes in the distributions of species. Species' ranges typically shifted toward the poles by about 400–2,000 km between glacial and interglacial periods (change of 4°C).
- 3) Ecological and biogeographic theory and models that accurately "predict" current distributions of species, based on fundamental principles of climatic tolerances.
- 4) Analyses of biological records starting from the 1700s, when the first researchers began to systematically record the timing of biological events and the locations of species. There are some variances within and among the historical records for any given species or locality as a result of genuine variance of the biological trait as well as small errors resulting from changes in the recorder, methods of recording, local urbanization, and other landscape changes. There are large differences in the length of records because interest in taking such records gradually has increased over the centuries. Total record length may vary from 300 to <10 years. This necessitates large-scale syntheses that assess the effects over many hundreds of species or studies so that any true global climate signal can emerge.

2.2.2.2. Complex Systems and Responses

Interpretation of changes in marine organisms is difficult because of the strong influence of oceanic currents on dispersal and local temperatures. As the links between ocean currents and atmospheric conditions become better understood, linking changes in marine biota to climate change will become easier.

Tree rings provide long series of yearly data spanning centuries, and data are easily replicated across taxa and geographic regions. The width of an annual ring indicates growth for that year, but growth is affected by disease, herbivory, acidification, nitrification, and atmospheric conditions [carbon dioxide (CO_2), ozone (O_3), ultraviolet (UV) radiation], as well as by yearly climate (Bartholomay *et al.*, 1997; Jacoby and D'Arrigo, 1997; Briffa *et al.*, 1998). Correlative studies can be conducted to assess the relative impacts of different climatic variables on tree rings by focusing on the 20th century, for which independent

climate data exist. If the correlations are strong, one can then attempt to reconstruct past climates (prior to the existence of climate stations) from the derived relationship. One cannot distinguish the primary cause of changes in ring width in any single case (Vogel *et al.*, 1996; Brooks *et al.*, 1998). However, because excellent geographic replication is possible, these complex causal factors can be statistically reduced to those with very large-scale effects; general global climatic conditions are one of the few factors that could simultaneously affect very distant organisms (Feng and Epstein, 1996; Tessier *et al.*, 1997; Briffa *et al.*, 1998).

Finally, an evolutionary response (a genetic change in a population/species) is possible (Berthold and Helbig, 1992; Rodríguez-Trelles *et al.*, 1996, 1998a). Modern molecular techniques make it possible to sequence DNA from small samples taken from museum specimens, which could then be compared to the DNA of current populations. Unfortunately, for most species, scientists do not yet know which genes are associated with climatic adaptations, so this method cannot provide useful data for more than a handful of species that have been intensively studied genetically (Rodríguez-Trelles *et al.*, 1996; Rodríguez-Trelles and Rodriguez, 1998).

2.2.2.3. Methodological Considerations

Studies that relate observed changes in natural biota to climatic changes are necessarily correlational. It is not possible to address this question through a standard experimental approach, so direct cause-and-effect relationships cannot be established. However, the level of uncertainty can be reduced until it is highly unlikely that any force other than climate change could be the cause of the observed biotic changes. Studies can reduce uncertainty in three ways:

- Maximize statistical power
- Design to control for major confounding factors
- For confounding factors that remain, directly analyze whether they could explain the biotic changes and, if so, quantify the strength of that relationship.

Statistical power is gained by using:

- Large sample sizes (numbers of populations/numbers of species)
- Data gathered over a large region
- Studies conducted over multiple regions
- Studies conducted on multiple taxa (different families, orders, phyla, etc.)
- Selecting populations or species without *a priori* knowledge of changes to minimize sample bias
- Data gathered over a long time period such that bi-directional responses to opposite climatic trends may be detected.

Confounding factors can be addressed in a correlational study. Biologists know that many nonclimatic anthropogenic forces

affect population dynamics, community stability, and species distributions. These forces fall largely under the main headings of land-use change, hydrological changes, pollution, and invasive species. The term “land-use change” comprises a suite of human interventions that eliminate or degrade natural habitats, leading to loss of species that are dependent on those habitats. Habitat loss can be overt destruction, as occurs with urbanization, conversion to agriculture, or clear-cut logging. Habitat degradation is more subtle; it usually results from changes in land management, such as changes in grazing intensity/timing, changes in fire intensity/frequency, or changes in forestry practices (coppicing, logging methods, reforestation strategies), as well as irrigation dams and associated flood control. Loss of habitat by either means not only causes extinctions at that site but endangers surrounding good habitat patches by increased fragmentation. As good habitat patches become smaller and more isolated from other good patches, the populations on those patches are more likely to become permanently extinct.

The main airborne pollutants that are likely to affect distributions and compositions of natural biotic systems are sulfates, which lead to acid rain; nitrates, which fertilize the soil; and CO₂, which affects basic plant physiology (particularly the carbon/nitrogen ratio). Urban areas, in addition to having locally high amounts of sulfates and nitrates, are artificial sources of heat. Aquatic and coastal marine systems suffer from runoff of fertilizers and pesticides from agricultural areas and improperly treated sewage, as well as fragmentation from dams and degradation resulting from trawling, dredging, and silting.

These confounding factors cannot be completely eliminated, but their influences can be minimized by (Parmesan, 1996, 2001; Parmesan *et al.*, 1999):

- Conducting studies away from large urban or agricultural areas
- Conducting studies in large natural areas (e.g., northern Canada, Alaska, areas in Australia)
- Choosing individual sites in preserved areas (national parks/preserves, field stations)
- Eliminating from consideration extreme habitat specialists or species known to be very sensitive to slight human modifications of the landscape.

If a particular confounding factor cannot be greatly minimized, it should be measured and analyzed alongside climatic variables to assess their relative effects.

Ideal target species, communities, or systems in which to look for biotic responses to climate change meet the following criteria (DeGroot *et al.*, 1995; Parmesan, 2001):

- Basic research has led to a process-based understanding of underlying mechanisms by which climate affects the organism or community. This knowledge may come from experimental laboratory or field studies of behavior and physiology or from correlational studies between field observations climatic data.

- The target is relatively insensitive to other anthropogenic influences, so the effects of possible confounding factors are minimized.
- Short (decadal) or no lag time is expected between climate change and response [e.g., tree distributional responses may have a lag time of centuries, so they may not be ideal for looking for distributional changes over recent decades (Lavoie and Payette, 1996)].
- There are good historical records, either from being a model system in basic research or by having a history of amateur collecting.
- Current data are available (from monitoring schemes, long-term research) or are easy to gather.

Use of indicator species or communities is crucial for defining the level of climate change that is important to natural systems and for giving baseline data on impacts. However, caution is advisable when extending these results to predictive scenarios because the indicators often are chosen specifically to pinpoint simple responses to climate change. Thus, these studies purposefully minimize known complexities of multiple interacting factors, such as:

- The direct effects of CO₂ on plants may vary with temperature.
- The outcome of competitive interactions between species is different under different thermal regimes (Davis *et al.*, 1998), and, conversely, competitive environment can affect sensitivity and response to particular climatic variables (Cescatti and Piutti, 1998).
- Different species have different lag times for response, which inevitably will cause the breakup of traditional communities (Davis and Zabinski, 1992; Overpeck *et al.*, 1992; Root and Schneider, 1995).
- The ability of wild plant and animal life to respond to climate change through movement is likely to be hindered by human-driven habitat fragmentation; those with lowest dispersal will be most affected (Hanski, 1999).

2.2.3. Detection in Managed Systems

2.2.3.1. Human Health

Because many wild organisms serve as vectors for human diseases, and these diseases are very well documented historically (with records going back hundreds of years), one might think of using the distribution and intensity of disease occurrence as an indicator of shifts in wild vector distributions or altered dynamics of pathogen transmission. Many disease vectors are known to be strongly influenced by climate (e.g., the anopheline mosquitoes that carry malaria).

The problem with using disease records is that the presence of the vector is necessary but not sufficient to cause disease transmission. Socioeconomic factors—such as sanitation systems, vaccination programs, nutritional conditions, and so forth—largely determine whether the presence of the disease in wild vectors actually

leads to outbreaks of disease in nearby human populations. In fact, transmission and virulence of disease are themselves directly affected by climate. Thus, although disease is a potentially important component of climate change impacts, it is not a useful indicator of the direct effects of climate change (see Chapter 9 and Section 19.2).

2.2.3.2. Agriculture

Crop plants, like plants in general, are more strongly affected by the direct effects of increased atmospheric CO₂ than are animals. Increased CO₂ alters the physical structures and the carbon/nitrogen balance in plants—which in turn alters the plant's growth rate, yield, susceptibility to pest attack, and susceptibility to water stress. These effects interact with the effects of climate change itself in complex ways. In addition, the effects of climate change are buffered in agricultural systems as farming methods are altered to adjust to current climate conditions (e.g., irrigation practices, crop varieties used) (see Sections 5.3 and 19.2). A few selected attributes and systems may be possible indicators of climate change effects. Possible traits are leafing dates of grapevines in orchard with old stock, and planting dates of yearly crops in areas that have not changed seed variety over a given length of time.

2.2.4. Advances since the SAR and Future Needs

Since the SAR, methods have been developed and applied to the detection of present impacts of 20th-century climate change on abiotic and biotic systems. Assessment of impacts on human and natural systems that already have occurred as a result of recent climate change is an important complement to model projections of future impacts. How can such effects be detected? Such detection is impeded by multiple, often intercorrelated, nonclimatic forces that concurrently affect those systems. Attempts to overcome this problem have involved the use of indicator species to detect responses to climate change and infer more general impacts of climate change on natural systems. An important component of this detection process is the search for systematic patterns of change across many studies that are consistent with expectations on the basis of observed or predicted changes in climate. Confidence in attribution of these observed changes to climate change increases as studies are replicated across diverse systems and geographic regions. Even though studies now number in the hundreds, some regions and systems are underrepresented. However, there is a substantial amount of existing data that could fill these gaps. Organized efforts are needed to identify, analyze, and synthesize those data sets.

2.3. Anticipated Effects of Climate Change

2.3.1. Background

This section outlines recent developments of methods and tools that are used to anticipate the effects of climate change—the

broad approaches to climate change impact and vulnerability assessment. It considers future research and development needs, particularly to facilitate more informed policy decisions.

Based on interviews with experts and reviews of impacts methodologies, seven questions frame recent progress and needs for impacts methods and tools:

- 1) What are the appropriate scales of analysis for impact assessments?
- 2) What should be the baselines for comparison?
- 3) How should integrated scenarios of climatic and socioeconomic change be used?
- 4) What are the prospects for assessing the impacts of climatic extremes and variability?
- 5) How can transient effects be included in methods and tools?
- 6) What is the recent progress in methods for assessing adaptive capacity?
- 7) How can vulnerability be related to policies for reducing GHG emissions?

Conclusions are provided in the following subsections; the succeeding subsections provide further insight.

2.3.2. What are the Appropriate Scales of Analysis for Impact Assessments?

Climate change impact assessments must begin with decisions about the scope and scale of the assessment: What are the main policy issues? What and who are exposed to climate change impacts? What is the appropriate scale—time frame, geographical extent, and resolution? Considerable progress has been achieved since the SAR in raising such framing questions at the outset of an assessment cycle, often in conjunction with representative stakeholders (see Carter *et al.*, 1994; Downing *et al.*, 2000).

Methods for identifying policy issues include checklists and inventories, document analysis, surveys and interviews, and simulations. The process of determining the scope of assessment should be iterative. The project design should specify what and who is exposed to climate change impacts—economic sectors, firms, or individuals. Evaluation of adaptation strategies should be cognizant of actors involved in making decisions or suffering consequences.

The choice of temporal scales, regional extent, and resolution should be related to the focus of the assessment. Often, more than one scale is required, under methods such as strategic scale cycling (Root and Schneider, 1995) or multi-level modeling (e.g., Easterling *et al.*, 1998). Linkage to global assessments may be necessary to understand the policy and economic context (e.g., Darwin *et al.*, 1995).

The most common set of methods and tools remains various forms of dynamic simulation modeling, such as crop-climate models or global vegetation dynamic models. A major

improvement in impact modeling has been application of process-oriented models, often with geographically explicit representations, instead of models that are based on correlations of climatic limits. Data for running and validating models is a recurrent issue. Intermodel comparisons have been undertaken in some areas (e.g., Mearns *et al.*, 1999), but much remains to be done.

Climate change is likely to have multiple impacts across sectors and synergistic effects with other socioeconomic and environmental stresses, such as desertification, water scarcity, and economic restructuring. Most studies (especially as reported in the SAR) have focused on single-sector impacts. Relatively few studies have attempted to integrate regionally or even identified segments of the population that are most at risk from climate change.

Vulnerability assessment may be one way of integrating the various stresses on populations and regions arising from climate change (see Briguglio, 1995; Clark *et al.*, 1998; Huq *et al.*, 1999; Kaly *et al.*, 1999; Mimura *et al.*, 2000; Downing *et al.*, 2001). There are some areas in which formal methods for vulnerability assessment have been well developed (e.g., famine monitoring and food security, human health) and applied to climate change. However, methods and tools for evaluating vulnerability are in formative stages of development.

Further development of methods and tools for vulnerability assessment appears warranted, especially for the human dimensions of vulnerability, integration of biophysical and socioeconomic impacts, and comparison of regional vulnerability. Conceptual models and applications of the evolution of vulnerability on the time scale of climate change are required. Formal methods of choosing indicators and combining them into meaningful composite indices must be tested. Combining qualitative insight and quantitative information is difficult but essential to full assessments. Finally, improved methods and tools should facilitate comparison of vulnerability profiles between at-risk regions and populations and highlight potential reductions in vulnerability, through policy measures or the beneficial effects of climate change.

2.3.3. What should be the Baseline for Comparison?

Climate change impacts generally are agreed to be the difference between conditions with and without climate change. However, there is controversy among researchers about how to set the baseline for estimating impacts (or evaluating adaptation).

Most studies apply scenarios of future climate change but estimate impacts on the basis of *current* environmental and socioeconomic baselines. Although this approach is expedient and provides information about the sensitivity of current systems, it skirts the issue of evolving sensitivity to climatic variations (Parry and Carter, 1998). Even without climate change, the environment and societal baselines will change because of ongoing socioeconomic development and, with climate change,

because of system responses and autonomous adaptation (e.g., as described for Bangladesh—Warrick and Ahmad, 1996). Strictly speaking, the effects of climate change should be evaluated by taking the moving baseline into account (further discussion on socioeconomic, climate, and sea-level rise scenarios appears in Chapter 3).

Given the uncertainty of the future and the complexity of the various driving forces affecting any given exposure unit, a wide range of different assumptions about future baselines is plausible. The emission scenarios in the *Special Report on Emissions Scenarios* (SRES) reflect this perspective and are based on multiple projections of “alternative futures” (see Chapter 3). Framing local concerns for adaptation to changing risks may require exploratory scenarios, extending the coarse driving forces inherent in the SRES suite. For example, coping with water shortages in Bangladesh is sensitive to scenarios of regional collaboration with India and Nepal (e.g., Huq *et al.*, 1999). For vulnerability and adaptation assessment, there is little apparent consistency regarding elements or procedures for development of these future baselines, including who is exposed, how to select sensitive sectors, and the drivers of social and institutional change at the scale of stakeholders exposed to climate impacts.

2.3.4. How should Integrated Scenarios of Climatic and Socioeconomic Change be Used?

As a result of time lags in the impact assessment research cycle, impact assessment studies included in this Third Assessment Report (TAR) do not necessarily employ the set of Intergovernmental Panel on Climate Change (IPCC) reference scenarios outlined in Chapter 3. This time lag is unavoidable because it takes almost half a year to define emissions of GHG after setting socioeconomic scenarios. Following that, it usually takes several months to produce local climate change data used in impact assessment studies. Thus, most of the impact studies reported in the TAR are based on the set of IS92 emission scenarios developed for the IPCC in 1992 and included in the SAR (e.g., Parry and Livermore, 1999).

To assist researchers, the IPCC took the initiative to create the IPCC Data Distribution Centre (<http://ipcc-ddc.cru.uea.ac.uk/>) and posted the SRES scenarios on the Consortium for International Earth Science Information Network (CIESIN) Web site (<http://sres.ciesin.org/index.html>). The IPCC is responsible for distributing consistent scenarios, including socioeconomic trends and regional climate change data. Consistent use of common scenarios provides a consistent reference for comparing and interpreting the results of different studies.

Vulnerability assessments can be conducted on temporal and spatial scales where the effects of climate change could feed back to GHG emissions and climatic changes. In such cases, there may be reason to ensure that scenarios of climate change that are based on GHG emissions and scenarios of changing

social, economic, and technological conditions are consistent. This is essential for global assessments and integrated assessment (see Section 2.4). It may not be as critical for studies of local adaptation where there is little feedback between mitigation and adaptation, particularly over a typical planning horizon of several decades. Downscaling the global reference scenarios to local socioeconomic and political conditions remains a significant methodological challenge.

2.3.5. What are the Prospects for Assessing the Impacts of Climatic Extremes and Variability?

Discrete climatic events cause substantial damage. Heavy losses of human life, property damage, and other environmental damages were recorded during the El Niño-Southern Oscillation (ENSO) event of 1997–1998. Details are reported in the regional chapters on Africa, Asia, and the Americas, and Chapter 8 assesses the damages from a financial services perspective. For many policymakers and stakeholders, the impacts of climatic extremes and variability are a major concern (Downing *et al.*, 1999b). The uneven impacts of climatic hazards raises humanitarian concerns for development and equity.

An increase in variability and frequency of extreme events could have greater impacts than changes in climate means (e.g., Katz and Brown, 1992; Mearns, 1995; Semenov and Porter, 1995; Wang and Erda, 1996). Extreme events are a major source of climate impacts under the present climate, and changes in extreme events are expected to dominate impacts under a changing climate (see Section 12.1).

Methodological issues concerning extreme events in the context of climate change include developing climate scenarios, estimating impacts, evaluating responses, and looking at large-scale effects.

2.3.5.1. Developing Scenarios of Changes in Variability and Extreme Events

Working Group I discusses methodologies for estimating changes in variability from the results of GCMs (see Sections 9.3.2 and 13.4.2). Despite certain shortcomings, GCMs can provide estimates of trends in climatic variability (TAR WGI Section 9.1.5). Using extreme events from historical data as analogs also is useful.

The frequency of extreme events is likely to change as mean values shift, even without changes in variability. Chapter 3 reviews potential changes in different climatic elements (see Table 3-10).

From the instrumental record, some regional changes in extremes have been identified, although it is difficult to say whether they are related to GHG-induced climate change. For example, there has been a recent increase in heavy and extreme precipitation in the mid to high-latitude countries of the northern

hemisphere, and in several regions of east Asia a decrease in the frequency of temperature extremes together with heavy and extreme precipitation have been observed (see TAR WGI Chapter 2).

2.3.5.2. Estimating First-Order Impacts

Many models that validate well for present climate conditions may not respond realistically to future climatic conditions and subsequent changes in extreme events. For some sectoral impacts, however, methods for evaluating a system's response to changes in variability change are improving. One example is estimation of changes in flooding by using 10-year return periods given by transient GCMs and applied to a watershed model (Takahashi *et al.*, 1998).

2.3.5.3. Analyzing Institutional and Stakeholder Responses

Because of nonlinear relationships, an increase in variability can result in a substantial increase in the frequency of extreme impacts. If a climate element exceeds an acceptable risk threshold (e.g., when the design risk threshold for water storage is exceeded and water shortage is experienced with higher frequency), vulnerability will become “unacceptable.” One issue in adaptation is the level at which to set acceptable risks in the future. Stakeholder-determined thresholds are an emerging area of research in Australia (see Section 12.1), and methods to evaluate stakeholder and institutional learning in response to changing climatic hazards are being developed (see Bakker *et al.*, 1999; see also <<http://www.eci.ox.ac.uk>>). Decision analytical techniques are described below (Section 2.7). An alternative is an inverse approach that focuses on sensitivity to present risks, characterization of the kinds of changes in hazards that would have large effects, and evaluation of response capacities (Downing *et al.*, 1999a).

Research on discrete climatic events is an area that also needs further research. Present GCM resolutions have not achieved the ability to estimate the intensity, route, and frequency of discrete events such as hurricanes (or tropical cyclones) (TAR WGI Sections 9.3.6 and 13.4.2.2). Though there are some indications from GCMs that ENSO-like conditions will become more persistent with global warming (Timmermann *et al.*, 1999), it is still difficult to incorporate these estimates into vulnerability assessments (TAR WGI Sections 9.3.6.3 and 13.4.2.1).

Empirical/analog methods are suitable for assessment of discrete events. Such methods were applied for detailed analyses of damages incurred by ENSO in 1997–1998, as well as the 1998 cyclones in Bangladesh. This method is applied to “if-then” (i.e., if climate change occurs, then such and such impacts may be induced) simulations. For example, analogs from the 1930s Dust Bowl period detailing water shortages and reductions in agriculture yields have been used to simulate the impacts of climate change in the U.S. corn belt (Rosenberg, 1993).

2.3.5.4. Large-Scale Effects

Because unique or singular events, referred to as fiasco scenarios (see Section 19.5.3.3)—such as changes in the thermohaline circulation (Broecker, 1997) and potential destabilization of the West Antarctic Ice Sheet (Oppenheimer, 1998)—have not been proven implausible, there is a need for further studies of potential catastrophic events and unacceptable impacts. However, limited knowledge of such large-scale impacts poses a challenge; to date, systematic vulnerability assessments have not been carried out.

2.3.6. How can Transient Effects be Included in Methods and Tools?

Transient climate scenarios are now widely used in impact assessment—an improvement on earlier use of equilibrium climate scenarios (even if scaled to temporal projections) (see Chapter 3). A corresponding shift from static to dynamic, process-oriented impact models is apparent (as shown in the sectoral chapters).

Many models applied for predicting climate change effects on the behavior of an exposure unit are derived from equilibrium models. These include many basin watershed models, crop models for potential agricultural productivity, and potential vegetation models. With such models, the change effected on the unit at a fixed point in time is estimated, ignoring potentially relevant processes of change.

Systems often consist of elements with different time responses to climate change. This means that the present equilibrium will not be maintained in the next point of time. The velocity of change is a key factor in deciding this transient pattern.

Some terrestrial biosphere research illustrates that the world's biomes will not shift as homogeneous entities in response to changing climate and land use (see Section 5.2.1). Competition between individuals and species, modified disturbance regimes (e.g., fires, windstorms), and migration of species all lead to significant time lags in biospheric responses. Furthermore, if mortality from increased disturbance occurs faster than regrowth of other vegetation, there will be a net release of carbon to the atmosphere, which will change climate forcing. Responses may be a function of spatial scale as well. Dynamic global vegetation models illustrate the shift to transient, scalable impact models (e.g., Woodward *et al.*, 1995).

To ensure a temporally sensitive assessment, impact models should include the different time responses of the system. For example, impacts of malaria depend on human tolerance to repeated infection (Martens *et al.*, 1999). Alternatively, the value of climate change damages could be related to the rate of change rather than solely to the magnitude of climate change (Tol and Fankhauser, 1996). Understanding of the temporal interactions between climate change, impacts, and responses in a truly transient methodology is still a major methodological challenge.

2.3.7. What Recent Progress has been Made in Assessing Adaptive Capacity?

In recent years, assessment of adaptive capacity has emerged as a critical focus of attention, for two reasons: the realization that the Kyoto Protocol is inadequate to prevent substantial changes in climate, and the rising expectation that social and natural systems can cope with climate change, at least within limits, and that adaptation is a viable option to reduce GHG emissions.

Although there are numerous examples of model calculations for adaptive shifts in flora, far less attention has been paid to assessing the adaptability of the system as a whole (e.g., White *et al.*, 1999). In contrast with other phenomena, such as changes in the water cycle, changes in natural ecosystems are related to a long-term process of adaptation and extinction. As noted above, transient climate change scenarios have become a mainstream research procedure.

The recent literature concerned with the impacts of climate change on the managed environment [e.g., on agriculture (see Section 5.3) and coastal zones (see Section 6.7)] generally considers adaptive strategies (e.g., Rosenzweig and Parry, 1994). Water management, for example, has a long history of evaluation of strategies for adapting to climate change and variation (Frederick *et al.*, 1997). However, adaptation often is approached narrowly in terms of technological options. Adaptation processes—including the environmental, behavioral, economic, institutional, and cultural factors that serve as barriers or incentives to adaptation over time—often are not considered.

Five methodological directions could enhance future work on adaptation (see Chapter 18). First, methods for increasing understanding of the relationship between adaptation, individual decisionmaking, and local conditions are required. For example, adaptation by farmers could avoid more than half of the potential impacts of climate change on agriculture (e.g., Darwin *et al.*, 1995; El-Shaer *et al.*, 1997). The mix of appropriate measures depends, however, on the local context of soils, climates, economic infrastructure, and other resources (Rosenzweig and Tubiello, 1997) and how they are perceived by farmers. Assessments of adaptation could address these issues of site-scale characteristics and local knowledge, perhaps through participatory methods (e.g., Cohen, 1997, 1998) or interviews and expert opinion (as in the UK Climate Impacts Programme—Mackenzie-Hedger *et al.*, 2000; see <<http://www.ukcip.org>>).

Second, interactions across scale are likely to be significant for adaptation. In the agricultural sector, for example, adaptive strategies are influenced by multi-scale factors—at the farm, national, and global levels—and their integration into decisionmaking. Methods and tools for examining these multi-scale interactions and their implications for adaptation are required, such as multi-level modeling (Easterling *et al.*, 1998), integrated assessment (see Section 2.4), and agent-based simulation (Downing *et al.*, 2000).

Third, specific measures (such as changing planting dates and cultivars) and longer term adaptation strategies and processes (such as monitoring and research) need to be addressed. Many studies focus on the former; assessing the latter is a major methodological challenge.

Fourth, comparative frameworks are required for assessing the priority of adaptation strategies across populations, regions, and sectors, in addition to evaluating specific measures. Fankhauser (1998) devised a list of adaptation policy options, discussed conceptual issues of economic evaluation, and illustrated typical cost/benefit calculation methods. Section 2.5 considers the use of economic evaluation methods, but nonmonetary frameworks are alternatives (see Huq *et al.*, 1999, for a case example). Issues of equity and valuation on indirect benefits and costs are salient.

Fifth, adaptation to extremes and variability already are important areas of assessment (see above) but need to be more explicitly tied to longer term climate change.

Sixth, stakeholder evaluation of adaptation strategies and measures is required—for example, using decision analytical tools, as noted in Section 2.7. Indicators of vulnerability could be used to monitor the effectiveness of adaptive strategies and measures (see Downing *et al.*, 2001).

2.3.8. How can Vulnerability Assessments be Related to Policies for Reducing GHG Emissions?

One approach to mitigation policy is to evaluate targets for reducing GHG emissions on the basis of reductions in vulnerability, rather than GHG concentrations or similar indirect measures of dangerous climate change. By applying existing methods for impact analysis, it is possible to invert the assessment procedure and start with defined sets or windows of impacts that are judged to be tolerable for humankind. This procedure results in emission corridors that embrace all future GHG emissions that are compatible with changes defined to be tolerable—the “safe landing” approach (WBGU, 1995; Alcamo and Kreileman, 1996; Petschel-Held *et al.*, 1999). This approach can be extended to include economic, social, or equity aspects—that is, to define tolerable windows for climate-related facets of these sectors and obtain emission corridors that simultaneously satisfy all possible windows (Toth *et al.*, 1997).

Such approaches require that climate impacts should be differentiated between smooth changes and thresholds that mark abrupt shifts in the system’s functioning. In the latter case, the definition of tolerable windows appears to be quite obvious: Damaging, abrupt shifts should be avoided. In the case of smooth changes, specification of tolerable windows is more difficult, confounded in part by uncertainty about adaptation.

Normative decisions on tolerable windows must be a consultative process involving scientists in close cooperation with stakeholders, decisionmakers, nongovernmental organizations (NGOs), and

others. There are various designs for this participatory process, such as policy exercises (Toth, 1986, 1988a,b) or what is known as the Delft Process (van Daalen *et al.*, 1998). Nevertheless, specification of windows remains somewhat arbitrary and preferably is used as an assumption in an “if-then” analysis rather than as an ultimate specification.

Methodological challenges include development and validation of reduced-form models, devising robust damage functions, identifying thresholds in adaptive systems, and concerns for equity in relating the distribution of impacts to systemic vulnerability.

2.4. Integrated Assessment

Policymakers require a coherent synthesis of all aspects of climate change. Researchers have spent the past decade developing integrated assessment methods to meet these needs of policymakers. An overview of the framework, including examination of impact and vulnerability, is in the SAR (Weyant *et al.*, 1996). In addition, Rotmans and Dowlatabadi (1998) have concentrated on the broader social science components of integrated assessment; as a result, they came closer to presenting a view within which impacts and adaptation might be most fully investigated with and without relying on models. They assert, “Integrated assessment is an interdisciplinary process of combining, interpreting, and communicating knowledge from diverse scientific disciplines in such a way that the whole set of cause-effect interactions of a problem can be evaluated.” Current integrated assessment efforts generally adopt one or more of four distinct methodological approaches:

- Computer-aided modeling in which interrelationships and feedbacks are mathematically represented, sometimes with uncertainties incorporated explicitly (see Chapter 19)
- Scenario analyses that work within representations of how the future might unfold [the MINK study, based on a climate analog of the dust bowl climate of the 1930s, is a classic example (see Rosenberg, 1993, for details)]
- Simulation gaming and participatory integrated assessment, including policy (see Parson and Ward, 1998, for a careful review)
- Qualitative assessments that are based on limited and heterogeneous data and built from existing experience and expertise. Cebon *et al.* (1998) contains a collection of papers that offer similar qualitative coverage; their insights can serve as the basis for a long-run research agenda that looks for regions and sectors in which uncertain futures most significantly cloud our view of where and when impacts might be most severe.

Schneider (1997) has developed a taxonomy of integrated assessments that creates an historically rooted taxonomy of modeling approaches. It begins with “premethodological assessments” that worked with deterministic climate change, with direct causal links and without feedbacks. It ends with “fifth-generation” assessments that try to include changing values

explicitly. In between are three other stages of development, differentiated in large measure by the degree to which they integrate disaggregated climate impacts, subjective human responses, and endogenous policy and institutional evolution.

Methodological bias is an issue in interpreting the results of integrated assessments, as it is in every research endeavor. Schneider (1997) also warns that models composed of many submodules adopted from a wide range of disciplines are particularly vulnerable to misinterpretation and misrepresentation. He underscores the need for validation protocols and explorations of predictability limits. At the very least, integrated assessments must record their underlying value-laden assumptions as transparently as possible. Including decisionmakers and other citizens early in the development of an assessment project can play an essential role in analytical processes designed to produce quality science and facilitate appropriate incorporation of their results into downstream decisions.

In the past decade, several research teams have been working on the development of such frameworks (see Tol and Fankhauser, 1998, for a compendium of current approaches). Known as integrated assessment models (IAMs), these frameworks have been used to evaluate a variety of issues related to climate policy. Although the current generation of IAMs vary greatly, in scope and in level of detail, they all attempt to incorporate key human and natural processes required for climate change policy analysis. More specifically, a full-scale IAM includes submodels for simulating:

- Activities that give rise to GHG emissions
- The carbon cycle and other processes that determine atmospheric GHG concentrations
- Climate system responses to changes in atmospheric GHG concentrations
- Environmental and economic system responses to changes in key climate-related variables.

Although IAMs provide an alternative approach to impact assessment, it is important to note that there is no competition between such integrated approaches and the more detailed sectoral and country case studies discussed in preceding sections. Each approach has its strengths and weaknesses and its comparative advantage in answering certain types of questions. In addition, there are considerable synergies between the two types of studies. Integrated approaches depend on more disaggregated efforts for specification and estimation of aggregate functions and, as such, can be only as good as the disaggregated efforts. Reduced-form integrated approaches make it relatively easy to change assumptions on the “causal chain.” That is, one can identify critical assumptions upon which a policy analysis might turn.

In conducting such sensitivity analyses, one can identify where the value of information is highest and where additional research may have the highest payoff from a policy perspective. This can provide some useful guidance to the impacts community about where to direct their efforts to resolve uncertainty. At the

same time, integrated models become more useful as uncertainty is narrowed (through the contributions of partial impact assessments); hence, the reduced-form representations become more realistic.

2.4.1. Integrated Assessment Analyses

There are many different approaches within the family of integrated models. This diversity is important for a balanced understanding of the issues because different types of models can shed light on different aspects of the same problem. For example, many analyses start with a particular emissions baseline and examine the economic and ecological implications of meeting a given emissions target (e.g., Alcamo, 1994; Edmonds *et al.*, 1997; Morita *et al.*, 1997b; Murty *et al.*, 1997; Yohe, *et al.*, 1998; Jacoby and Wing, 1999; Nordhaus and Boyer, 1999; Tol, 1999a,b; Yohe and Jacobsen, 1999). In such analyses, impacts are first assessed under a so-called “business-as-usual” or reference-case scenario. The analysis is then repeated with a constraint on the future. The change in impacts represents the climate-related benefits of the policy.

Other approaches select a different starting point. For example, Wigley *et al.* (1996) begin with atmospheric CO₂ concentrations and explore a range of stabilization targets. For each target they employ “inverse methods” to determine the implications for global CO₂ emissions. Recognizing that a particular concentration target can be achieved through a variety of emission pathways and that impacts may be path-dependent, they identify the implications of the choice of emissions pathway on temperature change and sea-level rise.

Two other approaches—“tolerable windows” (Toth *et al.*, 1997; Yohe, 1997; Petschel-Held *et al.*, 1999; Yohe and Toth, 2000) and “safe corridors” (Alcamo *et al.*, 1998)—also utilize inverse methods but begin further down the causal chain. Here the focus is on the range of emissions that would keep emission reduction costs and climate change impacts within “acceptable” limits. Working with policymakers, the analysts identify the set of impacts for consideration. Bounds are specified, and the cost of achieving the objective is calculated. If mitigation costs are deemed too costly, policymakers have the opportunity to relax the binding constraint. In this way, the team is able to move iteratively toward an acceptable solution.

Integrated assessment analyses also can be distinguished by their approach to optimization. For example, the focus of the UNFCCC is cost-effectiveness analysis. Article 2 states that the ultimate goal is “stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system.” Mitigation cost is more of a consideration in how the target is to be achieved. The Convention states that policies and measures to deal with climate change should be cost-effective to ensure global benefits at the lowest possible cost. Several analysts, beginning with Nordhaus (1991), have identified the least-cost path for achieving a particular concentration target.

Despite the goal of the UNFCCC, several integrated assessment frameworks are designed for benefit-cost analyses. These models identify the emissions pathway that minimizes the sum of mitigation costs and climate change damages. Such policy optimization models have been developed by Nordhaus (1991, 1992, 1994b), Peck and Teisberg (1992, 1994, 1995), Chattopadhyay and Parikh (1993), Parikh and Gokarn (1993), Maddison (1995), Manne *et al.* (1995), Manne and Richels (1995), Nordhaus and Yang (1996), Yohe (1996), Edmonds *et al.* (1997), Tol (1997, 1999c,d), and Nordhaus and Boyer (1999).

2.4.2 The State of the Art

Treatment of impacts in these models also varies greatly. Generally, however, impacts are one of the weakest parts of IAMs. To a large extent this is a reflection of the state of the art of the underlying research, but it also reflects the high complexity of the task at hand (see Tol and Fankhauser, 1998, for a survey). Despite the growing number of country-level case studies, our knowledge about climate change and climate change impacts at the regional level remains limited. A coherent global picture, based on a uniform set of assumptions, has yet to emerge. The basis of most global impact assessments remain studies undertaken in developed countries (often the United States), which are then extrapolated to other regions. Such extrapolation is difficult and will be successful only if regional circumstances are carefully taken into account, including differences in geography, level of development, value systems, and adaptive capacity. Not all analyses are equally careful in undertaking this task, and not all models rely on the latest available information in calibrating their damage functions.

The actual functional relationships applied in many integrated models remain simple and often ad hoc. This reflects our still poor understanding of how impacts change over time and as a function of climate parameters. Impacts usually are a linear or exponential function of absolute temperature, calibrated around static “snapshot” estimates (such as 2xCO₂) without distinguishing the different dynamics that may govern impacts in different sectors. Developing a better understanding of these relationships is one of the most important challenges for integrated model development.

Baseline trends—such as economic development, population growth, technological progress, changes in values, natural climate fluctuations, and increased stress on natural ecosystems—have strong repercussions for climate change vulnerability (e.g., Mendelsohn and Neumann, 1999). They must be better understood and their effect incorporated in the models. Unfortunately, these trends are inherently difficult, if not impossible, to predict over the longer term. This generic problem will not go away, but it can be overcome, at least partly, through broad scenario and sensitivity analysis.

Another key challenge is taking adaptation into account. Adaptation can significantly reduce people’s vulnerability to climate change, as shown in Chapter 18. However, adaptation

can take many different forms and is correspondingly difficult to model (see Section 19.4). To date there are no IAMs available that can adequately represent or guide the full range of adaptation decisions.

2.5. Methods for Costing and Valuation

Since the SAR, costing and valuation methods have been used increasingly to quantify the cost of potential impacts; these costs include the costs of adaptations required specifically to respond to climate change and climate variability, as well as the costs of residual damages. The bulk of this section focuses on the foundation of economic costs, but there are metrics other than the economic paradigm; these are reviewed briefly in Section 2.3.6.

Researchers have adapted fundamental costing and valuation techniques drawn from the economic paradigm to handle the complexities of increasingly intricate applications. Market mechanisms provide important ways with which we can aggregate across a diversity of individual valuations, but they are tied to historical distributions of resources. Other mechanisms have been exercised, and this section begins by displaying their conceptual foundations within the economic context from which they have all evolved. It proceeds by suggesting how relaxing each underlying economic assumption has been a conceptual challenge. Many of the responses to these challenges, however, are now part of the general economic paradigm.

2.5.1. Elements of Costing and Valuation Methods

2.5.1.1. Opportunity Cost and the Foundations of Valuation Methods

Opportunity cost is the fundamental building block of modern economic analysis. The true economic cost of one unit of some good X reflects the cost of opportunities foregone by devoting resources to its production. This cost measures the economic value of outputs, goods, and services that would have been possible to produce elsewhere with the resources used to produce the last unit of good X. The social opportunity cost of employing a resource for which there is no alternative economic use is thus zero, even if its price is positive, and opportunity cost will be different under conditions of full employment than under circumstances involving large quantities of visible or invisible unemployment. Moreover, opportunity cost applies only to small “marginal” changes from equilibrium in systems for which there are multiple equilibria. Likewise, the marginal benefit from consuming good X is the value of the last unit purchased, measured in terms of a real price that reflects the welfare that would have been enjoyed if the requisite expenditure had been devoted to consuming another good (or goods).

These concepts may appear circular, but that is an artifact of the circular nature of economic systems. Suppliers of some

economic goods are consumers of others. The opportunity cost of a good to the producer and the marginal benefit to the consumer are equal when all of the following conditions are obtained:

- All markets are perfectly competitive.
- Markets are comprehensively established in the sense that all current and future property rights are assigned.
- Marketed goods are exclusive (ownership is singular and well defined) and transferable (goods can be bought, sold, or given away).
- The underlying social and legal systems guarantee that property rights are (reasonably) secure.
- There are no transaction costs involved in creating and/or maintaining any current or future market.
- There is perfect and complete information about all current and future markets.

Under these conditions, the marginal opportunity cost of any good with multiple uses or multiple demanders is equal to its marginal benefit. Marginal (opportunity) cost and marginal benefit then match the accounting price that can be read from the market, and economic efficiency is assured in the sense that nobody can be made better off without hurting somebody.

It is not difficult, of course, to think of circumstances in which one or more of these conditions do not hold (and this is not news to the economics profession). Much of modern economics has been devoted to exploring how to measure and compare costs and benefits when these conditions break down. For researchers interested in impacts, however, theoretical results are less important than some practical insight into what to do.

Theory instructs, for example, that producers who have some monopoly power in imperfectly competitive markets would restrict output compared to the quantity that would prevail in a competitive market. Consequently, marginal opportunity cost would fall short of marginal benefit even if all of the other assumptions held, and the market price would overestimate marginal cost by an amount that is related to the price elasticity of demand.

Markets can fail if production or consumption produces a positive or negative externality (i.e., if either provides extra benefit or imposes extra cost on some other actor in the economy). Externalities occur, for example, when a producer who pollutes the air or water or contributes to GHG-induced warming does not pay the cost that this pollution imposes on others. Theory tells us that the private opportunity cost that might be reflected in the market price of even a competitive market would then underestimate or overestimate the true social (opportunity) cost, depending on whether the externality were positive or negative. By how much? There is the rub.

Goods whose consumption is not exclusive tend to be provided publicly. But how much should be provided? Theory reports that public goods should be provided up to the point at which the sum of marginal benefits across all consumers equals the

marginal opportunity cost of provision. How much should be charged for “consuming” such a good? That price could fall to zero if the good is truly nonexclusive. In these cases, people have an incentive not to reveal their true preferences, so there is a tendency for such goods to be underprovided.

Transaction costs can drive a measurable wedge between marginal opportunity cost and marginal benefit, sometimes to the point at which markets fail completely. Can opportunity cost or marginal benefit be measured when markets do not exist? If not, what then? The growing field of nonmarket valuation might then apply (see Section 2.3.3).

Uncertainty causes problems as well. Theory speaks of risk premiums and offers models of how people make decisions under uncertainty. Information can reduce risk and uncertainty, so it has value. Uncertainty can even cause markets to fail. The key is to keep track of who knows what and when they know it. It also is essential to understand why people and institutions find some information credible and other information incredible. These are questions whose answers confound cost accounting and valuation exercises.

The passage of time and the prevalence of asymmetric information raise issues of completeness and comprehensiveness. All of the markets that are necessary to sustain efficiency probably do not exist, particularly if future property rights and future participants are not reflected in the current workings of existing markets.

Finally, economic efficiency says little about equity. Indeed, the second theorem of welfare economics indicates that the aforementioned conditions (plus a few technicalities) are sufficient to guarantee that a market-based equilibrium derived from any initial distribution of economic resources will be efficient in the sense that nobody can be made better off without making somebody else worse off (see Varian, 1992, Section 17.7). This does not mean that the market equilibrium would be equitable. Nor does it mean that economics has nothing to say about equity. It also does not mean that there is no cost associated with inequity (even in economic terms). It does mean, however, that care must be taken to keep track of the distribution of resources and to highlight the possible tradeoff between equity and efficiency.

2.5.1.2. Specifying the Baseline

Each of the foregoing assumptions represents a qualitative dimension along which the baseline of an impact assessment must be defined. A researcher who wants to estimate the costs or benefits of changing conditions must define as fully as possible the socioeconomic, political, institutional, and cultural environments within which the change will be felt. A “first-best” analysis assumes that everything works efficiently in response to changing conditions in the context of all of the right information; results of first-best analyses reflect benchmarks of “best-news” scenarios. Second-best analyses assume that distortions caused by the failure of some or all of these

assumptions to hold will diminish the efficiency of the first-best world; they can produce dramatically different answers to cost and valuation questions. Indeed, baselines that are constructed to reflect the global externalities of climate change by definition reflect second-best circumstances.

It may be reasonable to assume that distortions will persist as change occurs over the short run. Making the same assumption over the long run could be a mistake, however. Will information not improve over time? If distortions are costly, they may persist over the long term if the beneficiaries have sufficient power to preserve their advantage. There is no right way to do second-best analysis; it is simply incumbent on the researcher to report precisely what assumptions define the baseline.

2.5.1.3. Discounting the Future

The discount rate allows costs and values occurring at different times to be compared by converting future economic values into their equivalent present values. Formally, the present value of some cost C_t that will come due in t years is

$$C_t / (1+d)^t,$$

where d is the appropriate discount rate. The discount rate is non-negative because resources invested today in physical and human capital usually can be transformed into more resources later on. The IPCC and others have focused an enormous amount of attention on the discount rate (for detailed discussions see Arrow *et al.*, 1996; Portnoy and Weyant, 1999; Chapter 1 of this volume). Toth (2000b) provides a review of this and other more recent literature, with particular emphasis on the implications of discounting to issues of intergenerational equity.

2.5.2. Market Impacts

Cost and valuation exercises work best when competitive markets exist. Even when markets are distorted, they provide some useful information. This section offers brief insights into how the elements described can be applied in these situations.

2.5.2.1. Deadweight Loss

Deadweight loss is a measure of the value of aggregate economic welfare that is lost when marginal social opportunity cost does not equal marginal social benefit. Aggregate economic welfare can be regarded as the sum of the total benefit derived from consuming a specific quantity of a specific good, net of the total opportunity cost of its production. Aggregate welfare is maximized in a competitive market. Deadweight loss therefore can be computed as the difference between economic welfare generated in a distorted market and economic welfare attained at the social optimum of a competitive market. More specifically, it is estimated as the area under a demand curve that reflects marginal social benefits and above a supply curve that reflects

marginal social cost between the observed or anticipated outcome and the social optimum—the outcome that would equate marginal social costs and benefits. Moreover, changes in deadweight loss can be deduced by computing the appropriate areas even if the social optimum cannot be identified. In either case, deadweight loss simply is the sum of a change in private benefits, differences between social and private benefits, a change in private costs, and differences between social and private costs.

2.5.2.2. Preexisting Distortions

Market-based exercises that evaluate the costs and benefits of change must carefully account for preexisting distortions in markets. In the presence of one distortion, in fact, creation of another might actually improve welfare. Changes may or may not work to reduce preexisting distortions, so they actually can produce benefits that would be missed entirely if analyses were confined to competitive conditions. Goulder and Schneider (1999), for example, have noted that preexisting subsidies to conventional energy industries reduce the costs of climate policies but that preexisting subsidies to alternative energy industries would increase costs. Moreover, they point out that the opportunity costs of research and development (R&D) could be reduced or even reversed if there were an ample supply of R&D providers rather than a scarcity.

2.5.3. Nonmarket Impacts

Many impacts involve changes in the direct and/or indirect flows of valued services to society. These services can offer a wide range of valuable attributes, but they frequently go unpriced in the economic sense. Markets simply do not exist for some attributes and some services; contemplating markets for some others (e.g., health services) has been questioned even given extensive competition for services and products. For others, markets that do exist fall short of being comprehensive or complete in the presence of externalities of production or consumption. In either case (and others), researchers have recognized the need to develop alternative means with which to assess value. More precisely, they have tried to extend the scope of the economic paradigm so that implicit and explicit tradeoffs between development and conservation of unpriced resources can be explored within the structures of standard decision analytic tools such as cost-benefit analysis, cost-effectiveness analysis, and so on. Parikh and Parikh (1997, 1998) provide a primer on valuation with case studies.

To be more specific, economists have built a theory of choice on the basis of the notions of consumer sovereignty and rationality. Economists assume, therefore, that individuals are able to value changes in nonmarket goods and services as easily as they can value changes in marketed goods and services. The only difference between the two cases is that markets provide the researcher with some indirect data with which to assess individuals' values of marketed products. Nevertheless,

individuals should be able to tell researchers what they would be willing to pay for changes in nonmarket conditions or willing to accept as compensation for those changes. In fact, willingness to accept (WTA) payment for foregoing a good and willingness to pay (WTP) for a good are the two general yardsticks against which values are judged.

It should be noted that WTA and WTP are seldom the same for most nonmarket goods or services. In fact, WTA and WTP can give wildly different estimates of the value of these services if there are no perfect substitutes (i.e., if it is impossible to fully compensate individuals unit by unit for their loss). When such a substitute does not exist, $WTA > WTP$. By how much? Cummings *et al.* (1986) report that it is not uncommon for estimated WTA to be more than 10 times larger than estimated WTP. These differences might be derivative of the method of estimation, but they also reflect the fact that WTA and WTP are two different concepts that need not match.

It also should be noted that WTA and WTP have analogs in the market context. Compensated variation (CV) is the extra income that individuals would require to accept an increase in the price of some marketed good; CV is the analog of WTA. Equivalent variation (EV) is the income that individuals would be willing to forego to see the price of some marketed good fall; EV is the analog of WTP. These measures sometimes are used in market-based analysis. It should be no surprise that $EV < CV$ unless the good in question has a perfect substitute.

2.5.3.1. Direct Methods of Valuation

Valuation methods usually are divided into two distinct approaches. Direct methods try to judge individuals' value for nonmarketed goods by asking them directly. Contingent valuation methods (CVMs), for example, ask people for their maximum WTP to effect a positive change in their environments or their minimum WTA to endure a negative change. Davis (1963) authored the first paper to report CVM results for environmental goods. Comprehensive accounts of these methods appear in Mitchell and Carson (1989), Hanley and Spash (1993), and Bateman and Willis (1995). This is a controversial method, and current environmental and resource literature continues to contain paper after paper confronting or uncovering problems of consistency, bias, truth-revelation, embedding, and the like. Hanley *et al.* (1997) offer a quick overview of these discussions and a thorough bibliography.

2.5.3.2. Indirect Methods of Valuation

Indirect methods of valuation try to judge individuals' value for nonmarketed goods by observing their behavior in related markets. Hedonic pricing methods, for example, assume that a person buys goods for their various attributes. Thus, for example, a house has attributes such as floor area; number of bathrooms; the view it provides; access to schools, hospitals, entertainment, and jobs; and air quality. By estimating the demand for houses

with different sets of attributes, we can estimate how much people value air quality. One can thus estimate "pseudo-demand curves" for nonmarketed goods such as air quality. Travel costs are another area in which valuation estimates of the multiple criteria on which utility depends can be finessed out of observable behavior. The hedonic method was first proposed by Lancaster (1966) and Rosen (1974). Tiwari and Parikh (1997) have estimated such a hedonic demand function for housing in Bombay. Mendelsohn *et al.* (2000) brought the hedonic approach to the fore in the global climate impacts arena. Braden and Kolstad (1991) and Hanley and Spash (1993) offer thorough reviews of both approaches. Is there a scientific consensus on the state of the science for these methods? Not really. There is, instead, a growing literature that warns of caveats in their application and interpretation (e.g., health services) and/or improves their ability to cope with these caveats. Smith (2000) provides a careful overview of this literature and an assessment of progress over the past 25 years.

2.5.4. The Cost of Uncertainty

This section reviews the primary methods for incorporating uncertainty into analyses of climate impacts. Here we look at how to judge the cost associated with uncertainty. Cost and valuation depend, in general, on the entire distribution of the range of outcomes.

2.5.4.1. Insurance and the Cost of Uncertainty

Risk-averse individuals who face uncertainty try to buy insurance to protect themselves from the associated risk (e.g., different incomes next year or over the distant future, depending on the state of nature that actually occurs). How much? Assuming the availability of "actuarially fair" coverage (i.e., coverage available from an insurance provider for which the expected cost of claims over a specified period of time equals the expected income from selling coverage), individuals try to insure themselves fully so that the uncertainty would be eliminated. How? By purchasing an amount of insurance that is equal to the difference between the expected monetary value of all possible outcomes and the certainty-equivalent outcome that insurance would guarantee—the income for which utility equals the *expected utility of all possible outcomes*.

For a risk-averse person, the certainty-equivalent income is less than the expected income, so the difference can be regarded as WTP to avoid risk. In a real sense, therefore, willingly paid insurance premiums represent a measure of the cost of uncertainty. Therefore, they can represent society's WTP for the assurance that nondiversifiable uncertainty would disappear (if that were possible). Thus, this is a precise, utility-based measure of economic cost. The cost of uncertainty would be zero if the objective utility function were risk-neutral; indeed, the WTP to avoid risk is positive only if the marginal utility of economic activity declines as income increases. Moreover, different agents could approach the same uncertain circumstance with

different subjective views of the relative likelihoods of each outcome and/or different utility functions. The amount of insurance that they would be willing to purchase would be different in either case. Application of this approach to society therefore must be interpreted as the result of contemplating risk from the perspective of a representative individual. Yohe *et al.* (2000), for example, apply these structures to and offer interpretations for the distributional international impact of Kyoto-style climate policy.

2.5.4.2. The Value of Information

A straightforward method of judging the value of information in an uncertain environment has been developed and applied (see Manne and Richels, 1992, for an early and careful description). The idea is simply to compute the expected cost of uncertainty with and without the information and compare the outcomes. For example, it might be that improved information about the range of uncertainty might change the mean and the variance of associated costs. If the researcher were interested only in the resulting change in costs, however, the value of information would simply be the difference between expected cost with and without the new information, and only the mean would matter. If the same researcher wanted to represent the value of information in terms of welfare that displays some degree of risk aversion so that variance also plays a role, however, a comparison of insurance-based estimates of the WTP to avoid uncertainty would be more appropriate.

2.5.4.3. Uncertainty and Discounting

Uncertainty about costs and/or values that are incurred or enjoyed over time can be handled in two ways. One method calculates the present value across the full range of possibilities; means and distributions of present values are the result. The second method, reported in Arrow *et al.* (1996), converts outcomes at each point in time into their certainty equivalents and then applies discounting techniques. This approach raises the possibility of including risk aversion into the calculation according to the foregoing definition.

The story is quite different when uncertainty surrounds selection of the discount rate itself. It may not be appropriate, in these sorts of cases, to use a certainty-equivalent discount rate (or an average over the range of possible rates). Weitzman (1998) has noted, in particular, that the “lowest possible” discount rate should be used for discounting the far-distant future. The reason, quite simply, is that the expected value of present value over a range of discount rates is not equal to the present value calculated with an average rate. Moreover, the difference between the two is exaggerated in the distant future. Present values computed with low rates, in fact, can dominate those computed with high rates by orders of magnitude when the future is extended; thus, their contribution to the expected value must be recognized explicitly in the selection of a discount rate.

2.5.5. Equity and Distribution

Assessments of the impacts of alternative climate change scenarios require assessments of their impacts on different groups, societies, nations, and even species. Indeed, this report reveals that many sectors and/or regions are at greater risk to climate change than others. This section addresses this need.

2.5.5.1. Interpersonal Comparisons

First principles of economic theory offer two approaches for comparing situations in which different people are affected differently. In the first—the utilitarian approach attributed to Bentham (1822) and expanded by Mills (1861)—a situation in which the sum of all individual utilities is larger is preferred. Because Bentham’s view of utility reflected “pleasure” and “pain,” this approach embraces the “greatest happiness principle.” Many objections have been raised against it, however, primarily because the whole notion of interpersonal comparisons of utility is problematic. Indeed, Arrow (1951 and 1963) objected strenuously in arguing that “interpersonal comparisons in the measurement of utilities has *no meaning* and, in fact, there is no meaning relevant to welfare comparisons in the measurability of individual utility.” For example, it is impossible to compare the pleasure that a person receives from listening to a concert with what another gets from watching a dance. Second, maximizing the sum total of utility, if it were possible, would require that the marginal utilities of all individuals be equal. But this would say nothing about the level of utility for each individual. They could be quite different, so the utilitarian rule is insensitive to distributional issues except in the special case in which all individuals have identical utility functions.

These difficulties led to the development of a second approach—the welfarist approach, in which a social welfare function of individual utilities is postulated. Utilitarianism is thus a special case in which the social welfare function is simply the sum of individual utilities. There are other options, of course. The Gandhian principle, for example, can support a function that judges every possible action on the basis of its impact on the poorest of the poor.

It also is possible to compare two situations without defining an explicit social welfare function and without making interpersonal comparisons of individual utilities. The Pareto principle offers one method, by which one judges any situation better than another if at least one person is better off and no one else is worse off. A partial social ordering with which unambiguous comparisons can be made in some (but not all) cases can be constructed from the Pareto principle if cardinal utilities can be added across individuals, if society accepts the principle of anonymity (i.e., only the distribution matters, not which particular person is in a particular place), and if there is an aversion to regressive transfers (i.e., transfers from the poor to the rich). To see how, consider two situations, X and Y. Assume that there are n individuals ordered from poorest to richest. Let them have incomes (or utilities) $\{X_1, \dots, X_n\}$ and $\{Y_1, \dots, Y_n\}$ in X

and Y, respectively. X can be deemed preferable to Y if $X_1 \geq Y_1$, $[X_1 + X_2] \geq [Y_1 + Y_2]$, and so on through $[X_1 + \dots + X_n] \geq [Y_1 + \dots + Y_n]$, with at least one strict inequality holding. Note that showing that X is not preferred to Y is not sufficient to show that Y is preferred to X.

Rothschild and Stiglitz (1973) took these notions further by showing three alternative but equivalent ways of comparing distributions X and Y. They concluded that X would be preferred to Y if all of the following obtain:

- The Lorenz curve for X were inside the Lorenz curve for Y.
- All those who valued equality preferred X to Y.
- Y could be obtained from X by transfers from the poor to the rich.

Note, in passing, that Lorenz curves simply plot the percentage of income received by various percentiles of populations when they are ordered from least to greatest. Rothschild and Stiglitz (1973) also point out, however, that these measures apply only to a one-good economy. This requirement is equivalent to assuming that income is desired by all individuals and there are no externalities; the implications of more than one good are “substantial.”

None of these measures speaks to estimating the cost of inequity when comparisons can be made. But just as insurance can be used as a utility-based measure of the cost of uncertainty, similarly constructed estimates that are based on social welfare functions that display aversion to inequality can be constructed. Insurance premiums computed in these cases simply represent a measure of what society would willingly pay to eliminate inequality. Such an approach assumes the possibility of defining an international social welfare function. Let us now look at the difficulties involved in defining it.

2.5.5.2. Comparisons Across Nations

Comparisons of interpersonal well-being across nations have been the focus of increasing attention over the past few years (see, e.g., Tol, 1999a,b), but it is clear that these comparisons involve more than one element. The conventional approach to making such comparisons is to use purchasing power parity (PPP) to adjust the calculation of gross domestic product (GDP). The technique is flawed, however, in many ways. First, GDP is now widely recognized to be a poor indicator of well-being (e.g., UNDP, 1990). This recognition has inspired many attempts to create other measures, such as the physical quality of life index (PQLI) (Morris, 1979) and various versions of the human development index (HDI) by the United Nations Development Programme (UNDP). However, many researchers, including Srinivasan (1994), have criticized the HDI for theoretical inadequacies. Nevertheless, the major point that GDP misses too much continues to be emphasized exclusively. Calculations of the Index of Sustainable Economic Welfare (ISEW) by Daly and Cobb (1994) have shown, for example,

that the ISEW for the United States has fallen since 1970 even though GDP has grown substantially.

In addition, real-world comparisons must account for many commodities, services, and attributes. This causes enormous index number problems in computing conversion factors such as the PPP. Indeed, one country’s income can be higher or lower than another depending on which country is used as the base for the PPP index.

Third, different societies, cultures, and nations have different social structures, mores, and public institutions. The public goods, services, and safety net provisions of each are different. Moreover, activity outside the marketplace can differ substantially. With industrial development, for example, the clan seems to change to a joint family structure, then to a nuclear family, and perhaps to temporary nuclear families in postindustrial societies. More to the point, the nature of social and human capital and the scope of the marketplace are very different from place to place, depending on the stage of development. And if welfare involves having, being, doing, relating, and caring, a more complex measure of welfare is required to accommodate the multiple stresses of climate change.

Fourth, Sen (1985) suggests that equality in persons’ “capabilities” that are determined by income and access to public goods, services, social capital, and institutions should be a global objective. Each of these determinants clearly varies from nation to nation.

Fifth, the principle of “anonymity” that is used in welfare comparisons is highly suspect. Deliberations of climate impacts and climate policy clearly should keep track of who is affected and where (within and across countries) they live.

2.5.5.3. Ensuring Equity

All of the complications outlined in Section 2.5.5.2 lead to a sad conclusion: Economics may be able to highlight a large menu of distributional issues that must be examined, but it has trouble providing broad answers to measuring and accounting for inequity, particularly across nations. Recourse to ethical principles clearly is in order.

2.5.6. Alternative Metrics for Measuring Costs

Application and extension of the economic paradigm certainly focuses attention on cost measures that are denominated in currency, but practitioners have been criticized on the grounds that these measures inadequately recognize nonmarket costs. Schneider *et al.* (2000), for example, have listed five numeraires or metrics with which the costs of climate change might be captured. Their list includes monetary losses, loss of life, changes in quality of life (including a need to migrate, conflict over resources, cultural diversity, loss of cultural heritage sites, etc.), species or biodiversity loss, and distributional equity.

Chapter 19 recognizes the content of these diverse numeraires in exploring magnitudes and/or rates of climate change that might be dangerous according to three lines of evidence: threatened systems, distributions of impacts, and aggregate impacts. The implications of the fourth line of evidence, large-scale discontinuous events, are then traced along these three dimensions.

When all is said and done, however, costs denominated in one numeraire must be weighed, at least subjectively, with costs denominated in another—and there are no objective quantitative methods with which to do so. A survey conducted by Nordhaus (1994a), however, offered some insight into 15 researchers' subjective views of the relative importance of several different measures along three different "what if" scenarios. Table 2-1 displays some of the results in terms of anticipated cost denominated in lost world GDP, the likelihood of high-consequence impacts, the distribution of costs across the global population, and the proportion of costs that would be captured by national income accounts. The survey results show wide disagreement across the first three metrics; this disagreement generally can be explained in terms of a dichotomy of views between mainstream economists and natural scientists. Nonetheless, Nordhaus (1994a) reports that a majority of respondents held the view that a high proportion of costs would be captured in national accounts. It

would seem, therefore, that natural scientists think that mainstream economists not only underestimate the severity of nonmarket impacts but also that the implications of those impacts into the monetized economy do not follow.

Multi-attribute approaches also could be applied in climate impact analysis. They have not yet found their way into the literature, however, except to the degree to which they are captured in indirect methods outlined above. Chapter 1 also notes that cultural theory can serve as a valuation framework.

2.6. Characterizing Uncertainty and "Levels of Confidence" in Climate Assessment

Uncertainty—or, more generally, debate about the level of certainty required to reach a "definitive" conclusion—is a perennial issue in science. Difficulties in explaining uncertainty have become increasingly salient as society seeks policy advice to deal with global environmental change. How can science be useful when evidence is incomplete or ambiguous, the subjective judgments of experts in the scientific and popular literature differ, and policymakers seek guidance and justification for courses of action that could cause—or prevent—significant environmental and societal changes? How can scientists improve

Table 2-1: Subjective expert opinion on climate change (Nordhaus, 1994a).

Cost Metric	Scenario A ^a	Scenario B ^b	Scenario C ^c
a) Loss in gross world product ^d			
– Mean	1.9	4.1	5.5
– Median	3.6	6.7	10.4
– High	21.0	35.0	62.0
– Low	0.0	0.0	0.8
b) Probability of high-consequence event ^e			
– Mean	0.5	3.0	5.0
– Median	4.8	12.1	17.5
– High	30.0	75.0	95.0
– Low	0.0	0.2	0.3
c) Top to bottom ratio of impacts ^f			
– Mean	4.2		
– Median	3.5		
– High	10.0		
– Low	1.0		
d) Percentage of total in national accounts			
– Mean	62.4	66.6	65.6
– Median	62.5	70.0	80.0

^a Scenario A postulated 3°C warming by 2090.

^b Scenario B postulated scenario A continuing to produce 6°C warming by 2175.

^c Scenario C postulated 6°C warming by 2090.

^d Percentage of global world product lost as a result of climate change.

^e Likelihood of a high-consequence event (a loss of 25% of gross world product, comparable to the Great Depression).

^f Proportion of loss felt by the poorest quintile of income distribution relative to the loss felt by the richest quintile; a value of 1 signifies an equal distribution of burden.

their characterization of uncertainties so that areas of slight disagreement do not become equated with paradigmatic disputes, and how can individual subjective judgments be aggregated into group positions? In short, how can the full spectrum of the scientific content of public policy debates be fairly and openly assessed?

The term “uncertainty” implies anything from confidence just short of certainty to informed guesses or speculation. Lack of information obviously results in uncertainty; often, however, disagreement about what is known or even knowable is a source of uncertainty. Some categories of uncertainty are amenable to quantification, whereas other kinds cannot be expressed sensibly in terms of probabilities (see Schneider *et al.*, 1998, for a survey of literature on characterizations of uncertainty). Uncertainties arise from factors such as lack of knowledge of basic scientific relationships, linguistic imprecision, statistical variation, measurement error, variability, approximation, and subjective judgment (see Box 2-1). These problems are compounded by the global scale of climate change, but local scales of impacts, long time lags between forcing and response, low-frequency variability with characteristic times that are greater than the length of most instrumental records, and the impossibility of before-the-fact experimental controls also come into play. Moreover, it is important to recognize that even good data and thoughtful analysis may be insufficient to dispel some aspects of uncertainty associated with the different standards of evidence (Morgan, 1998; Casman *et al.*, 1999).

This section considers methods to address such questions: first by briefly examining treatments of uncertainties in past IPCC assessments, next by reviewing recommendations from a guidance paper on uncertainties (Moss and Schneider, 2000) prepared for the TAR, and third by briefly assessing the state of the science concerning the debate over the quality of human judgments (subjective confidence) when empirical evidence is insufficient to form clear “objective” statements of the likelihood that certain events will occur.

2.6.1. Treatments of Uncertainties in Previous IPCC Assessments

The IPCC function is to assess the state of our understanding and to judge the confidence with which we can make projections of climate change and its impacts. These tentative projections will aid policymakers in deciding on actions to mitigate or adapt to anthropogenic climate change, which will need to be re-assessed on a regular basis. It is recognized that many remaining uncertainties need to be reduced in each of (many) disciplines, which is why IPCC projections and scenarios are often expressed with upper and lower limits. These ranges are based on the collective judgment of the IPCC authors and the reviewers of each chapter, but it may be appropriate in the future to draw on formal methods from the discipline of decision analysis to achieve more consistency in setting criteria for high and low range limits (McBean *et al.*, 1996; see Raiffa, 1968, for an introduction to decision analysis).

Box 2-1. Examples of Sources of Uncertainty

Problems with Data

- 1) Missing components or errors in the data
- 2) “Noise” in data associated with biased or incomplete observations
- 3) Random sampling error and biases (nonrepresentativeness) in a sample

Problems with Models

- 4) Known processes but unknown functional relationships or errors in structure of model
- 5) Known structure but unknown or erroneous values of some important parameters
- 6) Known historical data and model structure but reasons to believe parameters or model structure will change over time
- 7) Uncertainty regarding predictability (e.g., chaotic or stochastic behavior) of system or effect
- 8) Uncertainties introduced by approximation techniques used to solve a set of equations that characterize the model

Other Sources of Uncertainty

- 9) Ambiguously defined concepts and terminology
- 10) Inappropriate spatial/temporal units
- 11) Inappropriateness of/lack of confidence in underlying assumptions
- 12) Uncertainty resulting from projections of human behavior (e.g., future consumption patterns or technological change), as distinct from uncertainty resulting from “natural” sources (e.g., climate sensitivity, chaos)

Although the SAR on impacts, adaptation, and mitigation (IPCC, 1996b) explicitly links potentially serious climate change with mitigation and adaptation assessment in its Technical Summary, the body of the report is restricted mostly to describing sensitivity and vulnerability assessments (see also Carter *et al.*, 1994). Although this methodology is appropriate for testing sensitivity and vulnerability of systems, it is poorly suited for planning or policy purposes. IAMs available to SAR authors (e.g., Weyant *et al.*, 1996) generate outcomes that are plausible but typically contain no information on the likelihood of outcomes or much information on confidence in estimates of outcomes, how each result fits into broader ranges of uncertainty, or what the ranges of uncertainty may be for each outcome (see Chapter 1 and Section 2.4 for further discussions of integrated assessment issues). However, several studies since the SAR do use probability distributions (e.g., Morgan and Dowlatabadi, 1996, and citations in Schneider, 1997).

IPCC Working Group I (WGI) in its contribution to the SAR (IPCC, 1996a) uses two different methods or techniques to estimate climate change: scenarios and projections. A scenario is a description of a plausible future without estimation of its

likelihood (e.g. the individual IS92a-f emission scenarios or climate scenarios generated by GCMs in which a single emission path is used). Scenarios may contain several sources of uncertainty but generally do not acknowledge them explicitly.

Careful reading of the SAR WGI Technical Summary (IPCC, 1996a) reveals that the term projection is used in two senses:

- 1) A single trajectory over time produced from one or more scenarios (e.g., projected global temperature using the IS92a emissions scenario with a climate sensitivity of 2.5°C)
- 2) A range of projections expressed at a particular time in the future, incorporating one or more sources of uncertainty (e.g., projected global warming of 0.8–3.5°C by 2100, based on IS92a-f emission scenarios and a climate sensitivity of 1.5–4.5°C at 2xCO₂).

Projections are used instead of *predictions* to emphasize that they do not represent attempts to forecast the most likely evolution of climate in the future, only *possible* evolutions (IPCC, 1996a, Section F.1). In the SAR, *projection* and *scenario* are used to describe possible future states, with projections used mainly in terms of climate change and sea-level rise. This usage defines climate projection as a *single* trajectory of a subset of scenarios. When used as input into impact assessments, the same climate projections commonly are referred to as climate scenarios.

Projected *ranges* are constructed from two or more scenarios in which one or more sources of uncertainty may be acknowledged. Examples include projections of atmospheric CO₂ derived from the IS92a-f emission scenarios (IPCC, 1996a), global temperature ranges (IPCC, 1996a), and regional temperature

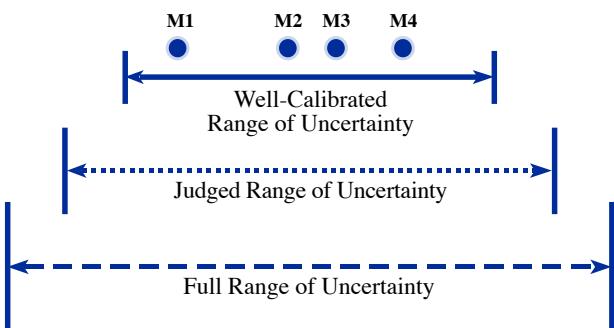

Figure 2-1: Schematic depiction of the relationship between “well-calibrated” scenarios, the wider range of “judged” uncertainty that might be elicited through decision analytic techniques, and the “full” range of uncertainty, which is drawn wider to represent overconfidence in human judgments. M1 to M4 represent scenarios produced by four models (e.g., globally averaged temperature increases from an equilibrium response to doubled CO₂ concentrations). This lies within a “full” range of uncertainty that is not fully identified, much less directly quantified by existing theoretical or empirical evidence (modified from Jones, 2000).

ranges (CSIRO, 1996). A range of projections will always be more likely to encompass what actually will transpire than a single scenario. Although projected ranges are more likely to occur than single scenarios, they are not full-fledged forecasts because they incorporate only part of the total uncertainty space. The relationship between scenarios and projected ranges as treated in the SAR is shown schematically in Figure 2-1.

A projected range is a quantifiable range of uncertainty situated within a population of possible futures that cannot be fully identified (termed “knowable” and “unknowable” uncertainties by Morgan and Henrion, 1990). The limits of this total range of uncertainty are unknown but may be estimated subjectively (e.g., Morgan and Keith, 1995). Given the finding in the cognitive psychology literature that experts define subjective probability distributions too narrowly because of overconfidence (see Section 2.6.5.3), the inner range represents the “well-calibrated” range of uncertainty. Thus, the wider range of uncertainty represents a “judged” range of uncertainty, based on expert judgments—which may not encompass the full range of uncertainty given the possibility of cognitive biases such as overconfidence. Although the general point remains that there is always a much wider uncertainty range than the envelope developed by sets of existing model runs, it also is true that there is no distinct line between “knowable” and “unknowable” uncertainties; instead, it is a continuum. The actual situation depends on how well our knowledge (and lack thereof) has been integrated into assessment models. Moreover, new information—particularly empirical data, if judged reliable and comprehensive—eventually may narrow the range of uncertainty to well inside the well-calibrated range by falsifying certain outlier values.

If the full range of uncertainty in Figure 2-1 were known, the probability of a particular outcome could be expressed as a forecast (provided we can state the probability). Although there are significant sources of uncertainty that cannot yet be quantified, decision analytic elicitation procedures (Section 2.4) can estimate the full range of uncertainties and conditional probabilities (see Section 2.5.5 for an assessment of the state of the science concerning human judgment). Conditional probabilities may be calculated within a projected range even though the probability of the range itself remains unknown.

Moss and Schneider (1997) document several cases in which the SAR authors in each of the three Working Groups use ranges to describe uncertain outcomes but unfortunately had no consistent criteria for assigning probabilities to range limits or for identifying outlier outcomes (those occurring beyond the well-calibrated range limits). Moreover, there was no consistent use of terms to characterize levels of confidence in particular outcomes or common methods for aggregating many individual judgments into a single collective assessment. Recognition of this shortcoming of the SAR led to preparation of a guidance paper on uncertainties (Moss and Schneider, 2000) for use by all three TAR Working Groups and which has been widely reviewed and debated.

Attempts to achieve more consistency in establishing end points of ranges and outlier values (or the distribution of subjective probabilities within and beyond the range) have not received much attention. Despite the difficulty of assigning a distribution of probabilities for uncertain outcomes or processes, the scientific complexity of the climate change issue and the need for information that is useful for policy formulation requires researchers and policymakers to work together toward improved management of uncertainties. A common basis for characterizing sources of uncertainties is one step; Box 2-1 represents an attempt in the uncertainties guidance paper (Moss and Schneider, 2000) to provide such a common basis.

In this situation, the research community must bear in mind that users of IPCC reports often assume for themselves what they think the authors believe to be the distribution of probabilities when the authors do not specify it themselves. The decision analytic literature (e.g., Morgan and Henrion, 1990) often suggests that it is preferable for scientists debating the specifics of a topic to provide their best estimates of probability distributions and possible outliers, based on their assessment of the literature, than to have users make their own guesses. This information, along with an appraisal of the limitations of the models, would make the ranges more meaningful to other scientists, the policy community, and the public.

2.6.2. “Objective” and “Subjective” Probabilities are not Always Explicitly Distinguished

Some scientists have expressed concern that scientific investigation requires a long sequence of observational records, replicable trials, or model runs (e.g., Monte Carlo simulations) so the results can be specified by a formal statistical characterization of the frequency and frequency distribution of outcomes being assessed. In statistical terms, “objective” science means attempting to verify any hypothesis through a series of experiments and recording the frequency with which that particular outcome occurs. The idea of a limitless set of identical and independent trials that is “objectively out there” is a heuristic device that we use to help us rigorously quantify uncertainty by using frequentist statistics. Although there may be a large number of trials in some cases, however, this is not the same as a “limitless” number, and these trials rarely are truly identical or independent.

Most interesting complex systems cannot possibly be put to every conceivable test to find the frequency of occurrence of some socially or environmentally salient event. The popular philosophical view of “objective science” as a series of “falsifications” breaks down when it confronts systems that cannot be fully tested. For example, because climate change forecasts are not empirically determinable (except by “performing the experiment” on the real Earth—Schneider, 1997), scientists must rely on “surrogate” experiments, such as computer simulations of the Earth undergoing volcanic eruptions or paleoclimatic changes. As a result of these surrogate experiments and many additional tests of the reliability of subcomponents

of such models, scientists attain confidence to varying degrees about the likelihood of various outcomes (e.g., they might assign with high confidence a low probability to the occurrence of extreme climate outcomes such as a “runaway greenhouse effect”). These confidence levels are not frequentist statistics but “subjective probabilities” that represent degrees of belief that are based on a combination of objective and subjective subcomponents of the total system. Because subjective characterization of the likelihood of many potentially important climatic events—especially those that might be characterized by some people as “dangerous”—is unavoidable, “Bayesian” or “subjective” characterization of probability will be more appropriate.

Bayesian assessments of probability distributions would lead to the following interpretation of probability statements: The probability of an event is the degree of belief that exists among lead authors and reviewers that the event will occur, given the observations, modeling results, and theory currently available, all of which contribute to estimation of a “prior” probability for the occurrence of an outcome. As new data or theories become available, revised estimates of the subjective probability of the occurrence of that event—so-called “posterior probability”—can be made, perhaps via the formalism of Bayes theorem (see, e.g., Edwards, 1992, for a philosophical basis for Bayesian methods; for applications of Bayesian methods, see, e.g., Howard *et al.*, 1972; Anderson, 1998; Tol and de Vos, 1998; Malakoff, 1999).

2.6.3. Making Estimates

2.6.3.1. Identifying Extreme Values, Ranges, and Thresholds

It is worth noting that by failing to provide an estimate of the full range of outcomes (i.e., not specifying outliers that include rapid nonlinear events), authors of previous assessments were not conveying to potential users a representation of the full range of uncertainty associated with the estimate. This has important implications with regard to the extent to which the report accurately conveyed to policymakers potential benefits or risks that may exist, even if at a low or unknown probability (see Figure 2-1). If it were necessary to truncate the range, it should have been clearly explained what the provided range includes and/or excludes. Furthermore, the authors might have specified how likely it is that the answer could lie outside the truncated distribution.

Pittock and Jones (1999) recommend construction of thresholds that can be linked to projected ranges of climate change. Such thresholds can account for biophysical and/or socioeconomic criteria in the initial stages of an assessment but must be expressed in climatic terms (e.g., above a certain temperature, rainfall frequency, water balance, or combination of several factors). Further analysis compares these thresholds with projected regional climate change. Similar approaches are contained in concepts of tolerable climate change (see Hulme and Brown, 1998).

2.6.3.2. Valuation Issues

Any comprehensive attempt to evaluate the societal value of climate change should include, in addition to the usual monetary value of items or services traded in markets, measures of valued items or services that are not easily marketed. Schneider *et al.* (2000) refer to this costing problem in vulnerability analysis as “The Five Numeraires”: monetary loss, loss of human life, reductions in quality of life (including forced migration, conflicts over environmentally dependent resources, loss of cultural diversity, loss of cultural heritage sites, etc.), loss of species/biodiversity, and increasing inequity in the distribution of material well-being. There is little agreement on how to place a monetary value on the nonmarket impacts of climate change, yet such valuation is essential to several analytic techniques to assess the efficiency or cost-effectiveness of alternative climate policy proposals (see Section 2.5.6).

One such technique for valuation is to survey expert opinion on subjective assessment of probability distributions of climate damage estimates (see Nordhaus, 1994a; Morgan and Keith, 1995; Titus and Narayanan, 1996, for examples of decision analytic elicitations of climate effects and impacts; see Morgan and Dowlatabadi, 1996, for examples of how such elicited subjective probability distributions can be incorporated into IAMs that examine “optimal” policies). An alternative valuation framework is to use “cultural theory” (Douglas and Wildavsky, 1982) to identify different value perspectives in designing policy strategies (see van Asselt and Rotmans, 1995, for an application to population growth). With this technique, subjective judgment about uncertainties may be described from the viewpoints of different cultural perspectives. Preferred policy options depend on the perspective adopted. Real policy choice, of course, depends on the logic and consistency of formulating a basis for policy choices (i.e., the role of decision analysis tools) and on the values of decisionmakers at all levels. More formal and explicit incorporation of uncertainties into decision analysis is the emphasis here.

2.6.4. Aggregation and the Cascade of Uncertainty

A single aggregated damage function or a “best guess” climate sensitivity estimate is a very restricted representation of the wide range of beliefs available in the literature or among lead authors about climate sensitivity or climate damages. If a causal chain includes several different processes, the aggregate distribution might have very different characteristics than the various distributions that constitute the links of the chain of causality (see Jones, 2000). Thus, poorly managed projected ranges in impact assessment may inadvertently propagate uncertainty. The process whereby uncertainty accumulates throughout the process of climate change prediction and impact assessment has been described as a “cascade of uncertainty” (Schneider, 1983) or the “uncertainty explosion” (Henderson-Sellers, 1993). The cascade of uncertainty

implied by coupling the separate probability distributions for emissions and biogeochemical cycle calculations to arrive at concentrations needed to calculate radiative forcing, climate sensitivity, climate impacts, and valuation of such impacts into climate damage functions has yet to be produced in the literature (see Schneider, 1997, Table 2). When the upper and lower limits of projected ranges of uncertainty are applied to impact models, the range of possible impacts commonly becomes too large for practical application of adaptation options (Pittock and Jones, 1999). This technique is less explicitly applied in assessments where two or more scenarios (e.g., M1 to M4 in Figure 2-1) are used and the results expressed as a range of outcomes. If an assessment is continued through to economic and social outcomes, even larger ranges of uncertainty can be accumulated (see Figure 2-2).

Because of the lack of consistent guidance on the treatment of uncertainties, diversity of subject areas, methods, and stage of development of the many fields of research to be assessed in the SAR, it was not possible to agree on a single set of terms to describe the confidence that should be associated with the many outcomes and/or processes that had been assessed. Thus, the uncertainties guidance paper (see also Box 1-1) suggests that the TAR authors agree on two alternative sets of terms from which writing teams can select (see Figures 2 and 3 in Moss and Schneider, 2000). As noted in the decision analysis literature (e.g., Morgan and Henrion, 1990), *it is important to attach a quantitative range to each verbal characterization* to assure that different users of the same language mean the same degree of confidence.

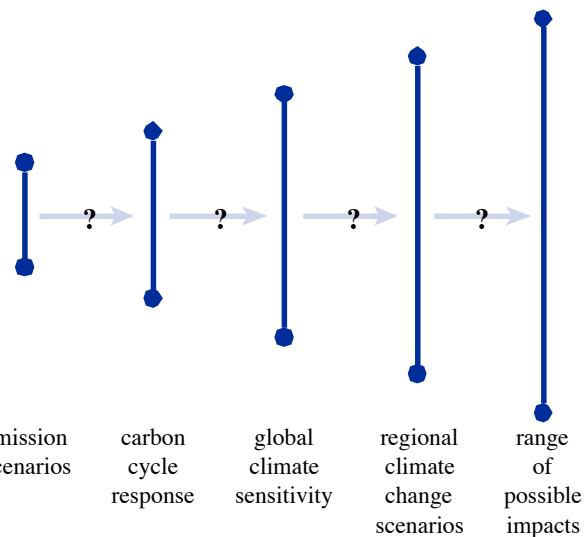

Figure 2-2: Range of major uncertainties that are typical in impact assessments, showing the “uncertainty explosion” as these ranges are multiplied to encompass a comprehensive range of future consequences, including physical, economic, social, and political impacts and policy responses (modified after Jones, 2000, and “cascading pyramid of uncertainties” in Schneider, 1983).

2.6.5. Debate over the Quality of Human Judgment

2.6.5.1. Deficiencies in Human Judgment

At some level, human judgment is an unavoidable element of all human decisions. The question, then, naturally arises: How good is human judgment? Psychological studies of human judgment provide evidence for shortcomings and systematic biases in human decisionmaking. Furthermore, not only do people—including experts—suffer various forms of myopia; they also often are oblivious of the fact. Indeed, statistical linear models summarizing the relationship between a set of predictor variables and a predicted outcome often (repeatedly) perform better than intuitive expert judgments (or subjective expert opinions). Burgeoning empirical evidence suggests that humans, including experts, can be inept at making judgments, particularly under conditions of high uncertainty.

Since the early 1970s, psychologists repeatedly have demonstrated human judgmental error and linked these errors to the operational nature of mental processes. The idea, spelled out in Kahneman *et al.* (1982), is that, because of limited mental processing capacity, humans rely on strategies of simplification, or mental heuristics, to reduce the complexity of judgment tasks. Although this strategy facilitates decisionmaking, these procedures are vulnerable to systematic error and bias.

2.6.5.2. Violation of Probability Laws

In a classic series of publications, Tversky and Kahneman (1974, 1983) and Kahneman and Tversky (1979, 1996) claim that human judgment under uncertainty violates normative rules of probability theory. For example, Tversky and Kahneman (1983) invoke the “judgment by a representativeness” heuristic to explain evidence for the *conjunction fallacy*, whereby a conjunction of events is judged to be more likely than one of its constituents. This is a violation of a perfectly simple principle of probability logic: If A includes B, the probability of B cannot exceed A. Nevertheless, respondents consistently give a higher likelihood to the possibility of a subset or joint event than to the whole set, thereby violating the conjunction rule. Typically, respondents judge likelihood by representativeness (or stereotypes) and thus fail to integrate statistically relevant factors.

However, Gigerenzer (1994, 1996) argues that people are naturally adapted to reasoning with probabilities in the form of frequencies and that the conjunction fallacy “disappears” if reasoning is in the form of frequencies. Several studies report that violations of the conjunction rule are rare if respondents are asked to consider the relative frequency of events rather than the probability of a single event.

Kahneman and Tversky (1996) disagree and argue that the frequency format provides respondents with a powerful cue to the relation of inclusion between sets that are explicitly compared or evaluated in immediate succession. When the structure of the conjunction is made more apparent, respondents who

appreciate the constraint supplied by the rule will be less likely to violate it.

Kahneman and Lovallo (1993) argue that people have a strong tendency to regard problems as unique although they would be viewed more advantageously as instances of a broader class. People pay particular attention to the distinguishing features of a particular case and reject analogies to other instances of the same general type as crudely superficial and unappealing. Consequently, they fall prey to fallacies of planning by anchoring their estimates on present values or extrapolations of current trends. Despite differing causal theories, both approaches find evidence for poor judgment under uncertainty or, alternatively, evidence that people are better off not attempting to assess probabilities for single events.

Nonetheless, public understanding of likelihood seems to be improved by adoption of frequentist formats. Several studies have shown that experts have great difficulty reasoning with subjective probabilities for unique or single events. However, respondents apparently are much more successful when the same problems are presented with frequencies rather than probabilities. Although experts have difficulties with the probability version—most give wrong answers—most undergraduates readily provide the correct answer to similar problems constructed with frequencies.

Psychological research suggests that measures of risk that are communicated in terms of frequencies rather than probabilities will be more readily understood and rationally responded to, although IAMs need to translate these frequencies into probability distributions (e.g., Morgan and Dowlatabadi, 1996) to portray the wide range of outcomes that currently reflect estimates in the literature and by most IPCC authors.

2.6.5.3. Overconfidence

Overconfidence is another cognitive illusion that has been reported to plague experts’ judgments. In the 1970s and 1980s, a considerable amount of evidence was amassed for the view that people suffer from an overconfidence bias. The common finding is that respondents are correct less often than their confidence assessments imply.

However, “ecological” theorists (*cf.* McClelland and Bolger, 1994) claim that overconfidence is an artifact of artificial experimental tasks and nonrepresentative sampling of stimulus materials. Gigerenzer *et al.* (1991) and Juslin (1994) claim that individuals are well adapted to their environments and do not make biased judgments. Overconfidence is observed because the typical general knowledge quiz used in most experiments contains a disproportionate number of misleading items. These authors have found that when knowledge items are randomly sampled, the overconfidence phenomenon disappears. Juslin *et al.* (2000) report a meta-analysis comparing 35 studies in which items were randomly selected from a defined domain with 95 studies in which items were selected by experimenters.

Although overconfidence was evident for selected items, it was close to zero for randomly sampled items—which suggests that overconfidence is not simply a ubiquitous cognitive bias. This analysis suggests that the appearance of overconfidence may be an illusion created by research, not a cognitive failure by respondents.

Furthermore, in cases of judgments of repeated events (weather forecasters, horse race bookmakers, tournament bridge players), experts make well-calibrated forecasts. In these cases, respondents might be identifying relative frequencies for sets of similar events rather than judging the likelihood of individual events. If we compare studies of the calibration of probability assessments concerning individual events (e.g., Wright and Ayton, 1992) with those in which subjective assessments have been made for repetitive predictions of events (Murphy and Winkler, 1984), we observe that relatively poor calibration has been observed in the former, whereas relatively good calibration has been observed in the latter.

It might be concluded that a frequentist rather than a Bayesian approach should be adopted when attempting to elicit judgment. However, there are occasions when there will be events for which no obvious reference class exists and one will be unable to assess likelihood by adopting the frequentist approach. This particularly applies to novel situations for which there is no actuarial history. One might well be able to account for the (no doubt varying) subjective probabilities offered by a sample of people by identifying mental heuristics. However, note that, without a reference class, we have no means of evaluating the validity of any judgments that might be offered. Consequently, any probability given to a unique event remains somewhat ambiguous.

2.6.6. Building Experience with Subjective Methods In a “Science for Policy” Assessment

Although one might be tempted to infer from the foregoing arguments that judgments of likelihood should be considered only with caution, for some decision analytic frameworks that often appear in the climate policy literature (e.g., cost-benefit analysis and IAMs), there often are few viable alternatives. However, as noted in the decision analysis frameworks guidance paper (Toth, 2000a; see also Section 2.4), several alternative decisional analytic methods are less dependent on subjective probability distributions; virtually all frameworks do require subjective judgments, however. Although physical properties such as weight, length, and illumination have objective methods for their measurement, there are no objective means for assessing in advance the probability of such things as the value future societies will put on now-endangered species or the circulation collapse of the North Atlantic Ocean from anticipated anthropogenic emissions. Even a highly developed understanding of probability theory would be of little avail because no empirical data set exists, and the underlying science is not fully understood. Some authors have argued that under these circumstances, for any practical application one ought to abandon any attempt to

produce quantitative forecasts and instead use more qualitative techniques such as scenario planning (e.g., Schoemaker, 1991; van der Heijden, 1998) or argumentation (Fox, 1994). On the other hand, others—though noting the cognitive difficulties with estimation of unique events—have argued that quantitative estimations are essential in environmental policy analyses that use formal and explicit methods (e.g., Morgan and Henrion, 1990).

Given its potential utility in applied and conservation ecology, it seems surprising that Bayesian analysis is relatively uncommon. However, logical and theoretical virtue is not sufficient to encourage its use by managers and scientists. The spread of a new idea or practice is an example of cultural evolution (in this case, within the scientific community). It is best understood as a social and psychological phenomenon (Anderson, 1998).

Helping to achieve such penetration of awareness of uncertainty analyses will be a multi-step process that includes “1) consistent methods for producing verbal summaries from quantitative data, 2) translation of single-event probabilities into frequencies with careful definition of reference classes, 3) attention to different cognitive interpretations of probability concepts, and 4) conventions for graphic displays” (Anderson, 1998). The latter also is advocated in the uncertainties guidance paper (Moss and Schneider, 2000), and an example is provided in Chapter 7 (Figure 7-2).

Although all arguments in the literature agree that it is essential to represent uncertainties in climatic assessments, analysts disagree about the preferred approach. Some simply believe that until empirical information becomes available, quantitative estimates of uncertain outcomes should be avoided because “science” is based on empirical testing, not subjective judgments. It certainly is true that “science” itself strives for “objective” empirical information to test, or “falsify,” theory and models (caveats in Section 2.5.2 about frequentism as a heuristic notwithstanding). At the same time, “science for policy” must be recognized as a different enterprise than “science” itself. Science for policy (e.g., Ravetz, 1986) involves being responsive to policymakers’ needs for expert judgment at a particular time, given information currently available, even if those judgments involve a considerable degree of subjectivity. The methods outlined above and in Moss and Schneider (2000) are designed to make such subjectivity more consistently expressed (linked to quantitative distributions when possible, as needed in most decision analytic frameworks) across the TAR and more explicitly stated so that well-established and highly subjective judgments are less likely to get confounded in media accounts or policy debates. The key point is that *authors should explicitly state their approach in each case*. Transparency is the key to accessible assessments.

2.7. Decision Analytic Methods and Frameworks

This section presents basic principles of decision analytic frameworks that have been or could be used in assessing

adaptation decisions in sectors and regions. Thus, it provides a common base for decision analysis-related discussions in sectoral and regional chapters of this report.

2.7.1. Decision Analysis to Support Adaptive Decisions—Introduction to Frameworks and Principles

Decisionmakers who are responsible for climate-sensitive economic sectors (e.g., forestry, agriculture, health care, water supply) or environmental assets (e.g., nature reserves) face questions related to undertaking adaptation measures on the basis of what impacts might be expected if global GHG emissions continue unabated or as a result of globally agreed mitigation action at different levels of control. The starting point for adaptation decisions is to explore the possible range of impacts to which one would need to adapt. This is a complex task in itself because it involves understanding possible regional patterns of climate change, the evolution of key socioeconomic and biophysical components of the sector or region under consideration, and the dynamics of the impacts of changing climatic conditions on the evolving social system.

Adaptation decisions in private sectors operating under free-market conditions will be made largely as part of a business-as-usual approach and will rely on analytical frameworks that are compatible with the management culture. The emerging literature on adaptation describes this as autonomous adaptation. The flexibility of private-sector actors and thus the range of options they are able to consider in adapting to any external impact (not only climatic ones) can be severely constrained by market distortions or by a lack of resources to implement any transformation. Under such circumstances, the potential for autonomous adaptation is limited. Planned adaptation will be required, and the importance of public policy is larger.

A standard example for autonomous adaptation is the farmer who switches from one cultivar of a given crop to another or from one crop to another in response to perceived changes in weather patterns, simultaneously considering changes in relative prices of input factors and agricultural commodities, the evolving technological and agronomic conditions behind them, and other factors affecting his profits. However, if prices are distorted by a quota system or state subsidy, decisions are excessively dominated by these considerations, which could lead to maladaptation. Similarly, subsistence farmers in less-developed countries are not profit maximizers, and they may not possess the resources required to make even minor shifts in response to changes in their external conditions. Under these conditions, the only possibility for them might be to give up their livelihood altogether.

With a view to the already significant atmospheric load of GHGs since the industrial revolution, as well as the huge inertia and long delays characterizing the atmosphere-ocean-biosphere system, adaptation to anthropogenic climate change appears inevitable over the coming decades. It is worth looking at some of the key differences in applications of DAFs that deal with

climate change mitigation (reducing GHG emissions) and adaptation (managing and counterbalancing the impacts of climate change).

The most crucial difference between mitigation- and adaptation-oriented DAF applications is to whom the benefits of action accrue. Except for “no-regret” options, benefits of mitigation will become a globally shared public good. Adaptation actions will predominantly benefit agents who adapt, in the case of private actors, or gains will be shared by the community in the case of local/regional public goods and services, such as flood protection.

The second important difference between mitigation and adaptation decisions is related to the timing of policy options. If climate protection were needed, as many scientists and policymakers maintain, policies and technologies that help reduce GHG emissions at the lowest possible social costs would be required immediately. On the adaptation side, in contrast, the bulk of more significant impacts of climate change may be felt 30, 50, or 100 years from now. This leaves a longer time period (compared to mitigation action) to steer the development of climate-sensitive sectors so that their climate vulnerability will be lower and, more important, to develop technologies that will help reduce remaining negative impacts by the time they really happen. Nevertheless, forethought and action might well be required in sectors with long-lived infrastructure and large social inertia (e.g., changing institutions such as misallocated property rights) to foster adaptation to future climate.

In terms of public policies, the foregoing analysis implies urgency on the mitigation side to formulate and put in place appropriate measures; by contrast, in general there is more time on the adaptation side to sort out potential impacts, adaptation needs, institutional and technological options involved in various adaptation measures, and public policies to develop and deliver them. At the same time, however, in many countries around the world that suffer from current climatic variability and extremes, there is an urgent need for appropriate adaptation policies and programs to be designed and implemented now to lessen adverse impacts; such actions also will help to build adaptive capacity for future climate changes.

Several other differences between mitigation and adaptation decisions must be considered in framing DAFs appropriately. Mitigation decisions are to be crafted globally, and their implementation may entail a global spread to reduce costs, whereas adaptation decisions are more limited to nations or subnational regions. The region in this context is intentionally defined loosely and given a broad interpretation. In considering climate change impacts and adaptation policies, a region typically would be a sociogeographical unit under the jurisdiction of a legally recognized policy entity within a country. However, a region in this sense also could correspond to a whole country, especially if it is relatively small and geographically homogeneous. Moreover, regional climate impact and adaptation studies also are conceivable (and in some cases have been undertaken) at the level of a supranational region, provided it has a recognized policymaking entity (e.g., the European Union).

Many market-sector impacts can be relieved at least partially by a combination of regional adjustments and interregional trade (especially in the agriculture and livestock sectors), but regions remain the prime focus of adaptation policies even in these cases. In terms of the public policy agenda, mitigation decisions have to be made today in the context of current short-term economic problems, social challenges, and policy debates. Adaptation and adaptation-related analyses will have to be developed in the context of long-term socioeconomic and technological development, with a special view to economic and technological trends in climate-sensitive economic sectors and environmental systems. This makes adaptation-oriented DAF applications easier because options to factor them in are much broader, but it also makes them more difficult because the future is difficult to predict and there is a clear need for policies that will be successful across a broad range of plausible futures (these policies commonly are called robust). The information base for adaptation decisions will improve over time, whereas DAFs to support near-term mitigation decisions must cope with current knowledge plagued with enormous uncertainties.

2.7.2. Major DAFs and their Use in Adaptation Studies

A broad range of DAFs could be used in principle; to date, however, only a few have been used in practice to provide substantial information to policymakers who are responsible for adaptation decisions at various levels. This subsection lists DAFs that appear to be most relevant for analyzing adaptation decisions. Many DAFs overlap in practice, and clear classification of practical applications sometimes is difficult. The IPCC Guidance Paper on DAFs (Toth, 2000a) provides a more comprehensive, yet incomplete, catalog.

Just as in analyzing decision options for overall climate policy (i.e., at what level should concentrations of GHGs be stabilized, considering the costs and benefits involved?) or for mitigation decisions (timing, location, ways and means of emission reductions), the proper mode to conduct analyses to support adaptation decisions also is sequential decisionmaking under uncertainty and considering future learning. The principal task is to identify adaptation strategies that will take regions or sectors to the best possible position for revising those strategies at later dates in light of new information about expected patterns of regional climate change, socioeconomic development, and changes in climate-sensitive sectors. Consequently, applications of all DAFs in adaptation studies should be formulated in the sequential decisionmaking mode.

The complexities involved in climate change decisionmaking and selecting appropriate tools to support it stem from the interconnectedness of the various realms of decisionmaking. Analysts provide advice for setting the global climate policy target at the global scale; these targets become external constraints when adaptation strategies are sought at the regional scale that are socially just, environmentally sustainable, and compatible with regional development objectives.

DAFs that are applicable in adaptation assessments can be distinguished according to whether they rely solely on “desk studies” (involving or not involving formal models) or entail participation of clients, stakeholder groups, or others. Model-based DAFs tend to focus primarily on structuring the problem, apply convenient simplifications, and find efficient solutions to the problem. Participatory DAFs, in contrast, can better accommodate diverse views on climate change impacts and often conflicting interests and options to restrain them. Insights from both kinds of studies are crucial for policymakers to craft effective and broadly acceptable policies.

2.7.2.1. Decision Analysis

Decision analysis (DA) is the product of integrating utility theory, probability, and mathematical optimization (see French, 1990; Morgan and Henrion, 1990; Chechile and Carlisle, 1991; Keeney and Raiffa, 1993; Kleindorfer *et al.*, 1993; Marshall and Oliver, 1995; Clemen, 1996). The process starts with problem identification and preparation of a possibly comprehensive list of decision options. Structural analysis would organize options into a decision tree, carefully distinguishing decision nodes (points at which the outcome is chosen by the decisionmaker) and chance nodes (points at which the outcome results from stochastic external events). Next, uncertainty analysis would assign subjective probabilities to chance nodes, and utility analysis would stipulate cardinal utilities (in terms of absolute values) for outcomes. Finally, optimization produces the best outcome according to a selected criterion, typically maximizing expected utility or any other that best reflects the risk attitude of the decisionmaker.

Advanced DA provides various extensions of the foregoing conceptual framework and supports a huge diversity of applications. In the literature, some features (sequential decisionmaking, hedging), specific versions (multi-criteria analysis), distinctive applications [risk assessment (RA)], or basic components (multi-attribute utility theory) of DA sometimes are emphasized and taken as separate DAFs, although they all are rooted in the same theoretical framework. As indicated, sequential decisionmaking is an indispensable mode of analysis of climate change in any DAF. It refers to framing of the analysis rather than a distinctive DAF. DA can be performed with a single criterion or with multiple criteria; multi-attribute utility theory provides the conceptual underpinnings for the latter. Finally, DA adapted to managing technological, social, or environmental hazards constitutes part of RA, in which a range of other methods also is available. RA involves estimation of the nature and size of risks. Its objective is to identify quantitative measures of hazards in terms of magnitude and probability. RA methods are diverse; the choice depends on the disciplinary focus and the nature of the hazard to be assessed, but all methods rely on extrapolation (see Kates and Kasperson, 1983). See Chapter 12 for applications of RA in climate impact assessment.

DA is a promising DAF for use in adaptation assessments. Problem formulation in DA allows for consideration of a broad

range of uncertain outcomes, different probability distributions assigned to them, and a variety of possible adaptation actions. Structuring the DAmodel in an intertemporal fashion is helpful for identifying robust adaptation strategies that prove to be effective under a broad range of possible futures and retain a sufficient degree of freedom for course correction.

2.7.2.2. Cost-Benefit Analysis

Cost-benefit analysis (CBA) involves valuing all costs and benefits of a proposed project over time on the basis of willingness to pay (or willingness to accept compensation) on the part of project beneficiaries (affected people) and specifying a decision criterion to accept or turn down the project (see Ray, 1984; Morgenstern, 1997). This criterion usually is the compensation principle, implying that those who benefit from the project should be able to compensate the losers. The applicability of CBA as a DAF for climate policy has been a fiercely debated issue. Although the debate continues about the extent to which traditional CBA can provide useful information for global-level decisionmaking, there is more agreement on its usefulness in adaptation decisions at the national and regional scales.

In practical applications, all costs (C) and benefits (B) are defined as follows:

$$B = \sum_{t=0}^n \frac{B_t}{(1+i)^t} \text{ and } C = \sum_{t=0}^n \frac{C_t}{(1+i)^t}$$

where i is the social discount rate, n is the project life, and t denotes the year. One can use different cost-benefit criteria for ranking projects or choosing the best among them: the cost-benefit ratio, $CBR = B/C > 1$; the net present value, $NPV = B - C > 0$; and the internal rate of return, $IRR > i$, where IRR is the discount rate to make $B = C$. When we evaluate a single project, these criteria lead to the same conclusion. In choosing the most desirable alternative, however, these criteria indicate different orders of desirability.

A CBA in the adaptation context takes potential regional climate change scenarios and their impacts as its starting point. The next step is to establish costs of alternative adaptive measures as a function of their scales of application—the marginal cost curve. A related task is to estimate how much damage can be averted by increasing the adaptation effort—WTP (marginal benefit curve). The decision principle suggests undertaking adaptive measures as long as marginal averted damages (benefits) exceed marginal costs. This rule of thumb is easier to apply in sectoral adaptation decisions, in which costs and benefits can be derived from market prices. Difficulties arise in nonmarket sectors in which the valuation behind the marginal cost and benefit curves often is debated. Difficulties multiply, in a regional context, when costs and benefits must be aggregated across many sectors.

A frequent critique of CBA and its applicability in adaptation studies is that the underlying measurements are incomplete

(especially in regional studies, which do not cover all important aspects), inaccurate (even the costs and benefits of adaptive actions included in the analysis are impossible to measure precisely), and debated (related to the two preceding points; the inclusion and exact valuation of many costs and benefits involve inherently subjective value judgments). These criticisms are largely valid. However, it is still better to get at least the measurable components right and complement them with a combination of judgments on hard-to-measure items and sensitivity tests to assess their implications than to abandon the whole method simply because it does not get everything perfect. Nevertheless, it is important that users of these tools and their results fully understand the limitations and confidence attached to them. Duke and Kammen (1999) argue that accounting for dynamic feedback between the demand response and price reductions from production experience can be used to account for deadweight loss and other market dynamics that determine the benefit-cost ratio of economic and policy measures to expand the market for clean energy technologies. These results further support a broader role for market transformation programs to commercialize new environmentally attractive technologies. The same dynamic feedback processes also are relevant for CBA applications to adaptation decisions. For example, consider changing precipitation patterns that would increase the frequency of high-water conditions. Take flood-related damages as the function of flood return periods: Annual flooding may cause the least damages, whereas a 5-year return flood will cause somewhat more, a 20-year return flood even more, and so on. Adaptation costs increase along the same axis because it takes higher dikes and larger flood protection reservoirs to control a 50-year return flood than a 5-year return flood. The level at which a given society will decide to protect itself against floods depends on local economic conditions and geographical and technological endowments. A CBA suggests that it should be in the neighborhood of where marginal costs of additional flood protection would be equal to WTP for additional flood protection.

2.7.2.3. Cost-Effectiveness Analysis

Cost-effectiveness analysis (CEA) takes a predetermined objective (often an outcome negotiated by key stakeholder groups in a society) and seeks ways to accomplish it as inexpensively as possible. The thorny issues of compensations and actual transfers boil down to less complex but still contentious issues of burden sharing.

CBA will always be controversial because of the intricacies of valuing benefits of many public policies, especially intangible benefits of environmental policies, properly. CEA takes the desired level of a public good as externally given (a vertical marginal benefit curve) and minimizes costs across a range of possible actions. Like other target-based approaches, CEA often turns into an implicit CBA, especially if even the minimum costs turn out to be too high and beyond the ability to pay of the society. In this case, the target is iteratively revised until an acceptable solution is found.

Consider the foregoing example of changing precipitation pattern induced by climate change and resulting high-water conditions. In many countries, legally binding criteria exist regarding the level of flood protection (e.g., protection against a 50- or 100-year return flood). CEA would take these or other socially agreed flood protection targets and seek the mix of dams, reservoirs, and other river basin management options that would minimize the costs of achieving the specified target.

2.7.2.4. Policy Exercise Approach

The policy exercise (PE) approach involves a flexibly structured process that is designed as an interface between academics and policymakers. Its function is to synthesize and assess knowledge accumulated in several relevant fields of science for policy purposes in light of complex practical management problems. At the heart of the process are scenario writing (“future histories,” emphasizing nonconventional, surprise-rich, but still plausible futures) and scenario analyses via interactive formulation and testing of alternative policies that respond to challenges in the scenario. These scenario-based activities take place in an organizational setting that reflects the institutional features of the issues addressed. Throughout the exercise, a wide variety of hard (mathematical and computer models) and soft methods are used (Brewer, 1986; Toth, 1988a,b; Parson, 1997).

The product of a PE is not necessarily new scientific knowledge or a series of explicit policy recommendations but a new, better structured view of the problem in the minds of participants. The exercise also produces statements concerning priorities for research to fill gaps of knowledge, institutional changes that are needed to cope more effectively with the problems, technological initiatives that are necessary, and monitoring and early warning systems that could ease some of the problems in the future. In recent years we have witnessed increasing use of the PE approach to address climate change at the national scale (see Klabbers *et al.*, 1995, 1996) and at the global level.

2.7.3. Relevance and Use of DAFs in Sectoral Adaptation Decisions—Selected Examples

Working Group II has reviewed a huge volume of climate impact assessment studies conducted to date. Most of these studies investigate possible implications of climate change for a single economic sector or environmental component. An increasing, yet still small, fraction of these studies lists options to alleviate impacts, but few take even the next step of exploring direct and indirect costs of those adaptation options. Even fewer studies provide comprehensive assessments of direct and indirect benefits.

Although these studies qualitatively indicate that many policy options proposed as adaptation measures to reduce negative impacts of climate change would be justified even in the absence of climate change (dubbed “no regret” measures on the impacts adaptation side), to date very few have been developed

to the point at which comprehensive and quantitative assessment of adaptation options would be possible. Nevertheless, they are a prerequisite for establishing appropriate applications of the more quantitative DAFs reviewed in Section 2.7.2. The main reason is that, despite uncertainties of regional climate change patterns and resulting impacts, some information is generated about possible biophysical impacts. However, little is known about future socioeconomic sensitivity and even less about future adaptive capacity. Resolving this would require fairly detailed regional development scenarios to provide the broader context for sectoral assessments. All these factors together make rigorous applications of quantitative DAFs difficult.

A simple ranking of climate impact and adaptation studies according to how far they get in using DA tools would start with those that are preoccupied almost exclusively with impacts and casually mention some obvious adaptation options. The next category would be studies that attempt to produce a comprehensive list of possible adaptive measures. More advanced studies would explore positive and, if they exist, negative effects of listed options and try to establish at least a qualitative ranking. By assigning monetary values to those comprehensive effects, CBA could help determine the optimal level of adaptation measures; CEA would select the least-cost solution to provide a predetermined level of adaptation objective.

Perhaps the most crucial area of public policy in climate change adaptation is water resource management. A set of papers arranged by Frederick *et al.* (1997a) looks at different aspects of climate change and water resources planning. Their general conclusion is that DAFs adopted in public policy procedures of water management are largely “appropriate for planning and project evaluation under the prospect of climate change, but new applications and extensions of some criteria may be warranted” (Frederick *et al.*, 1997b). The authors mention nonstationarity, interest rates, and multiple objectives as issues on which progress is required to support better assessments of climate change adaptation decisions.

Water is an important factor to consider in most other sectoral impact and adaptation assessments, even if their primary focus is on a single sector. With a view to the complexity of interactions among sectoral impacts on one hand and adaptation measures on the other, integrated regional assessments increasingly are considered to be indispensable to understand climate-related risks.

2.7.4. Relevance and Use of DAFs in Regional Adaptation Decisions—Selected Examples

Sectoral adaptation decisions must be considered in the broader regional context in which evolution in related sectors and their responses to changing climatic conditions represent additional factors to consider in planning a given sector’s own adaptation strategy. This process is likely to involve a broad mix of private and public stakeholders and their interactions. From the perspectives of regional planners and policymakers who are

responsible for the overall socioeconomic development of a specific region, the challenge is to create conditions under which relevant sectoral actors can formulate their own adaptive strategies efficiently and install public policies that will help adaptation in sectors that provide public services and manage public resources.

Designing and implementing regional climate change studies that incorporate full-fledged DAFs to support the development of regional climate adaptation policies has proven to be an insurmountable challenge to date. This is understandable, in view of the difficulties involved, and indicates a crucial research area for the future.

Most statements on regional adaptation policies in the literature stem from limited but logical extensions of sectoral climate impact assessment studies. Once possible biophysical changes and their direct or indirect socioeconomic consequences are established, impact assessors mention a few options that could mitigate those impacts or moderate their consequences. Seldom are these lists comprehensive, and they scarcely entail even direct cost estimates, let alone assessments of indirect costs and ancillary benefits involved in the specified adaptation options.

The study by Ringius *et al.* (1996) on climate change vulnerability and adaptation in Africa is a good example. Focusing on impacts on agriculture and water, the authors develop a typology of adaptive responses and discuss their effectiveness from the perspectives of different stakeholders. Although the study is extremely useful in pointing out that a convenient and crucial starting point for decisions on adapting to expected climate change in Africa is to reduce present vulnerability and enhance the capacity to respond to any environmental and economic perturbations (not just climate and weather), no attempt has been made to evaluate the costs and benefits of different options or to rank them in terms of their effectiveness.

An early policy-oriented impact assessment study adopted the PE approach to synthesize results of sectoral studies in a DAF in selected countries in southeast Asia (Toth, 1992a,b). The project included data collection, modeling, completion of first-order impact assessments, analysis of socioeconomic impacts on the impact assessment side, development of background scenarios, and pre-interviews with "policy" participants as preparations for PE workshops. The results of these workshops indicate that the PE approach might be a useful tool in structuring the numerous uncertain facets that are related to developing robust regional adaptation policies.

A partially integrated regional cost-benefit assessment has been prepared for the entire coastal area of Poland (Zeidler, 1997). Scenarios of sea-level rise have been combined with different assumptions about socioeconomic development in the potentially affected coastal region to explore mainly direct and relatively easy-to-estimate costs and benefits of three specifically defined adaptation strategies: retreat (no adaptation), limited protection, and full protection. Because of its numerous merits and despite its limitations, this study has demonstrated the feasibility of

using CBA to formulate climate change adaptation problems in a simple DAF and the potential usefulness of its results to policymakers.

2.7.5. Contribution of DAFs in Adaptation to Integrated Climate Change Decisions on Balancing Mitigation and Adaptation

Information generated in applying DAFs in sectoral and regional climate impact assessment studies is oriented primarily toward decisionmakers who have the mandate to initiate and implement public policies to reduce future adverse impacts of climate change. Just the attempt to integrate adaptation options into selected DAFs would force analysts to think comprehensively and achieve internal consistency, to consider broader factors beyond the influence of sectoral or regional stakeholders. Even though a comprehensive CBA or DAF remains difficult to develop, the overall quality of the impact assessment improves.

A second, equally important use of these results is to help define GHG mitigation objectives. National and regional positions at global negotiations on long-term climate stabilization targets (with respect to anthropogenic forcing) apparently are influenced by perceived risks involved in climate change as well as net damage remaining even after plausible and affordable adaptation options have been considered.

Admittedly, it is a difficult task to formulate impact/adaptation studies properly in any DAF. This explains the modest progress in the field since the SAR. Regional and sectoral chapters in this volume review a small number of DAF applications, whereas there was hardly any application on which to report in the SAR.

2.8. Conclusion

In the decade prior to the SAR, the preponderance of studies employed methods and tools largely for the purpose of ascertaining the biophysical impacts of climate change, usually on a sectoral basis. Thus, the methods included models and other means for examining the impacts of climate change on water resources, agriculture, natural ecosystems, or coasts. Such methods have improved with regard to detection of climate change in biotic and physical systems and produced new substantive findings. In addition, since the SAR, cautious steps have been taken to expand the "toolbox" to address more effectively the human dimensions of climate as cause and consequence of change and to deal more directly with cross-sectoral issues concerning vulnerability, adaptation, and decisionmaking. In particular, more studies have begun to apply methods and tools for costing and valuing effects, treating uncertainties, integrating effects across sectors and regions, and applying DAFs to evaluate adaptive capacity. Overall, these modest methodological developments are encouraging analyses that will build a more solid foundation for understanding how decisions regarding adaptation to future climate change might be taken.

EXECUTIVE SUMMARY

What are Scenarios and What is Their Role?

A scenario is a coherent, internally consistent, and plausible description of a possible future state of the world. Scenarios commonly are required in climate change impact, adaptation, and vulnerability assessments to provide alternative views of future conditions considered likely to influence a given system or activity. A distinction is made between climate scenarios—which describe the forcing factor of focal interest to the Intergovernmental Panel on Climate Change (IPCC)—and nonclimatic scenarios, which provide socioeconomic and environmental “context” within which climate forcing operates. Most assessments of the impacts of future climate change are based on results from impact models that rely on quantitative climate and nonclimatic scenarios as inputs.

Types of Scenarios

Socioeconomic scenarios can serve multiple roles within the assessment of climate impacts, adaptation, and vulnerability. Until recently, they have been used much more extensively to project greenhouse gas (GHG) emissions than to assess climate vulnerability and adaptive capacity. Most socioeconomic scenarios identify several different topics or domains, such as population or economic activity, as well as background factors such as the structure of governance, social values, and patterns of technological change. Scenarios make it possible to establish baseline socioeconomic vulnerability, pre-climate change; determine climate change impacts; and assess post-adaptation vulnerability.

Land-use and land-cover scenarios should be a major component of scenarios for climate change impact and adaptation assessments. A great diversity of land-use and land-cover change scenarios have been constructed. However, most of these scenarios do not address climate change issues explicitly; they focus instead on other issues—for example, food security and carbon cycling. Large improvements have been made since the Second Assessment Report (SAR) in defining current and historic land-use and land-cover patterns, as well as in estimating future scenarios. Integrated assessment models currently are the most appropriate tools for developing land-use and land-cover change scenarios.

Environmental scenarios embrace changes in environmental factors other than climate that will occur in the future regardless of climate change. Because these changes could have an important role in modifying the impacts of future climate change, scenarios are required to portray possible future environmental conditions,

such as atmospheric composition [e.g., carbon dioxide (CO_2), tropospheric ozone (O_3), acidifying compounds, and ultraviolet (UV)-B radiation]; water availability, use, and quality; and marine pollution. Apart from the direct effects of CO_2 enrichment, changes in other environmental factors rarely have been considered alongside climate changes in past impact assessments, although their use is increasing with the emergence of integrated assessment methods.

Climate scenarios of three main types have been employed in impact assessments: incremental scenarios, analog scenarios, and climate model-based scenarios. Of these, the most common use outputs from general circulation models (GCMs) and usually are constructed by adjusting a baseline climate (typically based on regional observations of climate over a reference period such as 1961–1990) by the absolute or proportional change between the simulated present and future climates. Most recent impact studies have constructed scenarios on the basis of transient GCM outputs, although some still apply earlier equilibrium results. Regional detail is obtained from the coarse-scale outputs of GCMs by using three main methods: simple interpolation, statistical downscaling, and high-resolution dynamic modeling. The simple method, which reproduces the GCM pattern of change, is the most widely applied in scenario development. In contrast, the statistical and modeling approaches can produce local climate changes that are different from the large-scale GCM estimates. More research is needed to evaluate the value added to impact studies of such regionalization exercises. One reason for this caution is the large uncertainty of GCM projections, which requires further quantification through model intercomparisons, new model simulations, and pattern-scaling methods. Such research could facilitate future evaluation of impacts in a risk assessment framework.

Sea-level rise scenarios are required to evaluate a diverse range of threats to human settlements, natural ecosystems, and landscape in coastal zones. Relative sea-level scenarios (i.e., sea-level rise with reference to movements of the local land surface) are of the most interest for impact and adaptation assessments. Tide gauge and wave height records of 50 years or more are required, along with information on severe weather and coastal processes, to establish baseline levels or trends. Although some components of future sea-level rise can be modeled regionally, using coupled ocean-atmosphere models, the most common method of obtaining scenarios is to apply global mean estimates from simple models. Changes in the occurrence of extreme events such as storm surges and wave set-up, which can lead to major coastal impacts, sometimes are investigated by superimposing historically observed events

onto rising mean sea level. More recently, some studies have begun to express future sea-level rise in probabilistic terms, enabling rising levels to be evaluated in terms of the risk that they will exceed a critical threshold of impact.

How Useful have Scenarios Been in Past Impact and Adaptation Assessments?

Study of past assessments has highlighted problems of compatibility in the development and application of scenarios. These problems include difficulties in obtaining credible and compatible projections over long time horizons across different scientific disciplines, inconsistencies in scenarios adopted and their methods of application between different impact assessments, and time lags between reporting of recent climate science and the use of this science in developing scenarios for impact assessment. Furthermore, the use of nonclimatic scenarios at the regional level, alongside more conventional climate scenarios, is only a relatively recent introduction to impact assessment, and methods of scenario development (especially of socioeconomic scenarios) still are at a rudimentary level.

Scenarios of the 21st Century

The IPCC recently completed the *Special Report on Emissions Scenarios* (SRES) to replace the earlier set of six IS92 scenarios developed for the IPCC in 1992. These new scenarios consider the period 1990–2100 and include a range of socioeconomic assumptions [e.g., a global population by 2100 of 7.0–15.1 billion; average gross domestic product (GDP) of \$197–550 trillion (1990 US\$)]. Their implications for other aspects of global change also have been calculated. For example, mean ground-level O₃ concentrations in July over the industrialized continents of the northern hemisphere are projected to rise from about 40 ppb in 2000 to more than 70 ppb in 2100 under the highest illustrative SRES emissions scenarios. Estimates of CO₂ concentration range from 478 to 1099 ppm by 2100, accounting for the range of SRES emissions and uncertainties about the carbon cycle. This range of implied radiative forcing gives rise to an estimated global warming from 1990 to 2100 of 1.4–5.8°C, assuming a range of climate sensitivities. This range is somewhat higher than the 0.7–3.5°C of the SAR because of higher levels of radiative forcing in the SRES scenarios than in the IS92a-f scenarios, primarily because of lower sulfate aerosol emissions, especially after 2050. The equivalent range of estimates of global sea-level rise (for this range of global temperature change in combination with a range of ice-melt sensitivities) to 2100 is 9–88 cm (compared to 15–95 cm in the SAR).

In terms of *mean changes of climate*, results from GCMs that have been run to date—assuming the new SRES emissions scenarios—display many similarities with previous runs. Rates of warming are expected to be greater than the global average over most land areas and most pronounced at high latitudes in

winter. As warming proceeds, northern hemisphere snow cover and sea-ice extent will be reduced. Models indicate warming below the global average in the North Atlantic and circumpolar southern ocean regions, as well as in southern and southeast Asia and southern South America in June–August. Globally, there will be increases in average water vapor and precipitation. Regionally, December–February precipitation is expected to increase over the northern extratropics and Antarctica and over tropical Africa. Models also agree on a decrease in precipitation over Central America and little change in southeast Asia. Precipitation in June–August is expected to increase in high northern latitudes, Antarctica, and south Asia; to change little in southeast Asia; and to decrease in Central America, Australia, southern Africa, and the Mediterranean region.

Changes in the frequency and intensity of extreme climate events also can be expected. Based on the conclusions of the Working Group I report and the likelihood scale employed there, under GHG forcing to 2100, it is very likely that daytime maximum and minimum temperatures will increase, accompanied by an increased frequency of hot days. It also is very likely that heat waves will become more frequent; the number of cold waves and frost days (in applicable regions) will decline. Increases in high-intensity precipitation events are likely at many locations, and Asian summer monsoon precipitation variability also is likely to increase. The frequency of summer drought will increase in many interior continental locations, and it is likely that droughts, as well as floods, associated with El Niño events will intensify. The peak wind intensity and mean and peak precipitation intensities of tropical cyclones are likely to increase. The direction of changes in the average intensity of mid-latitude storms cannot be determined with current climate models.

How can We Improve Scenarios and Their Use?

Methods of scenario construction and application are evolving rapidly, but numerous deficiencies still must be addressed:

- Representing and integrating future nonclimatic (socioeconomic, environmental, and land-use) changes in scenarios for impact assessment
- Treatment of scenario uncertainties
- The requirement for scenario information at higher spatial and temporal resolution
- Representing changes in variability and the frequency of extreme events in scenarios
- Reducing time lags between climate modeling and climate scenario development
- Increasing attention on the construction of policy-relevant scenarios (e.g., stabilization of atmospheric CO₂ concentration)
- Recognizing linkages between scenarios for studies of mitigation, impacts, and adaptation
- Improving guidance material and training in construction and application of scenarios.

3.1. Definitions and Role of Scenarios

3.1.1. Introduction

This chapter examines the development and application of scenarios required for assessment of climate change impacts, adaptation, and vulnerability. Scenarios are one of the main tools for assessment of future developments in complex systems that often are inherently unpredictable, are insufficiently understood, and have high scientific uncertainties. The central goals of the chapter are to set out the different approaches to scenario use, to evaluate the strengths and weaknesses of these approaches, and to highlight key issues relating to scenario application that should be considered in conducting future assessments.

Recognizing the central role of scenarios in impact and adaptation studies, scenarios are treated separately for the first time by Working Group II.¹ This chapter builds on Chapter 13 of the WGI contribution to the Third Assessment Report (TAR), which describes construction of climate scenarios, by embracing scenarios that portray future developments of any factor (climatic or otherwise) that might have a bearing on climate change vulnerability, impacts, and adaptive capacity. A distinction is drawn between climate scenarios, which describe the forcing factor of key interest in this report, and nonclimatic scenarios (e.g., of projected socioeconomic, technological, land-use, and other environmental changes), which provide the “context”—a description of a future world on which the climate operates. Many early impact assessments tended to focus on climate forcing without properly considering the context, even though this might have an important or even dominant role in determining future vulnerability to climate.

In addition to serving studies of impacts, scenarios are vital aids in evaluating options for mitigating future emissions of greenhouse gases (GHGs) and aerosols, which are known to affect global climate. For instance, projections of future socioeconomic and technological developments are as essential for obtaining scenarios of future emissions as they are for evaluating future vulnerability to climate (see TAR WGIII Chapter 2). Thus, although the focus of this chapter is on the development and use of scenarios in impact and adaptation assessment, reference to scenarios that have been developed for purposes of addressing mitigation is important and unavoidable.

There is a varied lexicon for describing future worlds under a changing climate; alternative terms often reflect differing disciplinary origins. Therefore, for the sake of consistency in this chapter, working definitions of several terms are presented in Box 3-1.

¹Hereafter the Working Group I, II, and III contributions to the Third Assessment Report (TAR) are referred to as WGI, WGII, and WGIII, respectively.

Box 3-1. Definitions

Projection. The term “projection” is used in two senses in this chapter. In general usage, a projection can be regarded as any description of the future and the pathway leading to it. However, a more specific interpretation was attached to the term “climate projection” throughout the Second Assessment Report (SAR) to refer to model-derived estimates of future climate.

Forecast/Prediction. When a *projection* is branded “most likely,” it becomes a forecast or prediction. A forecast is often obtained by using deterministic models—possibly a set of such models—outputs of which can enable some level of confidence to be attached to projections.

Scenario. A scenario is a coherent, internally consistent, and plausible description of a possible future state of the world (IPCC, 1994). It is not a *forecast*; each scenario is one alternative image of how the future can unfold. A *projection* may serve as the raw material for a scenario, but scenarios often require additional information (e.g., about *baseline* conditions). A set of scenarios often is adopted to reflect, as well as possible, the range of uncertainty in projections. Indeed, it has been argued that if probabilities can be assigned to such a range (while acknowledging that significant unquantifiable uncertainties outside the range remain), a new descriptor is required that is intermediate between *scenario* and *forecast* (Jones, 2000). Other terms that have been used as synonyms for scenario are “characterization” (*cf.* Section 3.8), “storyline” (*cf.* Section 3.2), and “construction.”

Baseline/Reference. The baseline (or reference) is any datum against which change is measured. It might be a “current baseline,” in which case it represents observable, present-day conditions. It also might be a “future baseline,” which is a projected future set of conditions, excluding the driving factor of interest. Alternative interpretations of reference conditions can give rise to multiple baselines.

3.1.2. Function of Scenarios in Impact and Adaptation Assessment

Selection and application of baseline and scenario data occupy central roles in most standard methodological frameworks for conducting climate change impact and adaptation assessment (e.g., WCC, 1993, 1994; IPCC, 1994; Smith *et al.*, 1996; Feenstra *et al.*, 1998; see Section 2.1). Many assessments treat scenarios *exogenously*, as an input, specifying key future socioeconomic and environmental baselines of importance for

an exposure unit,² possibly with some aspects of adaptation potential also considered. Other assessments—especially those that use integrated assessment models (IAMs)—generate projections (e.g., of emissions, concentrations, climate, sea level) *endogenously* as outcomes, requiring only prior specification of the key driving variables (e.g., economic development, population). Outputs from such assessments might be applied themselves as scenarios for downstream analysis. Moreover, in IAMs, some of the original driving variables may be modified through modeled feedbacks.

Scenarios are widely used in climate change-related assessments. For some uses, scenarios are qualitative constructions that are intended to challenge people to think about a range of alternative futures that might go beyond conventional expectations or “business as usual” (BAU). Some of the socioeconomic and technological assumptions underlying GHG emissions scenarios are of this type (see TAR WGIII Chapter 2). For other uses, scenarios may be mainly quantitative, derived by running models on the basis of a range of different input assumptions. Most assessments of the impacts of future climate change are based on results from impact models that rely on quantitative climate and nonclimatic scenarios as inputs. Some scenario exercises blend the two approaches. However, not all impact assessments require a scenario component; in some cases, it may be sufficient that system sensitivities are explored without making any assumptions about the future.

3.1.3. Approaches to Scenario Development and Application

The approaches employed to construct scenarios vary according to the purpose of an assessment. For instance, scenarios may be required for:

- Illustrating climate change (e.g., by depicting the future climate expected in a given region in terms of the present-day climate currently experienced in a familiar neighboring region)
- Communicating potential consequences of climate change (e.g., by specifying a future changed climate to estimate potential future shifts in natural vegetation and identifying species at risk of local extinction)
- Strategic planning (e.g., by quantifying possible future sea-level and climate changes to design effective coastal or river flood defenses)
- Guiding emissions control policy (e.g., by specifying alternative socioeconomic and technological options for achieving some prespecified GHG concentrations)
- Methodological purposes (e.g., by describing altered conditions, using a new scenario development technique, or to evaluate the performance of impact models).

A broad distinction can be drawn between exploratory scenarios, which project anticipated futures, and normative scenarios,

which project prescribed futures. In practice, however, many scenarios embrace aspects of both approaches.

3.1.3.1. Exploratory Scenarios

Exploratory (or descriptive) scenarios describe how the future might unfold, according to known processes of change or as extrapolations of past trends. They are sometimes described as BAU scenarios; often they involve no major interventions or paradigm shifts in the organization or functioning of a system but merely respect established constraints on future development (e.g., finite resources, limits on consumption). However, the term “business-as-usual” may be misleading because exploratory scenarios also can describe futures that bifurcate at some point (an example might be uptake or rejection of a new technology) or that make some assumptions about regulation and/or adaptation of a system. The simplest model is a direct extrapolation of past trends (e.g., projection of future agricultural crop productivity often is based on extrapolation of recorded increases in productivity; Mela and Suvanto, 1987; Alexandratos, 1995). Most climate scenarios considered in this report can be regarded as exploratory: They are future climates that might occur in the absence of explicit policies of GHG reduction.

3.1.3.2. Normative Scenarios

Normative (or prescriptive) scenarios describe a prespecified future, presenting “a picture of the world achievable (or avoidable) only through certain actions. The scenario itself becomes an argument for taking those actions” (Ogilvy, 1992). Normative scenarios span a wide spectrum, according to their degree of prescriptiveness. At one end of the spectrum are scenarios that are constrained in only one or a few dimensions. For example, scenarios that lead to a substantial degree of climate change sometimes are used as a reference for assessing the “worst case” as far as impacts are concerned (e.g., scenarios that explore extreme events and tails of frequency distributions).

At the other extreme of the spectrum are comprehensive, multidimensional normative scenarios that are constructed to meet the constraints of a prescribed target world. Examples are scenarios that constrain emissions within bounds (“safe emissions corridors”) that avoid inducing a critical climate change, defined according to a subjectively selected impact criterion (Alcamo and Kreileman, 1996). Most of the emissions stabilization scenarios explored by the IPCC in recent assessments (IPCC, 1996a; Schimel *et al.*, 1997a) are founded on similar premises.

3.1.4. What Changes are Being Considered?

The types of scenarios examined in this chapter are depicted schematically in Figure 3-1; they include scenarios of:

- *Socioeconomic factors* (Section 3.2), which are the major underlying anthropogenic cause of environmental

²An exposure unit is an activity, group, region, or resource that is exposed to significant climatic variations (IPCC, 1994).

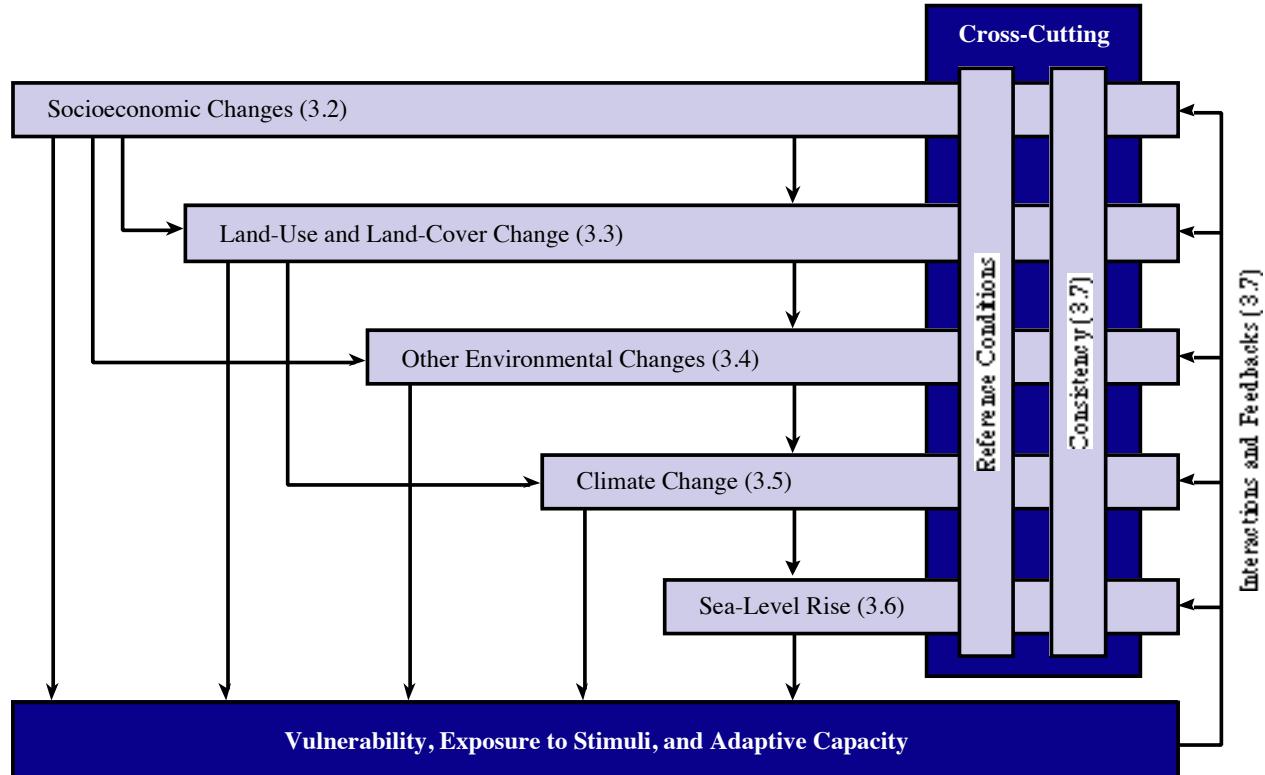

Figure 3-1: Types of scenarios required in climate impact, adaptation, and vulnerability assessment and their interactions. Numbers in parentheses refer to sections of this chapter.

- change and have a direct role in conditioning the vulnerability of societies and ecosystems to climatic variations and their capacity to adapt to future changes.
- *Land use and land cover* (Section 3.3), which currently are undergoing rapid change as a result of human activities. Climate change itself may induce land-use and land-cover changes, with probable feedbacks to the climate system. Furthermore, future land cover may be influenced by efforts to sequester carbon and offset GHG emissions into the atmosphere.
 - *Other environmental factors* (Section 3.4), which is a catch-all for a range of nonclimatic changes in the natural environment (e.g., CO₂ concentration, air pollution, stratospheric ozone depletion, and freshwater availability) that are projected to occur in the future and could substantially modify the vulnerability of a system or activity to impacts from climate change.
 - *Climate* (Section 3.5), which is the focus of the IPCC and underpins most impact assessments reported in this volume.
 - *Sea level* (Section 3.6), which generally is expected to rise relative to the land (with some regional exceptions) as a result of global warming—posing a threat to some low-lying coasts and islands.

Issues that are common to all scenarios concerning scenario consistency and the interactions and feedbacks between scenarios

are treated in Section 3.7. Characterizations of future climate and related conditions during the 21st century, based on the new IPCC emissions scenarios, are introduced in Section 3.8, and the chapter closes with a brief examination of key gaps in knowledge and emerging new methods of scenario development.

3.2. Socioeconomic Scenarios

3.2.1. Purpose

The main purposes of socioeconomic scenarios in the assessment of climate impacts, adaptation, and vulnerability are:

- To characterize demographic, socioeconomic, and technological driving forces underlying anthropogenic GHG emissions that cause climate change
- To characterize the sensitivity, adaptive capacity, and vulnerability of social and economic systems in relation to climate change.

This section focuses on the second use. However, in integrated global assessments, scenarios underpinning these two applications should be consistent with one another. Many key parameters, such as population and economic growth, are common to both types of exercise. More flexibility with regard to consistency may be appropriate at local and regional scales. Regional trends

may be diverse, and developments in a specific region may diverge from those at the global level.

The use of socioeconomic scenarios in assessing vulnerability to climate change is less well developed than their use in exploring GHG emissions. The IPCC *Technical Guidelines for Assessing Climate Change Impacts and Adaptations* (IPCC, 1994) recommend the use of socioeconomic scenarios, with and without climate change, to assess impacts and adaptive responses. At that time, few studies had reached that ideal. As new frameworks for characterizing vulnerability develop (Downing *et al.*, 1999), impact studies can begin to use more consistent, global scenario approaches.

Socioeconomic scenarios in impact assessment have tended to focus on quantitative characterization of key parameters and to ignore the qualitative “storyline” elements of a fully developed scenario approach. If the implications of climate change impacts and adaptation on sustainable development are to be assessed (Munasinghe, 2000), much more sophisticated descriptions of vulnerable impact units will be required, along with better understanding of institutional and economic coping capacity. Section 3.2.4 provides examples of emerging work of this kind.

Socioeconomic scenarios in general have been developed to aid decisionmaking under conditions of great complexity and uncertainty in which it is not possible to assign levels of probability to any particular state of the world at a future point in time. Therefore, it usually is not appropriate to make a statement of confidence concerning a specific socioeconomic scenario (Moss and Schneider, 2000). However, this does not mean that all scenarios are equally likely. Some, used to test sensitivities, may be at the limits of the range of plausibility. More robust statements may be possible about the level of confidence in specific quantitative indicators, such as population or GDP, associated with given scenarios.

3.2.2. Representing Baseline Conditions

The socioeconomic baseline describes the present or future state of all nonenvironmental factors that influence an exposure unit. The factors may be geographical (land use or communications), technological (pollution control, water regulation), managerial (forest rotation, fertilizer use), legislative (water-use quotas, air quality standards), economic (income levels, commodity prices), social (population, diet), or political (levels and styles of decisionmaking). The IPCC has published a set of baseline statistics for 195 countries that are representative of the early to mid-1990s (IPCC, 1998). The data were collected from a variety of sources, such as the World Bank, the United Nations Environment Programme (UNEP), and the Food and Agriculture Organization (FAO) (see Table 3-1). These are only selected, summary data; individual impact studies are likely to require information on other factors or at a much higher spatial resolution.

Climate change impact assessment requires sound understanding of current socioeconomic vulnerabilities. These vulnerabilities

have implications for deliberate adaptations that “involve conscious actions to mitigate or exploit the effects of climate change” (Adger, 1999). Many of those who are exposed will be vulnerable to a range of other stresses, *irrespective* of climate change (e.g., high population growth, rapid urbanization, environmental degradation, ambient air pollution, social inequality, infrastructure degradation, and health hazards). In time, stresses associated with the development process may reinforce those generated by climate change. For instance, sea-level rise causes saltwater intrusion, which can be aggravated by diverting freshwater outflows to satisfy the needs of agriculture, energy, and human consumption.

3.2.3. Constructing Socioeconomic Scenarios

Socioeconomic scenarios can be constructed in the same variety of ways and for the same variety of purposes as global change scenarios in general. In practice, a variety of approaches may be combined in a single exercise. The UNEP country studies program has developed detailed guidance on construction and use of socioeconomic scenarios (Tol, 1998). This guidance emphasizes the importance of avoiding simple extrapolation—especially for developing countries, which may be undergoing demographic or economic transition; the role of formal modeling in filling in, but not defining, scenarios; and the role of expert judgment in blending disparate elements into coherent and plausible scenarios.

Most socioeconomic scenarios cover several different topics or domains, such as population or economic activity. Table 3-1 shows the range of issues covered in recent scenario or scenario-based exercises.

3.2.3.1. Basic Drivers

Population and economic activity are characterized in quantitative terms in most scenario exercises. The degree of disaggregation according to world region, country, or sector varies from one study to another. Coverage of other socioeconomic domains also can vary markedly among different activities.

3.2.3.2. Underlying Socioeconomic Drivers

Some scenarios incorporate explicit assumptions about underlying socioeconomic drivers of change such as social values and governance institutions. These scenarios usually are generated through synthetic or expert judgment-led approaches, expressed in qualitative terms. Social values can affect the willingness of societies to preserve ecosystems or protect biodiversity. Institutional and governance factors affect the capacity of a society to organize and direct the resources needed to reduce climate vulnerability (Adger, 1999). Qualitative factors such as institutional effectiveness and social values are key determinants of the effectiveness of coping strategies for adapting to climate change (see Chapter 18). They

determine adaptive capacity and hence the vulnerability of socioeconomic systems. They are critical in any assessment of the implications of climate change for development, equity, and sustainability (Munasinghe, 2000).

3.2.3.3. Technological Change

Technology critically affects the capacity to adapt to climate change; it confers opportunities and risks. For example, genetic modification of crops and other developments in agricultural technology could enhance that sector's ability to adapt to different climatic conditions. However, excessive reliance on one particular strain of plant might increase vulnerability.

Technological change must be characterized in quantitative and qualitative terms. It may be very difficult to identify specific

features of a technology that could affect vulnerability to climate change. Expert judgments are needed about the direction in which change takes place, public acceptability of different options, and the rate of adoption in the marketplace. Quantitative assumptions will be needed about the rate of improvement of a technology, including its cost, overall efficiency in using resources to meet the need for a given service, and possible impacts at various scales.

3.2.3.4. Time Horizons

The appropriate time horizon for socioeconomic scenarios depends on the use to which they are put. Climate modelers often use scenarios that look forward 100 years or more. Socioeconomic scenarios with similar time horizons may be needed to drive models of climate change, climate impacts, and

land-use change. However, policymakers also may wish to use socioeconomic scenarios as decision tools in framing current policies for climate change adaptation. In this context, time horizons on the order of 20 years may be more appropriate, reflecting the immediate needs of decisionmakers.

Short-term socioeconomic scenarios can still be very uncertain. “Surprises” such as economic slumps or booms, wars, or famines frequently occur in social and economic systems. Over the course of 50–100 years, even the most basic scenario drivers, such as population and aggregate economic activity, are highly uncertain, and their future development can be projected with any credibility only by using alternative scenarios. Moreover, technologies will have been replaced at least once, and those in use 100 years hence could have unimagined effects on climate sensitivity and vulnerability. Politically led developments in local, regional, and international systems of governance also will unfold along unpredictable paths.

3.2.3.5. Spatial Resolution

Global emissions scenarios form the framework for predicting climate change and variability impacts at the national level. To assess vulnerability and adaptation potential, national scenarios must account for biophysical and socioeconomic impacts. The potential for autonomous adaptations must be understood, reflecting the ability of nature and society to cope with climate change and climate variability. Many of the impacts of climate change on the coping ability of human systems are likely to be location-specific. Impact assessors therefore should make use of local/regional scenarios, where appropriate, and be wary of generalizing experiences from one location to another. Matching of regional scenarios may be difficult, however—for example, if data on population and land use are available at different levels of resolution.

3.2.3.6. Sectoral Scenarios

As illustrated in Table 3-1, scenario exercises often make specific assumptions about individual sectors. These sectors usually are chosen because they are considered particularly sensitive to climate change (e.g., water, agriculture/food) or because they are important sources or sinks for GHGs (e.g., energy, forestry). Detailed quantitative assumptions often are made about levels of future economic activity or the price of key commodities, which will influence adaptation strategies.

Formal modeling work generally is used to improve the detail, coherence, and internal consistency of socioeconomic variables that are susceptible to quantification. Expert judgment or stakeholder consultations may be used to build consensus around the characterization of more subjective and less quantifiable variables that relate to values and institutions. Stakeholder engagement also can provide a wealth of local expertise about specific impacts and vulnerabilities.

3.2.4. Use of Socioeconomic Scenarios

This section presents a set of case studies that illustrates a range of specific approaches to the construction of socioeconomic scenarios that are relevant to climate impact assessment.

3.2.4.1. IPCC Special Report on Emissions Scenarios

The IPCC’s *Special Report on Emissions Scenarios* (SRES) (Nakicenovic *et al.*, 2000) was prepared to improve on the earlier set of six IS92 scenarios developed in 1992 (Leggett *et al.*, 1992). The SRES describes 40 scenarios in all—based on an extensive literature assessment, six alternative modeling approaches, and an “open process” that solicited worldwide participation and feedback. The scenarios (which are described in more detail in Section 3.8) cover the main demographic, economic, technological, and land-use driving forces of future emissions. They include emissions of all relevant GHGs plus sulfur dioxide (SO_2), carbon monoxide (CO), nitrogen oxides (NO_x), and nonmethane volatile organic hydrocarbons (VOCs). The IPCC specified that the scenarios should not include future policies that explicitly address climate change. However, they necessarily encompass other policies that may indirectly influence GHG sources and sinks. The scenarios suggest that assumptions about technology, rather than population and economic development, may be the most important driving force of future emissions.

The SRES emissions scenarios serve several purposes. First, they provide baselines of socioeconomic, technological, and land-use change, in combination with emissions trajectories, for the assessment of mitigation policies and measures (see TAR WGIII Chapter 2). Second, they can be used to drive the assessment of climate change (see TAR WGI and Section 3.8). Third, they provide a global socioeconomic framework for regional-scale assessment of impacts and adaptation [e.g., see the United Kingdom Climate Impacts Programme (UKCIP) and European ACACIA examples, below].

3.2.4.2. UNEP Pakistan Country Study

The Pakistan Environment Ministry has produced a suite of three socioeconomic scenarios to inform national climate impact and adaptation planning (Government of Pakistan, 1998). The scenarios focus on two reference years—2020 and 2050—and include a combination of quantitative and qualitative indicators. Quantitative scenarios are presented for population, economic growth, agricultural production, energy demand, and industrial output. Variations in future rates of literacy, health care, import tariffs, forest cover, and infrastructure are expressed in qualitative terms. The 2020 scenario is the more detailed of the two; it is a composite of existing national projections and scenarios produced for “nonclimate” policymaking. The 2020–2050 scenarios were developed for the sole purpose of informing climate impact assessments and are much less detailed (Tol, 1998).

3.2.4.3. UKCIP “Nonclimate Scenarios” for Climate Impact Assessment

A set of “nonclimate scenarios” has been developed to provide a common framework for assessing climate impacts and adaptation under the stakeholder-led UKCIP (Berkhout *et al.*, 1999). The scenarios were based on a broader “Environmental Futures” exercise (UK National Foresight Programme, 1999)—which, in turn, had drawn on emerging SRES work.

Four scenarios for the 2020s and 2050s were defined by two factors affecting the capacity and willingness of society to adapt to climate change: the extent to which social values reflect environmental concern and the effectiveness of governance institutions. Development of the scenarios involved extensive consultations with stakeholders (Lorenzoni *et al.*, 2000). As a result, detailed scenario characterization was confined to the 2020s. For each scenario, key national indicators were developed. These indicators included population and GDP, as well as more specific variables relating to land-use change, patterns of agricultural activity, water demand, and investment in coastal defense. In addition, climate vulnerability was assessed qualitatively in several “impact domains,” including agriculture, water, biodiversity, coastal zone management, and infrastructure and the built environment.

The framework scenarios were found to be a useful starting point for subsequent studies. However, the scenarios needed to be articulated in more detail to be useful at the regional or sectoral level. More quantification generally was required. This exercise underlined the need for scenarios to be tailored for end users, while maintaining broad consistency about key indicators such as population and GDP.

3.2.4.4. ACACIA Scenarios for Europe

ACACIA (A Concerted Action Towards A Comprehensive Climate Impacts and Adaptations Assessment for the European Union) assessed climate impacts and potential adaptation in Europe to the 2080s (Parry, 2000). ACACIA elaborated four scenarios on the basis of a combination of the UKCIP and SRES approaches (Jordan *et al.*, 2000; see also Chapter 13). This analysis concluded that certain systems will thrive under some scenarios and will be inherently more vulnerable in others, *independent of* climate change. Adaptive strategies are likely to differ across the four scenarios. In addition, the manner in which society values different parts of the human and physical environment is markedly different under the different scenarios, with clear implications for adaptation policies.

3.2.4.5. U.S. National Assessment

The approach to socioeconomic scenarios adopted by the U.S. National Assessment of Climate Impacts was determined by the nature of the assessment process, with a national synthesis linking separate analyses in nine U.S. regions and five sectors

(National Assessment Synthesis Team, 1998). Recognizing that the sensitivity of particular regions or sectors may depend on highly specific socioeconomic characteristics, the assessment adopted a two-part approach to scenario development. First, to allow national aggregation, high, medium, and low scenarios were specified for variables such as population and GDP to be used by all subnational analyses (NPA Data Services, 1999). Second, teams were asked to identify a small number of additional socioeconomic variables that would have the strongest and most direct influence on their particular region or sector. They developed and documented their own assumptions for these variables, following a consistent template developed by the National Assessment Synthesis Team (NAST) (Parson, 1999). High and low values then could be assumed for each key impact variable, without having to specify what combination of demographic, market, ecosystem, and technological factors caused it to take a particular value. Teams were advised to construct a small set of high- and low-impact scenarios on the basis of different combinations of assumptions about key impact variables. Instead of an idealized approach to scenario development, which would have attempted to specify all factors consistently across different sectors and regions, the more pragmatic and pluralistic approach adopted in the U.S. National Assessment allowed regional and sectoral specificities to be reflected.

3.3. Land-Use and Land-Cover Change Scenarios

3.3.1. Purpose

The land cover of the Earth has a central role in many important biophysical and socioeconomic processes of global environmental change. Contemporary land cover is changed mostly by human use; therefore, understanding of land-use change is essential in understanding land-cover change (Turner *et al.*, 1995). Land use is defined through its purpose and is characterized by management practices such as logging, ranching, and cropping. Land cover is the actual manifestation of land use (i.e., forest, grassland, cropland) (IPCC, 2000). Land-use change and land-cover change (LUC-LCC) involve several processes that are central to the estimation of climate change and its impacts (Turner *et al.*, 1995). First, LUC-LCC influences carbon fluxes and GHG emissions (Houghton, 1995; Braswell *et al.*, 1997). This directly alters atmospheric composition and radiative forcing properties. Second, LUC-LCC changes land-surface characteristics and, indirectly, climatic processes (Bonan, 1997; Claussen, 1997). Third, LUC-LCC is an important factor in determining the vulnerability of ecosystems and landscapes to environmental change (Peters and Lovejoy, 1992). LCC, for example—through nitrogen addition, drainage and irrigation, and deforestation (Skole and Tucker, 1993; Vitousek *et al.*, 1997)—may alter the properties and possible responses of ecosystems. Finally, several options and strategies for mitigating GHG emissions involve land cover and changed land-use practices (IPCC, 1996b).

The central role of LUC-LCC highlights the importance of its inclusion in scenario development for assessing global change

impacts. To date this has not been done satisfactorily in most assessments (Leemans *et al.*, 1996a). For instance, in earlier emission scenarios (e.g., Leggett *et al.*, 1992), constant emission factors were applied to define land use-related methane (CH_4) and nitrous oxide (N_2O) emissions. Furthermore, linear extrapolations of observed deforestation rates were assumed, along with an averaged carbon content in deforested areas. The SRES scenarios (Nakicenovic *et al.*, 2000) have improved on the underlying LUC-LCC assumptions, considerably enhancing scenario consistency. Unfortunately, these SRES scenarios provide highly aggregate regional LUC-LCC information, which is difficult to use in impact assessments. A comprehensive treatment of the other roles of LUC-LCC in the climate system is still deficient. To highlight these shortcomings, this section reviews studies and approaches in which LUC-LCC information is applied to develop scenarios for both impact and mitigation assessment.

3.3.2. Methods of Scenario Development

3.3.2.1. Baseline Data

The SAR evaluated land-use and land-cover data sets and concluded that they often were of dubious quality (Leemans *et al.*, 1996a). Since the SAR, many statistical data sources have been upgraded and their internal consistency improved (e.g., FAO, 1999), although large regional differences in quality and coverage remain. In addition, the high-resolution global database, DISCover, has become available (Loveland and Belward, 1997). This database is derived from satellite data and consists of useful land-cover classes. Furthermore, attempts also have been made to develop historical land-use and land-cover databases (Ramankutty and Foley, 1999; Klein Goldewijk, 2001). These databases use proxy sources—such as historic maps, population-density estimates, and infrastructure—to approximate land-cover patterns. All of these improvements to the information base are important for initializing and validating the models used in scenario development for global change assessments.

3.3.2.2. Regional and Sector-Specific Approaches

A large variety of LUC-LCC scenarios have been constructed. Many of them focus on local and regional issues; only a few are global in scope. Most LUC-LCC scenarios, however, are developed not to assess GHG emissions, carbon fluxes, and climate change and impacts but to evaluate the environmental consequences of different agrosystems (e.g., Koruba *et al.*, 1996), agricultural policies (e.g., Moxey *et al.*, 1995), and food security (e.g., Penning de Vries *et al.*, 1997) or to project future agricultural production, trade, and food availability (e.g., Alexandratos, 1995; Rosegrant *et al.*, 1995). Moreover, changes in land-cover patterns are poorly defined in these studies. At best they specify aggregated amounts of arable land and pastures.

One of the more comprehensive attempts to define the consequences of agricultural policies on landscapes was the

“Ground for Choices” study (Van Latesteijn, 1995). This study aimed to evaluate the consequences of increasing agricultural productivity and the Common Agricultural Policy in Europe and analyzed the possibilities for sustainable management of resources. It concluded that the total amount of agricultural land and employment would continue to decline—the direction of this trend apparently little influenced by agricultural policy. Many different possibilities for improving agricultural production were identified, leaving room for development of effective measures to preserve biodiversity, for example. This study included many of the desired physical, ecological, socioeconomic, and regional characteristics required for comprehensive LUC-LCC scenario development but did not consider environmental change.

Different LUC-LCC scenario studies apply very different methods. Most of them are based on scenarios from regression or process-based models. In the global agricultural land-use study of Alexandratos (1995), such models are combined with expert judgment, whereby regional and disciplinary experts reviewed all model-based scenarios. If these scenarios were deemed inconsistent with known trends or likely developments, they were modified until a satisfactory solution emerged for all regions. This approach led to a single consensus scenario of likely agricultural trends to 2010. Such a short time horizon is appropriate for expert panels; available evidence suggests that expert reviews of longer term scenarios tend to be conservative, underestimating emerging developments (Rabbinge and van Oijen, 1997).

3.3.2.3. Integrated Assessment Models

Most scenarios applied in climate change impact assessments fail to account satisfactorily for LUC-LCC. By incorporating land-use activities and land-cover characteristics, it becomes feasible to obtain comprehensive estimates of carbon fluxes and other GHG emissions, the role of terrestrial dynamics in the climate system, and ecosystem vulnerability and mitigation potential. Currently, the only tools for delivering this are IAMs (Weyant *et al.*, 1996; Parson and Fisher-Vanden, 1997; Rotmans and Dowlatabadi, 1998; see also Section 1.4.6), but only a few successfully incorporate LUC-LCC, including Integrated Climate Assessment Model (ICAM—Brown and Rosenberg, 1999), Asian-Pacific Integrated Model (AIM—Matsuoka *et al.*, 1995), Integrated Model for the Assessment of the Greenhouse Effect (IMAGE—Alcamo *et al.*, 1998b), and Tool to Assess Regional and Global Environmental and Health Targets for Sustainability (TARGETS—Rotmans and de Vries, 1997). These models simulate interactions between global change and LUC-LCC at grid resolution (IMAGE, AIM) or by regions (ICAM, TARGETS). All of these models, however, remain too coarse for detailed regional applications.

LUC-LCC components of IAMs generally are ecosystem and crop models, which are linked to economic models that specify changes in supply and demand of different land-use products for different socioeconomic trends. The objectives of each model

differ, which has led to diverse approaches, each characterizing a specific application.

ICAM, for example, uses an agricultural sector model, which integrates environmental conditions, different crops, agricultural practices, and their interactions (Brown and Rosenberg, 1999). This model is implemented for a set of typical farms. Productivity improvements and management are explicitly simulated. Productivity levels are extrapolated toward larger regions to parameterize the production functions of the economic module. The model as a whole is linked to climate change scenarios by means of a simple emissions and climate module. A major advantage of ICAM is that adaptive capacity is included explicitly. Furthermore, new crops, such as biomass energy, can be added easily. Land use-related emissions do not result from the simulations. ICAM is used most effectively to assess impacts but is less well suited for the development of comprehensive spatially explicit LUC-LCC scenarios.

IMAGE uses a generic land-evaluation approach (Leemans and van den Born, 1994), which determines the distribution and productivity of different crops on a 0.5° grid. Achievable yields are a fraction of potential yields, set through scenario-dependent regional “management” factors. Changing regional demands for land-use products are reconciled with achievable yields, inducing changes in land-cover patterns. Agricultural expansion or intensification lead to deforestation or afforestation. IMAGE simulates diverse LUC-LCC patterns, which define fluxes of GHGs and some land-climate interactions. Changing crop/vegetation distributions and productivity indicate impacts. Emerging land-use activities (Leemans *et al.*, 1996a,b) and carbon sequestration activities defined in the Kyoto Protocol, which alter land-cover patterns, are included explicitly. This makes the model very suitable for LUC-LCC scenario development but less so for impact and vulnerability assessment because IMAGE does not explicitly address adaptive capacity.

3.3.3. Types of Land-Use and Land-Cover Change Scenarios

3.3.3.1. Driving Forces of Change

In early studies, the consequences of LUC often were portrayed in terms of the CO₂ emissions from tropical deforestation. Early carbon cycle models used prescribed deforestation rates and emission factors to project future emissions. During the past decade, a more comprehensive view has emerged, embracing the diversity of driving forces and regional heterogeneity (Turner *et al.*, 1995). Currently, most driving forces of available LUC-LCC scenarios are derived from population, income, and agricultural productivity assumptions. The first two factors commonly are assumed to be exogenous variables (i.e., scenario assumptions), whereas productivity levels are determined dynamically. This simplification does not yet characterize all diverse local driving forces, but it can be an effective approximation at coarser levels (Turner *et al.*, 1995).

3.3.3.2. Processes of LUC-LCC

The central role of LUC-LCC in determining climate change and its impacts has not fully been explored in the development of scenarios. Only limited aspects are considered. Most scenarios emphasize arable agriculture and neglect pastoralism, forestry, and other land uses. Only a few IAMs have begun to include more aspects of land use. Most scenarios discriminate between urban and rural population, each characterized by its specific needs and land uses. Demand for agricultural products generally is a function of income and regional preferences. With increasing wealth, there could be a shift from grain-based diets toward more affluent meat-based diets. Such shifts strongly alter land use (Leemans, 1999). Similar functional relations are assumed to determine the demand for nonfood products. Potential productivity is determined by climatic, atmospheric CO₂, and soil conditions. Losses resulting from improper management, limited water and nutrient availability, pests and diseases, and pollutants decrease potential productivity (Penning de Vries *et al.*, 1997). Most models assume constant soil conditions. In reality, many land uses lead to land degradation that alters soil conditions, affecting yields and changing land use (Barrow, 1991). Agricultural management, including measures for yield enhancement and protection, defines actual productivity. Unfortunately, management is demonstrably difficult to represent in scenarios.

Most attempts to simulate LUC-LCC patterns combine productivity calculations and demand for land-use products. In this step, large methodological difficulties emerge. To satisfy increased demand, agricultural land uses in some regions intensify (i.e., increase productivity), whereas in others they expand in area. These processes are driven by different local, regional, and global factors. Therefore, subsequent LCC patterns and their spatial and temporal dynamics cannot be determined readily. For example, deforestation is caused by timber extraction in Asia but by conversion to pasture in Latin America. Moreover, land-cover conversions rarely are permanent. Shifting cultivation is a common practice in some regions, but in many other regions agricultural land also has been abandoned in the past (Foster *et al.*, 1998) or is abandoned regularly (Skole and Tucker, 1993). These complex LUC-LCC dynamics make the development of comprehensive scenarios a challenging task.

The outcome of LUC-LCC scenarios is land-cover change. For example, the IMAGE scenarios (Alcamo *et al.*, 1998b) illustrate some of the complexities in land-cover dynamics. Deforestation continues globally until 2050, after which the global forested area increases again in all regions except Africa and Asia. Pastures expand more rapidly than arable land, with large regional differences. One of the important assumptions in these scenarios is that biomass will become an important energy source. This requires additional cultivated land.

3.3.3.3. Adaptation

Adaptation is considered in many scenarios that are used to estimate future agricultural productivity. Several studies (Rosenberg, 1993;

Rosenzweig and Parry, 1994; Brown and Rosenberg, 1999; Mendelsohn and Neumann, 1999) assume changes in crop selection and management and conclude that climate change impacts decrease when available measures are implemented. Reilly *et al.* (1996) conclude that the agricultural sector is not very vulnerable because of its adaptive capability. However, Risbey *et al.* (1999) warn that this capability is overestimated because it assumes rapid diffusion of information and technologies.

In contrast, most impact studies on natural ecosystems draw attention to the assumed fact that LCC will increase the vulnerability of natural systems (Peters and Lovejoy, 1992; Huntley *et al.*, 1997). For example, Sala *et al.* (2000) use scenarios of LUC-LCC, climate, and other factors to assess future threats to biodiversity in different biomes. They explicitly address a biome's adaptive capacity and find that the dominant factors that determine biodiversity decline will be climate change in polar biomes and land use in tropical biomes. The biodiversity of other biomes is affected by a combination of factors, each influencing vulnerability in a different way.

3.3.4. Application and Interpretation of Scenarios and their Uncertainties

LUC-LCC scenarios are all sensitive to underlying assumptions of future changes in, for example, agricultural productivity and demand. This can lead to large differences in scenario conclusions. For example, the FAO scenario (Alexandratos, 1995) demonstrates that land as a resource is not a limiting factor, whereas the IMAGE scenarios (Alcamo *et al.*, 1996) show that in Asia and Africa, land rapidly becomes limited over the same time period. In the IMAGE scenarios, relatively rapid transitions toward more affluent diets lead to rapid expansion of (extensive) grazing systems. In contrast, the FAO study does not specify the additional requirement for pastureland. The main difference in assumptions is that animal productivity becomes increasingly dependent on cereals (FAO) compared to pastures (IMAGE). This illustrates how varying important assumptions may lead to discrepancies and inconsistencies between scenario conclusions. In interpreting LUC-LCC scenarios, their scope, underlying assumptions, and limitations should be carefully and critically evaluated before resulting land-cover patterns are declared suitable for use in other studies. A better perspective on how to interpret LUC-LCC both as a driving force and as a means for adaptation to climate change is strongly required. One of the central questions is, "How can we better manage land and land use to reduce vulnerability to climate change and to meet our adaptation and mitigation needs?" Answering this question requires further development of comprehensive LUC-LCC scenarios.

3.4. Environmental Scenarios

3.4.1. Purpose

Observations during the 20th century have demonstrated clearly the multifaceted nature of anthropogenic environmental changes.

Therefore, it is reasonable to expect that changes in climate anticipated for the future will occur in combination with other changes in the environment. Some of these changes will occur independently of climate change (e.g., groundwater depletion, acidification); others are a cause of climate change (e.g., changing atmospheric CO₂ concentration); and still others are a direct consequence of climate change (e.g., sea-level rise). All of these could have a role in modifying the impacts of future climate change. Hence, realistic scenarios of nonclimatic environmental factors are required to facilitate analysis of these combined effects and quantify them in impact assessments.

This section introduces environmental changes that are of importance at scales from subcontinental to global and describes how scenarios commonly are constructed to represent them. Requirements for environmental scenarios are highly application- and region-specific. For example, scenarios of CO₂ concentration may be important in considering future vegetation productivity under a changing climate but are unlikely to be required for assessment of human health impacts. Most of the scenarios treated here relate to atmospheric composition: CO₂, SO₂, sulfur and nitrogen deposition, tropospheric O₃, and surface UV-B radiation. Scenarios of water resources and marine pollution also are examined. Changes in the terrestrial environment are addressed in Section 3.3, and changes in sea level are addressed in Section 3.6.

3.4.2. CO₂ Scenarios

3.4.2.1. Reference Conditions

Aside from its dominant role as a greenhouse gas, atmospheric CO₂ also has an important direct effect on many organisms, stimulating photosynthetic productivity and affecting water-use efficiency in many terrestrial plants. In 1999, the concentration of CO₂ in the surface layer of the atmosphere (denoted as [CO₂]) was about 367 ppm (see Table 3-2), compared with a concentration of approximately 280 ppm in preindustrial times (see TAR WGI Chapter 3). CO₂ is well mixed in the atmosphere, and, although concentrations vary somewhat by region and season (related to seasonal uptake by vegetation), projections of global mean annual concentrations usually suffice for most impact applications. Reference levels of [CO₂] between 300 and 360 ppm have been widely adopted in CO₂-enrichment experiments (Cure and Acock, 1986; Poorter, 1993; see Table 3-2) and in model-based impact studies. [CO₂] has increased rapidly during the 20th century, and plant growth response could be significant for responsive plants, although the evidence for this from long-term observations of plants is unclear because of the confounding effects of other factors such as nitrogen deposition and soil fertility changes (Kirschbaum *et al.*, 1996).

3.4.2.2. Development and Application of [CO₂] Scenarios

Projections of [CO₂] are obtained in two stages: first, the rate of emissions from different sources is evaluated; second,

concentrations are evaluated from projected emissions and sequestration of carbon. Because CO₂ is a major greenhouse gas, CO₂ emissions have been projected in successive IPCC scenarios (Scenarios A–D—Shine *et al.*, 1990; IS92 scenarios—Leggett *et al.*, 1992; SRES scenarios—Nakicenovic *et al.*, 2000). To obtain scenarios of future [CO₂] from those of emissions, global models of the carbon cycle are required (e.g., Schimel *et al.*, 1995). Some estimates of [CO₂] for the SRES emissions scenarios are given in Table 3-2.

In recent years, there has been growing interest in emissions scenarios that lead to [CO₂] stabilization (see Section 3.8.4). Typically, levels of [CO₂] stabilized between 350 and 1000 ppm have been examined; these levels usually are achieved during the 22nd or 23rd century, except under the most stringent emissions targets (Schimel *et al.*, 1997a). Work to develop storylines for a set of stabilization scenarios is reported in

Chapter 2 of WGIII. Whatever scenarios emerge, it is likely to be some time before a set of derivative CO₂-stabilization impact and adaptation assessments are completed, although a few exploratory studies already have been conducted (UK-DETR, 1999).

Experimental CO₂-enrichment studies conventionally compare responses of an organism for a control concentration representing current [CO₂] with responses for a fixed concentration assumed for the future. In early studies this was most commonly a doubling (Cure and Acock, 1986), to coincide with equilibrium climate model experiments (see Section 3.5). However, more recent transient treatment of future changes, along with the many uncertainties surrounding estimates of future [CO₂] and future climate, present an infinite number of plausible combinations of future conditions. For example, Table 3-2 illustrates the range of [CO₂] projected for 2050 and 2100 under the SRES emissions

Table 3-2: Some illustrative estimates of reference and future levels of atmospheric constituents that typically are applied in model-based and experimental impact studies. Global values are presented, where available. European values also are shown to illustrate regional variations at the scale of many impact studies.

Scenario	[CO ₂] ^a (ppm)	[SO ₂] ^b ($\mu\text{g m}^{-3}$)	S-Deposition ^c (meq $\text{m}^{-2} \text{a}^{-1}$)	N-Deposition ^c (meq $\text{m}^{-2} \text{a}^{-1}$)	Ground-Level [O ₃] ^d (ppb)

^a **Carbon dioxide concentration.** Reference: Observed 1999 value (Chapter 3, WG I TAR). Experiments: Typical ranges used in enrichment experiments on agricultural crops. Some controls used ambient levels; most experiments for future conditions used levels between 600 and 1000 ppm (Strain and Cure, 1985; Wheeler *et al.*, 1996). Future: Values for 2010, 2050, and 2100 are for the range of emissions from 35 SRES scenarios, using a simple model (data from S.C.B. Raper, Chapter 9, TAR WGI); note that these ranges differ from those presented by TAR WGI (see Footnote c of Table 3-9 for an explanation).

^b **Sulphurdioxide concentration.** Reference: Global values are background levels (Rovinsky and Yegorov, 1986; Ryaboshapko *et al.*, 1998); European values are annual means at sites in western Europe during the early 1980s (Saunders, 1985). Experiments: Typical purified or ambient (control) and elevated (future) concentrations for assessing long-term SO₂ effects on plants (Kropff, 1989).

^c **Deposition of sulphur/nitrogen compounds.** Reference: Global values are mean deposition over land areas in 1992, based on the STOCHEM model (Collins *et al.*, 1997; Bouwman and van Vuuren, 1999); European values are based on EMEPmodel results (EMEP, 1998) and show 5th and 95th percentiles of grid box (150 km) values for 1990 emissions, assuming 10-year average meteorology (maximum in parentheses). Future: Global values for 2015 are from the STOCHEM model, assuming current reduction policies; European values are based on EMEPresults for 2010, assuming a “current legislation” scenario under the Convention on Long-Range Transboundary Air Pollution (UN/ECE, 1998) and, for 2050 and 2100, assuming a modification of the preliminary SRES B1marker emissions scenario (B1-SR scenario—Mayerhofer *et al.*, 2000).

^d **Ground-level ozone concentration.** Reference: Global/hemispheric values are model estimates for industrialized continents of the northern hemisphere, assuming 2000 emissions (Chapter 4, TAR WGI); European values are based on EMEPmodel results (Simpson *et al.*, 1997) and show 5th and 95th percentiles of mean monthly grid box (150 km) ground-level values for May-July during 1992–1996 (maximum in parentheses). Experiments: Typical range of purified or seasonal background values (control) and daily or subdaily concentrations (future) for assessing O₃ effects on agricultural crops (Unsworth and Hogsett, 1996; Krupa and Jäger, 1996). Future: Model estimates for 2060 and 2100 assuming the A1FI and A2 illustrative SRES emissions scenarios (Chapter 4, TAR WGI).

scenarios, using simple models. To cover these possibilities, although doubled $[CO_2]$ experiments are still common, alternative concentrations also are investigated (Olesen, 1999)—often in combination with a range of climatic conditions, by using devices such as temperature gradient tunnels (Wheeler *et al.*, 1996).

3.4.3. Scenarios of Acidifying Compounds

3.4.3.1. Reference Conditions

Sulfur dioxide and nitrogen compounds are among the major air pollutants emitted by industrial and domestic sources. SO_2 is further oxidized to sulfate, which exists in the atmosphere mainly as aerosols. The main anthropogenic components of emissions of nitrogen compounds to the atmosphere are NO_x and ammonia (NH_3). Increased atmospheric SO_2 concentrations from anthropogenic sources are known to have negative effects on tree growth and crop yield (Kropff, 1989; Semenov *et al.*, 1998) and are described below. Concentrations of nitrogen compounds are not considered because scenarios seldom are required for impact studies. However, wet and dry deposition of sulfur and nitrogen from the atmosphere onto the Earth's surface can lead to acidification, with detrimental effects on soils, surface waters, building materials, and ecosystems (Grennfelt *et al.*, 1996). Nitrogen deposition may serve simultaneously as a plant fertilizer, positively influencing carbon gain in forests (Reich *et al.*, 1990; Woodward, 1992; Pettersson *et al.*, 1993). Thus, deposition scenarios also are important.

Current global background concentrations of SO_2 are monitored at stations belonging to the Background Atmospheric Pollution Monitoring Network (BAPMoN), established by the World Meteorological Organization (WMO) and UNEP, as well as in regional networks. Annual mean SO_2 concentrations ($[SO_2]$) over land areas are estimated to be approximately 0.1–10 mg m⁻³ (Rovinsky and Yegorov, 1986; Ryaboshapko *et al.*, 1998). However, they can be much higher locally (Table 3-2). For example, annual average values of more than 80 mg m⁻³ were measured at some sites in Czechoslovakia in the 1970s (Materna, 1981). Model results have shown that $[SO_2]$ averaged over the vegetative season reached 35 mg m⁻³ in some regions of Europe during 1987–1993 (Semenov *et al.*, 1998, 1999). In recent years reductions of SO_2 and NO_2 emissions have been recorded in many regions, accompanied by large-scale decreases in concentrations, especially evident in remote areas (Whelpdale and Kaiser, 1997). Typical rates of regional total (dry + wet) deposition of sulfur and nitrogen compounds, based on model simulations, are shown in Table 3-2.

Reference concentrations of SO_2 adopted in impact assessments vary according to the objective of the study. For example, in some field experiments an enhanced $[SO_2]$ treatment is compared to a control case at ambient background concentrations. The latter concentrations can vary from year to year, depending on ambient weather and air quality conditions (Kropff, 1989). Alternatively, other experiments at locations close to pollution sources have used air purification systems to attain preindustrial levels of

$[SO_2]$ in closed chambers, comparing plant responses to those under (locally high) ambient concentrations.

3.4.3.2. Development and Application of Sulfur and Nitrogen Scenarios

Several models have been developed to project atmospheric concentrations and deposition of sulfur and (in some cases) nitrogen compounds. At the regional scale these models include: for Europe, RAINS (Alcamo *et al.*, 1990; Schöpp *et al.*, 1999) and ASAM (ApSimon *et al.*, 1994), both of which use output from mechanistic models developed by the Cooperative Programme for Monitoring and Evaluation of the Long-Range Transmission of Air Pollutants in Europe (EMEP); for Asia, RAINS-Asia (Foell *et al.*, 1995); and for North America and Asia, ATMOS (Arndt *et al.*, 1997). There also are global models: GRANTOUR (Penner *et al.*, 1994), MOGUNTIA (Langner and Rodhe, 1991), ECHAM (Feichter *et al.*, 1996), and STOCHEM (Collins *et al.*, 1997).

There have been few studies of the joint impacts of acidifying compounds and climate change. Some of these studies are multifactorial model simulations of plant response (e.g., Semenov *et al.*, 1998). There also have been some modeling studies based on the IS92a emissions scenario (Posch *et al.*, 1996; Fischer and Rosenzweig, 1996), under which a substantial increase in annual sulfur deposition is projected to occur by 2050, with commensurate suppression of modeled GHG warming in some regions. However, this scenario is now thought to overestimate future emissions of sulfur (Grübler, 1998), as reflected in the new SRES scenarios (see Section 3.8.1). Not all of the models used in developing the SRES scenarios provide information on nitrogen emissions, but those that do can be used to produce consistent scenarios of $[NO_x]$, $[SO_2]$, sulfur and nitrogen deposition, and climate change for impact studies (Mayerhofer *et al.*, 2000; Stevenson *et al.*, 2000; see Table 3-2).

3.4.4. Scenarios of Tropospheric Ozone

3.4.4.1. Reference Conditions

Tropospheric ozone forms part of the natural shield that protects living organisms from harmful UV-B rays. In the lowest portion of the atmosphere, however, excess accumulations of ozone can be toxic for a wide range of plant species (Fuhrer, 1996; Semenov *et al.*, 1998, 1999). Ozone is produced by a chain of chemical and photochemical reactions involving, in particular, NO , NO_2 , and VOCs (Finlayson-Pitts and Pitts, 1986; Derwent *et al.*, 1991; Alexandrov *et al.*, 1992; Simpson, 1992, 1995a; Peters *et al.*, 1995). These chemical precursors of ozone can be human-derived (e.g., energy production, transport) or natural (e.g., biogenic emissions, forest fires). Surface ozone concentrations are highly variable in space and time (Table 3-2); the highest values typically are over industrial regions and large cities.

Global background concentrations of ground-level ozone (annual means) are about 20–25 ppb (Semenov *et al.*, 1999). Background concentrations have increased in Europe during the 20th century from 10–15 to 30 ppb (Grennfelt, 1996). In the northern hemisphere as a whole, trends in concentrations since 1970 show large regional differences: increases in Europe and Japan, decreases in Canada, and only small changes in the United States (Lelieveld and Thompson, 1998). In an effort to reverse the upward trends still recorded in many regions, a comprehensive protocol to abate acidification, eutrophication, and ground-level ozone was signed in 1999, setting emissions ceilings for sulfur, NO_x, NH₃, and VOCs for most of the United Nations Economic Commission for Europe (UN/ECE) region.

3.4.4.2. Development and Application of Tropospheric Ozone Scenarios

Results from the first intercomparison of model-based estimates of global tropospheric ozone concentration assuming the new SRES emissions scenarios (see Section 3.8.1) are reported in TAR WGI Chapter 4. Estimates of mean ground-level O₃ concentrations during July over the industrialized continents of the northern hemisphere under the SRES A2 and A1FI scenarios are presented in Table 3-2. These scenarios produce concentrations at the high end of the SRES range, with values in excess of 70 ppb for 2100 emissions (TAR WGI Chapter 4). Local smog events could enhance these background levels substantially, posing severe problems in achieving the accepted clean-air standard of <80 ppb in most populated areas.

Regional projections of ozone concentration also are made routinely, assuming various emissions reduction scenarios (e.g., SEPA, 1993; Simpson, 1995b; Simpson *et al.*, 1995). These projections sometimes are expressed in impact terms—for example, using AOT40 (the integrated excess of O₃ concentration above a threshold of 40 ppb during the vegetative period), based on studies of decline in tree growth and crop yield (Fuhrer, 1996; Semenov *et al.*, 1999).

There are few examples of impact studies that have evaluated the joint effects of ozone and climate change. Some experiments have reported on plant response to ozone and CO₂ concentration (Barnes *et al.*, 1995; Ojanperä *et al.*, 1998), and several model-based studies have been conducted (Sirotenko *et al.*, 1995; Martin, 1997; Semenov *et al.*, 1997, 1998, 1999).

3.4.5. UV-B Radiation Scenarios

3.4.5.1. Reference Conditions

Anthropogenic emissions of chlorofluorocarbons (freons) and some other substances into the atmosphere are known to deplete the stratospheric ozone layer (Albritton and Kuijpers, 1999). This layer absorbs ultraviolet solar radiation within a wavelength range of 280–320 nm (UV-B), and its depletion

leads to an increase in ground-level flux of UV-B radiation (Herman *et al.*, 1996; Jackman *et al.*, 1996; McPeters *et al.*, 1996; Madronich *et al.*, 1998; McKenzie *et al.*, 1999). Enhanced UV-B suppresses the immune system and may cause skin cancer in humans and eye damage in humans and other animal species (Diffey, 1992; de Gruijl, 1997; Longstreth *et al.*, 1998). It can affect terrestrial and marine ecosystems (IASC, 1995; Zerefos and Alkiviadis, 1997; Caldwell *et al.*, 1998; Hader *et al.*, 1998; Krupa *et al.*, 1998) and biogeochemical cycles (Zepp *et al.*, 1998) and may reduce the service life of natural and synthetic polymer materials (Andrady *et al.*, 1998). It also interacts with other atmospheric constituents, including GHGs, influencing radiative forcing of the climate (see TAR WGI Chapters 4, 6, and 7).

Analyses of ozone data and depletion processes since the early 1970s have shown that the total ozone column has declined in northern hemisphere mid-latitudes by about 6% in winter/spring and 3% in summer/autumn, and in southern hemisphere mid-latitudes by about 5% on a year-round basis. Spring depletion has been greatest in the polar regions: about 50% in the Antarctic and 15% in the Arctic (Albritton and Kuijpers, 1999). These five values are estimated to have been accompanied by increases in surface UV-B radiation of 7, 4, 6, 130, and 22%, respectively, assuming other influences such as clouds to be constant. Following a linear increase during the 1980s, the 1990s springtime ozone depletion in Antarctica has continued at about the same level each year. In contrast, a series of cold, protracted winters in the Arctic have promoted large depletions of ozone levels during the 1990s (Albritton and Kuijpers, 1999).

3.4.5.2. Development and Application of UV-B Scenarios

Scenarios of the future thickness of the ozone column under given emissions of ozone-depleting gases can be determined with atmospheric chemistry models (Alexandrov *et al.*, 1992; Brasseur *et al.*, 1998), sometimes in combination with expert judgment. Processes that affect surface UV-B flux also have been investigated via models (Alexandrov *et al.*, 1992; Matthijssen *et al.*, 1998). Furthermore, several simulations have been conducted with coupled atmospheric chemistry and climate models, to investigate the relationship between GHG-induced climate change and ozone depletion for different scenarios of halogenated compounds (Austin *et al.*, 1992; Shindell *et al.*, 1998). It is known that potential stratospheric cooling resulting from climate change may increase the likelihood of formation of polar stratospheric clouds, which enhance the catalytic destruction of ozone. Conversely, ozone depletion itself contributes to cooling of the upper troposphere and lower stratosphere (see TAR WGI Chapter 7).

Serious international efforts aimed at arresting anthropogenic emissions of ozone-depleting gases already have been undertaken—namely, the Vienna Convention for the Protection of the Ozone Layer (1985) and the Montreal Protocol on Substances that Deplete the Ozone Layer (1990) and its Amendments. The abundance of ozone-depleting gases in the atmosphere peaked

in the late 1990s and now is expected to decline as a result of these measures (Montzka *et al.*, 1996), recovering to pre-1980 levels around 2050 (Albritton and Kuijpers, 1999). Without these measures, ozone depletion by 2050 was projected to exceed 50% in northern mid-latitudes and 70% in southern mid-latitudes—about 10 times larger than today. UV-B radiation was projected to double and quadruple in northern and southern mid-latitudes, respectively (Albritton and Kuijpers, 1999).

There have been numerous experimental artificial exposure studies of the effects of UV-B radiation on plants (Runeckles and Krupa, 1994). There also have been a few investigations of the joint effects of enhanced UV-B and other environmental changes, including climate (Unsworth and Hogsett, 1996; Gwynne-Jones *et al.*, 1997; Sullivan, 1997). A study of the impacts of UV-B on skin cancer incidence in The Netherlands and Australia to 2050, using integrated models, is reported by Martens (1998), who employed scenarios of future ozone depletion based on the IS92a emissions scenario and two scenarios assuming compliance with the London and Copenhagen Amendments to the Montreal Protocol.

3.4.6. Water Resource Scenarios

3.4.6.1. Reference Conditions

Water is a resource of fundamental importance for basic human survival, for ecosystems, and for many key economic activities, including agriculture, power generation, and various industries. The quantity and quality of water must be considered in assessing

present-day and future resources. In many parts of the world, water already is a scarce resource, and this situation seems certain to worsen as demand increases and water quality deteriorates, even in the absence of climate change. Abundance of the resource at a given location can be quantified by water availability, which is a function of local supply, inflow, consumption, and population. The quality of water resources can be described by a range of indicators, including organic/fecal pollution, nutrients, heavy metals, pesticides, suspended sediments, total dissolved salts, dissolved oxygen, and pH.

Several recent global analyses of water resources have been published (Raskin *et al.*, 1997; Gleick, 1998; Shiklomanov, 1998; Alcamo *et al.*, 2000). Some estimates are shown in Table 3-3. For regional and local impact studies, reference conditions can be more difficult to specify because of large temporal variability in the levels of lakes, rivers, and groundwater and human interventions (e.g., flow regulation and impoundment, land-use changes, water abstraction, effluent return, and river diversions; Arnell *et al.*, 1996).

Industrial wastes, urban sewage discharge, application of chemicals in agriculture, atmospheric deposition of pollutants, and salinization negatively affect the quality of surface and groundwaters. Problems are especially acute in newly industrialized countries (UNEP/GEMS, 1995). Fecal pollution of freshwater basins as a result of untreated sewage seriously threatens human health in some regions. Overall, 26% of the population (more than 1 billion people) in developing countries still do not have access to safe drinking water, and 66% do not have adequate environmental sanitation facilities—contributing

Table 3-3: Estimates of global and regional water intensity and water withdrawals in 1995 and scenarios for 2025.

^a Calculated by using estimates of water availability from UN Comprehensive Assessment of the Freshwater Resources of the World (Shiklomanov, 1998) and population from footnoted source.

^b World Commission on Water for the 21st Century (Alcamo *et al.*, 2000).

^c Business-as-usual scenario (domestic water intensity increases, then stabilizes with increasing incomes, some increase in water-use efficiency).

^d Technology, Economics, and Private Sector scenario (relative to BAU: similar population and income level; domestic water-use intensity one-third lower; higher water-use efficiency in industrialized countries).

^e Values and Lifestyles scenario (relative to BAU: lower population and higher income; domestic water-use intensity two-thirds lower; much higher water-use efficiency in all countries).

^f Conventional Development scenario (Raskin *et al.*, 1997—population slightly higher than in BAU scenario; per capita water use falls in developed world and rises in developing world).

^g Commonwealth of Independent States.

to almost 15,000 deaths each day from water-related diseases, nearly two-thirds of which are diarrheal (WHO, 1995; Gleick, 1998; see Chapter 9).

3.4.6.2. Development and Application of Water Resource Scenarios

Water resource scenarios have been developed at different time and space scales. For example, projections to 2025 on the basis of national water resource monitoring data have been reported by Shiklomanov (1998). Model-based projections of water use and availability to 2025 at the river basin scale have been made by Alcamo *et al.* (2000), assuming a BAU scenario and two alternative, normative scenarios that focus on water conservation. Some results of these scenario exercises are shown in Table 3-3. Among the most developed scenarios of water quality are model-based scenarios of acidification of freshwaters in Europe (e.g., NIVA, 1998). More general normative scenarios describing rural and urban access to safe drinking water by 2025 and 2050 are presented by Raskin *et al.* (1998). Scenarios of water availability have been applied in several climate change impact studies. Most of these are in the water resources sector and are reported in Chapter 4. However, they are increasingly being applied in multi-sectoral and integrated assessments (e.g., Strzepek *et al.*, 1995).

3.4.7. Scenarios of Marine Pollution

3.4.7.1. Reference Conditions

Marine pollution is the major large-scale environmental factor that has influenced the state of the world oceans in recent decades. Nutrients, oxygen-demanding wastes, toxic chemicals (such as heavy metals, chlorinated hydrocarbons, potential endocrine-disrupting chemicals, and environmental estrogens), pathogens, sediments (silt), petroleum hydrocarbons, and litter are among the most important contaminants leading to degradation of marine ecosystems (Izrael and Tsyban, 1989; GESAMP, 1990; Tsyban, 1997). The following ranges of concentrations of heavy metals are characteristic of open ocean waters: mercury (0.3–7 ng l⁻¹), cadmium (10–200 ng l⁻¹), and lead (5–50 ng l⁻¹); levels of chlorinated hydrocarbons are a few ng l⁻¹. Chemical contaminants and litter are found everywhere in the open ocean, from the poles to the tropics and from beaches to abyssal depths. Nonetheless, the open ocean still remains fairly clean relative to coastal zones, where water pollution and the variability of contaminant concentrations are much higher (often by one to two orders of magnitude; specific values depend on the pattern of discharge and local conditions).

3.4.7.2. Development and Application of Marine Pollution Scenarios

Data characterizing the state of the marine environment have been obtained through national as well as international monitoring

programs in recent decades, and analysis of tendencies may serve as an initial basis for developing environmental scenarios. At present, expert judgment appears to be the most promising method of scenario development because modeling methods are insufficiently developed to facilitate prediction.

In qualitative terms, trends in marine pollution during the 21st century could include enhanced eutrophication in many regions, enhancement of exotic algal blooms, expanded distribution and increased concentration of estrogens, invasion of nonindigenous organisms, microbiological contamination, accumulation of pathogens in marine ecosystems and seafood, and increases of chemical toxicants (Izrael and Tsyban, 1989; Goldberg, 1995).

3.5. Climate Scenarios

3.5.1. Purpose

The purpose of this section is to provide a summary of major methodological issues in the science of climate scenario development and to relate these developments to applications of scenarios in this report. We distinguish between a climate scenario, which refers to a plausible future climate, and a climate change scenario, which implies the *difference* between some plausible future climate and the present-day climate, though the terms are used interchangeably in the scientific literature. This brief overview is distilled largely from material presented in TAR WGI Chapter 13. See that chapter, as well as TAR WGI Chapters 8, 9, and 10, for more complete coverage of this subject.

3.5.2. Methods

Methods of climate scenario development largely have been ignored in earlier IPCC assessments, although some aspects of scenario development have been alluded to (e.g., palaeoclimatic analogs in Folland *et al.*, 1990; downscaling methods in Kattenburg *et al.*, 1996). Table 3-4 provides an overview of the main methods, which also are discussed in TAR WGI Chapter 13. Thus, we present only a very brief summary of three major methods. A fourth method, expert judgement, that also has been used in developing climate scenarios (NDU, 1978; Morgan and Keith, 1995), is discussed further in Section 3.5.5.

3.5.2.1. Incremental Scenarios for Sensitivity Studies

In this approach, particular climatic (or related) elements are changed by realistic but arbitrary amounts. They are commonly applied to study the sensitivity of an exposure unit to a wide range of variations in climate and to construct impact response surfaces over multivariate climate space. Most studies have adopted incremental scenarios of constant changes throughout the year (e.g., Terjung *et al.*, 1984; Rosenzweig *et al.*, 1996), but some have introduced seasonal and spatial variations in the changes (e.g., Rosenthal *et al.*, 1995); others have examined

Table 3-4: The role of various types of climate scenarios and an evaluation of their advantages and disadvantages according to the five criteria described in the text. Note that in some applications, a combination of methods may be used—for example, regional modeling and a weather generator (WGI TAR Chapter 13, Table 13.1).

Scenario Type or Tool	Description/Use	Advantages ^a	Disadvantages ^a
<i>Incremental</i>	<ul style="list-style-type: none"> • Testing system sensitivity • Identifying key climate thresholds 	<ul style="list-style-type: none"> • Easy to design and apply (5) • Allows impact response surfaces to be created (3) 	<ul style="list-style-type: none"> • Potential for creating unrealistic scenarios (1,2) • Not directly related to GHG forcing (1)
<i>Analog</i> Palaeoclimatic	<ul style="list-style-type: none"> • Characterizing warmer periods in past 	<ul style="list-style-type: none"> • Physically plausible changed climate that really did occur in the past of a magnitude similar to that predicted for ~2100 (2) 	<ul style="list-style-type: none"> • Variables may be poorly resolved in space and time (3,5) • Not related to GHG forcing (1)
<i>Instrumental</i>	<ul style="list-style-type: none"> • Exploring vulnerabilities and some adaptive capacities 	<ul style="list-style-type: none"> • Physically realistic changes (2) • Can contain a rich mixture of well-resolved, internally consistent, variables (3) • Data readily available (5) 	<ul style="list-style-type: none"> • Not necessarily related to GHG forcing (1) • Magnitude of climate change usually quite small (1) • No appropriate analogs may be available (5)
<i>Spatial</i>	<ul style="list-style-type: none"> • Extrapolating climate/ecosystem relationships • Pedagogic 	<ul style="list-style-type: none"> • May contain a rich mixture of well-resolved variables (3) 	<ul style="list-style-type: none"> • Not related to GHG forcing (1,4) • Often physically implausible (2) • No appropriate analogs may be available (5)
<i>Climate Model-Based</i> Direct AOGCM outputs	<ul style="list-style-type: none"> • Starting point for most climate scenarios • Large-scale response to anthropogenic forcing 	<ul style="list-style-type: none"> • Information derived from the most comprehensive, physically based models (1,2) • Long integrations (1) • Data readily available (5) • Many variables (potentially) available (3) 	<ul style="list-style-type: none"> • Spatial information poorly resolved (3) • Daily characteristics may be unrealistic except for very large regions (3) • Computationally expensive to derive multiple scenarios (4,5) • Large control run biases may be a concern for use in certain regions (2)

Scenario Type or Tool	Description/Use	Advantages ^a	Disadvantages ^a
<i>Climate Model-Based (cont.)</i>			
Statistical downscaling	<ul style="list-style-type: none"> Providing point/high spatial resolution information 	<ul style="list-style-type: none"> Can generate information on high-resolution grids or nonuniform regions (3) Potential, for some techniques, to address a diverse range of variables (3) Variables are (probably) internally consistent (2) Computationally (relatively) inexpensive (5) Suitable for locations with limited computational resources (5) Rapid application to multiple GCMs (4) 	<ul style="list-style-type: none"> Assumes constancy of empirical relationships in the future (1,2) Demands access to daily observational surface and/or upper air data that span range of variability (5) Not many variables produced for some techniques (3,5) Dependent on (usually biased) inputs from driving AOGCM (2)
Climate scenario generators	<ul style="list-style-type: none"> Integrated assessments Exploring uncertainties Pedagogic 	<ul style="list-style-type: none"> May allow for sequential quantification of uncertainty (4) Provides “integrated” scenarios (1) Multiple scenarios easy to derive (4) 	<ul style="list-style-type: none"> Usually rely on linear pattern-scaling methods (1) Poor representation of temporal variability (3) Low spatial resolution (3)
<i>Weather Generators</i>	<ul style="list-style-type: none"> Generating baseline climate time series Altering higher order moments of climate Statistical downscaling 	<ul style="list-style-type: none"> Generates long sequences of daily or subdaily climate (2,3) Variables usually are internally consistent (2) Can incorporate altered frequency/intensity of ENSO events (3) 	<ul style="list-style-type: none"> Poor representation of low-frequency climate variability (2,4) Limited representation of extremes (2,3,4) Requires access to long observational weather series (5) In absence of conditioning, assumes constant statistical characteristics (1,2)
<i>Expert Judgment</i>	<ul style="list-style-type: none"> Exploring probability and risk Integrating current thinking on changes in climate 	<ul style="list-style-type: none"> May allow for “consensus” (4) Has potential to integrate very broad range of relevant information (1,3,4) Uncertainties can be readily represented (4) 	<ul style="list-style-type: none"> Subjectivity may introduce bias (2) Representative survey of experts may be difficult to implement (5)

^aNumbers in parentheses within the Advantages and Disadvantages columns indicate that they are relevant to the criteria described. The five criteria follow: 1) *Consistency* at regional level with global projections; 2) *physical plausibility and realism*, such that changes in different climatic variables are mutually consistent and credible and spatial and temporal patterns of change are realistic; 3) *appropriateness* of information for impact assessments (i.e., resolution, time horizon, variables); 4) *representativeness* of potential range of future regional climate change; and 5) *accessibility* for use in impact assessments.

arbitrary changes in interannual, within-month, and diurnal variability, as well as changes in the mean (e.g., Williams *et al.*, 1988; Mearns *et al.*, 1992, 1996; Semenov and Porter, 1995). Some of these studies are discussed in Chapter 5.

3.5.2.2. Analog Approaches

Temporal and spatial analogs also have been used in constructing climate scenarios. Temporal analogs make use of climatic information from the past as an analog of possible future climate

(Pittock, 1993). They are of two types: palaeoclimatic analogs and instrumentally based analogs.

Palaeoclimatic analogs: Palaeoclimatic analogs are based on reconstructions of past climate from fossil evidence, such as plant or animal remains and sedimentary deposits. Two periods have received particular attention: the mid-Holocene (~5–6 ky BP³), when northern hemisphere temperatures are estimated to

³ky BP = 1,000 years before present.

have been about 1°C warmer than today, and the Last (Eemian) Interglacial (~120–130 ky BP), when temperatures were about 2°C warmer.

The major disadvantages of this method are the causal differences between past changes in climate and posited future changes (Crowley, 1990; Mitchell, 1990) and the large uncertainties about the quality of palaeoclimatic reconstructions (Covey, 1995; Kneshgi and Lapen, 1996; Borzenkova, 1998). However, these scenarios continue to be used occasionally in impact assessments (Anisimov and Nelson, 1996; Budyko and Menzhulin, 1996) and are useful for providing insights about system vulnerability to climate change.

Instrumentally based analogs: Periods of observed regional or global-scale warmth during the historical period also have been used as an analog of a GHG-induced warmer world. Scenarios are constructed by estimating the difference between the regional climate during the warm period and that of the long-term average or that of a similarly selected cold period (Lough *et al.*, 1983; Rosenberg *et al.*, 1993). Major objections to the use of these analogs include the relatively minor changes in climate involved (although small changes could be adequate for examining near-term climate change) and, again, differences between the causes of historical fluctuations and those of posited larger future climate changes (Glantz, 1988; Pittock, 1989).

Spatial analogs: These are regions that today have a climate analogous to that anticipated in the study region in future. For example, Berghósson *et al.* (1988) used temperatures in northern Britain as a spatial analog for the potential future temperatures over Iceland. The approach is severely restricted, however, by the frequent lack of correspondence between other important features (climatic and nonclimatic) of the two regions. Nevertheless, spatial analogs are still adopted in a few studies—for example, to assess potential effects of climate change on human health (see Chapter 9).

3.5.2.3. Use of Climate Model Outputs

The most common method of developing climate scenarios for quantitative impact assessments is to use results from GCM experiments. Most estimates of impacts described in this report rely on this type of scenario. GCMs are three-dimensional mathematical models that represent physical and dynamical processes that are responsible for climate. All models are first run for a control simulation that is representative of the present-day or preindustrial times. They have been used to conduct two types of “experiment” for estimating future climate: equilibrium and transient-response experiments. In the former, the equilibrium response (new stable state) of the global climate following an instantaneous increase (e.g., doubling) of atmospheric CO₂ concentration or its radiative equivalent, including all GHGs, is evaluated (Schlesinger and Mitchell, 1987; Mitchell *et al.*, 1990). Transient experiments are conducted with coupled atmosphere-ocean models (AOGCMs), which link, dynamically, detailed models of the ocean with those of the atmosphere. AOGCMs

are able to simulate time lags between a given change in atmospheric composition and the response of climate (see TAR WGI Chapter 8). Most recent evaluations of impacts, as reflected in this report, are based on scenarios formed from results of transient experiments as opposed to equilibrium experiments.

3.5.3. Baseline Climatologies

3.5.3.1. Baseline Period

Any climate scenario must adopt a reference baseline period from which to calculate changes in climate. This baseline data set serves to characterize the sensitivity of the exposure unit to present-day climate and usually serves as the base on which data sets that represent climate change are constructed. Among the possible criteria for selecting the baseline period (IPCC, 1994), it should be representative of the present-day or recent average climate in the study region and of a sufficient duration to encompass a range of climatic variations, including several significant weather anomalies (e.g., severe droughts or cool seasons).

A popular climatological baseline period is a 30-year “normal” period, as defined by the WMO. The current WMO normal period is 1961–1990, which provides a standard reference for many impact studies. Note, however, that in some regions, observations during this time period may exhibit anthropogenic climate changes relative to earlier periods.

3.5.3.2. Sources and Characteristics of Data

Sources of baseline data include a wide variety of observed data, reanalysis data (a combination of observed and model-simulated data), control runs of GCM simulations, and time series generated by stochastic weather generators. Different impact assessments require different types and resolutions of baseline climatological data. These can range from globally gridded baseline data sets at a monthly time scale to single-site data at a daily or hourly time scale. The variables most often required are temperature and precipitation, but incident solar radiation, relative humidity, windspeed, and even more exotic variables sometimes may be needed.

Two important issues in the development of baseline data sets are their spatial and temporal resolution and uncertainties related to their accuracy (New, 1999) (see TAR WGI Section 13.3.2 for further details). Evaluation of the differences between baseline data sets recently has become an important step in scenario development because these differences can have an important bearing on the results obtained in an impact assessment (Arnell, 1995; Pan *et al.*, 1996).

3.5.4. Construction of Scenarios

Techniques for constructing climate scenarios (i.e., scenario information that is directly usable in impact studies) have

evolved very slowly during the past 2 decades. However, in the past few years several new developments in climate modeling and scenario development have expanded the array of techniques for scenario formation. The following subsections discuss some of these issues and present some background illustrative material.

3.5.4.1. Choosing Variables of Interest

In principle, GCM-based scenarios can be constructed for a wide range of variables at time resolutions down to subdaily time steps. In practice, however, not all data are available at the desired temporal and spatial resolutions. Most scenarios are conventionally based on changes in monthly mean climate, although with greater quantities of model output now being saved operationally, daily output and information on certain types of extreme events (e.g., mid-latitude cyclone intensities)

can be accessed readily. However, consideration must be given to whether model output regarding a particular phenomenon is deemed “meaningful.” For example, although information on changes in the frequency and intensity of El Niño-Southern Oscillation (ENSO) events may be desirable from an impacts point of view, analyses of possible future changes in this oscillation still are very preliminary (see TAR WGI Chapter 9).

3.5.4.2. Selecting GCM Outputs

Many equilibrium and transient climate change experiments have been performed with GCMs (Kattenberg *et al.*, 1996; TAR WGI Chapter 9). Several research centers now serve as repositories of GCM information (see, e.g., Hulme *et al.*, 1995; CSIRO, 1997). The IPCC Data Distribution Centre (IPCC-DDC, 1999) complements these existing sources. Table 3-5 lists GCM

Table 3-5: Catalog of GCM experiments used to develop scenarios applied by impact studies referenced in this report. Columns show the acronym of the modeling center; the common model acronym found in the impacts literature; a code for the model experiment; reference number for the experiment from Chapter 8, WGI TAR; main reference sources; type of experiment (EQ = equilibrium; TRS = transient with simple ocean; TRC = transient cold start with dynamic ocean; TRW = transient warm start with dynamic ocean); increase in CO₂-equivalent concentration; effective climate sensitivity [equilibrium warming at CO₂-doubling from AOGCM experiments (see Chapter 9, WG I TAR); in some cases this differs from climate sensitivities cited elsewhere derived from atmosphere-only GCMs]; and availability from IPCC Data Distribution Centre.

experiments that have been used to develop scenarios for impacts studies evaluated in this report.

Four criteria for selecting GCM outputs from such a large sample of experiments are suggested by Smith and Hulme (1998):

- 1) *Vintage*: Recent model simulations are likely (though by no means certain) to be more reliable than those of an earlier vintage since they are based on recent knowledge and incorporate more processes and feedbacks.
- 2) *Resolution*: In general, increased spatial resolution of models has led to better representation of climate.
- 3) *Validation*: Selection of GCMs that simulate the present-day climate most faithfully is preferred, on the premise that these GCMs are more likely (though not guaranteed) to yield a reliable representation of future climate.
- 4) *Representativeness of results*: Alternative GCMs can display large differences in estimates of regional climate change, especially for variables such as precipitation. One option is to choose models that show a range of changes in a key variable in the study region.

3.5.4.3. Constructing Change Fields

Because climate model results generally are not sufficiently accurate (in terms of absolute values) at regional scales to be used directly (Mearns *et al.*, 1997), mean differences between the control (or current climate) run and the future climate run usually are calculated and then combined with some baseline observed climate data set (IPCC, 1994). Conventionally, differences (future climate minus control) are used for temperature variables, and ratios (future climate/control) are used for other variables such as precipitation, solar radiation, relative humidity, and windspeed. Most impact applications consider one or more fixed time horizon(s) in the future (e.g., the 2020s, the 2050s, and the 2080s have been chosen as 30-year time windows for storing change fields in the IPCC-DDC). Some other applications may require time-dependent information on changes, such as vegetation succession models that simulate transient changes in plant composition (e.g., VEMAP members, 1995).

3.5.4.4. Spatial Scale of Scenarios

One of the major problems in applying GCM projections to regional impact assessments is the coarse spatial scale of the gridded estimates—on the order of hundreds of kilometers—in relation to many of the exposure units being studied (often at one or two orders of magnitude finer resolution). Concern about this issue is raised in Chapters 4 and 5. Several solutions have been adopted to obtain finer resolution information.

3.5.4.4.1. Simple methods

Conventionally, regional “detail” in climate scenarios has been incorporated by appending changes in climate from the nearest

coarse-scale GCM grid box to the study area (observation point or region) (e.g., Rosenzweig and Parry, 1994) or by interpolating from GCM grid box resolution to a higher resolution grid or point location (Leemans and van den Born, 1994; Harrison and Butterfield, 1996).

Three major methods have been developed to produce higher resolution climate scenarios at the sub-GCM grid scale: regional climate modeling (Giorgi and Mearns, 1991, 1999; McGregor, 1997), statistical downscaling (von Storch *et al.*, 1993; Rummukainen, 1997; Wilby and Wigley, 1997), and variable- and high-resolution GCM experiments (Fox-Rabinovitz *et al.*, 1997). All three methods are presented in Table 3-4 and discussed in detail in TAR WGI Chapter 10, but we briefly review here the first two, since they have been most commonly applied to impact assessments. Both methods are dependent on large-scale circulation variables from GCMs. Large-scale circulation refers to the general behavior of the atmosphere at large (i.e., continental) scales.

3.5.4.4.2. Regional climate modeling

The basic strategy with regional models is to rely on the GCM to reproduce the large-scale circulation of the atmosphere and to use the regional model, run at a higher resolution, to simulate sub-GCM scale regional distributions of climate. In numerous experiments with regional models driven by control and doubled CO₂ output from GCMs for regions throughout the world, the spatial pattern of changed climate—particularly changes in precipitation—simulated by the regional model departs from the more general pattern over the same region simulated by the GCM (TAR WGI Chapter 10).

3.5.4.4.3. Statistical methods

Statistical methods are much less computationally demanding than dynamic methods; they offer an opportunity to produce ensembles of high-resolution climate scenarios (for reviews, see von Storch, 1995; Wilby and Wigley, 1997). However, these techniques rely on the (questionable) assumption that observed statistical relationships will continue to be valid under future radiative forcing—that is, they are time-invariant (Wilby, 1997).

Although regional modeling and statistical techniques have been available for at least a decade—their developers claiming use in impact assessments as one of their important applications—it is only recently that they have actually provided scenarios for impact assessments (Mearns *et al.*, 1998, 1999, 2001; Sælthun *et al.*, 1998; Hay *et al.*, 1999; Brown *et al.*, 2000; Whetton *et al.*, 2001). Mearns *et al.* (1999, 2001) demonstrate that a high-resolution scenario results in agricultural impacts that differ from those produced with a coarser resolution GCM scenario (discussed in Chapter 5). Hay *et al.* (1999) found differences in runoff calculations, based on a GCM-scenario and a statistically downscaled scenario.

3.5.4.5. Temporal Resolution (Mean versus Variability)

For the most part, climate changes calculated from climate model experiments have been mean monthly changes in relevant variables. Techniques for generating changes in variability emerged in the 1990s (Mearns *et al.*, 1992, 1996, 1997; Wilks, 1992; Semenov and Barrow, 1997). The most common technique involves manipulation of the parameters of stochastic weather generators to simulate changes in variability on daily to interannual time scales (e.g., Bates *et al.*, 1994, 1996). Several studies have found important differences in the estimated impacts of climate change when effects of variance change were included (Mearns *et al.*, 1997; Semenov and Barrow, 1997). Combined changes in mean and variability also are evident in a broad suite of statistical downscaling methods (Katz and Parlange, 1996; Wilby *et al.*, 1998). Other types of variance change still are difficult to incorporate, such as possible changes in the frequency and intensity of El Niño events (Trenberth and Hoar, 1997). However, where ENSO signals are strong, weather generators can be conditioned on ENSO phases, enabling scenarios of changed ENSO frequency to be generated stochastically (e.g., Woolhiser *et al.*, 1993). However, climate models still are not capable of clearly indicating how ENSO events might change in the future (TAR WGI Chapter 9).

3.5.4.6. Incorporation of Extremes in Scenarios

Whereas changes in both the mean and higher order statistical moments (e.g., variance) of time series of climate variables affect the frequency of extremes based on these variables (e.g., extreme high daily or monthly temperatures; drought and flood episodes), other types of extremes are based on complex atmospheric phenomena (e.g., hurricanes). Given the importance of the more complex extremes—such as hurricanes, tornadoes, and storm surges (see Table 1-1)—it would be desirable to incorporate changes in the frequency of such phenomena into scenarios. Unfortunately, very little work has been performed on how to accomplish this, and there is only limited information on how the frequency, intensity, and spatial characteristics of such phenomena might change in the future (see Section 3.8.5).

An example of an attempt to incorporate such changes into impact assessments is the study of McInnes *et al.* (2000), who developed an empirical/dynamical model that gives return period versus height for tropical cyclone-related storm surges for a location on the north Australian coast. The model can accept changes in tropical cyclone characteristics that may occur as a result of climate change, such as changes in cyclone intensity. Other methods for incorporating such changes into quantitative climate scenarios remain to be developed; further advances in this area of research can be expected over the next few years.

3.5.4.7. Surprises: Low-Probability, High-Impact Events

Several types of rapid, nonlinear response of the climate system to anthropogenic forcing, sometimes referred to as “surprises,”

have been suggested. These include reorganization of the thermohaline circulation, rapid deglaciation, and fast changes to the carbon cycle (e.g., Stocker and Schmittner, 1997). For instance, it has been suggested that a sudden collapse of the thermohaline circulation in the North Atlantic—an event that has not been simulated by any AOGCM (TAR WGI Chapter 9) but cannot be ruled out on theoretical grounds (TAR WGI Chapter 7)—could cause major disruptions in regional climate over northwest Europe. Such a possibility has been used to create synthetic arbitrary climate scenarios to investigate possible extreme impacts (Alcamo *et al.*, 1994; Klein Tank and Können, 1997).

3.5.5. Uncertainties of Climate Scenarios

The concept of uncertainty is implicit in the philosophy of climate scenario development, and characterization and quantification of uncertainty has become one of the most vigorous and dynamic branches of climate scenario research. Some important sources of uncertainty are detailed in TAR WGI Chapter 13, of which three major sources are:

- 1) Uncertainties in future GHG and aerosol emissions. The IS92 and SRES emissions scenarios described in Section 3.8 exemplify these uncertainties; each scenario implies different atmospheric compositions and hence different radiative forcing.
- 2) Uncertainties in global climate sensitivity,⁴ mainly as a result of differences in the way physical processes and feedbacks are simulated in different models. This means that some GCMs simulate greater mean global warming per unit of radiative forcing than others.
- 3) Uncertainties in regional climate changes, which are apparent from differences in regional estimates of climate change by different GCMs for the same mean global warming.

Many early impact studies employed a climate scenario derived from a single GCM. However, it was recognized early on that different GCMs yield different regional climate responses, even when they are perturbed with identical forcing (e.g., Smith and Tirpak, 1989). Therefore, various approaches have been used to capture this range of responses in impact studies. These approaches include using all available GCM results (e.g., Santer, 1985; Yohe *et al.*, 1999); using a selected subset of GCM experiments, in some cases based on the performance of the GCMs at simulating the current climate (e.g., Robock *et al.*, 1993; Risbey and Stone, 1996; Smith *et al.*, 1996); using results from different GCMs that have been “pattern-scaled” in conjunction with simple climate models to represent different types of uncertainty (e.g., Barrow *et al.*, 2000; see also Section 3.8.3); or using the mean or median GCM response (e.g., Rotmans

⁴Climate sensitivity is the long-term (equilibrium) change in global mean surface temperature following a doubling of atmospheric equivalent CO₂ concentration.

et al., 1994). The effect is to generate a range of future impacts. Much of the quantitative, scenario-based, impacts literature assessed in IPCC (1990) and IPCC (1996b) reported these kinds of analyses. More recently, impact studies have begun to consider the impacts of anthropogenic climate change alongside the effects of natural multi-decadal climate variability (Hulme *et al.*, 1999a). This creates a distribution of impact indicator values for the present day to compare with the range of future impacts under alternative climate scenarios.

There have been a few preliminary attempts to derive frequency distributions of future climate by using expert judgment (Morgan and Keith, 1995; Hulme and Carter, 1999) or by projecting the statistical fit of modeled versus observed 20th-century climate onto modeled future changes (Allen *et al.*, 2000). This information may be useful for impact assessment because it offers an opportunity to express impacts in terms of risk—for example, the risk of exceeding a given threshold impact (Jones, 2000; Pittock, 1999).

3.6. Sea-Level Rise Scenarios

3.6.1. Purpose

Sea-level rise scenarios are constructed to assess climate change impacts and adaptations in the coastal zone. Variations in sea level are measured in two ways. Eustatic sea level represents the level of the ocean independent of land movements. Relative sea level is measured relative to the local land surface (Klein and Nicholls, 1998), so it consists of two components: eustatic sea-level change and local land movements. Climate modelers largely concentrate on estimating eustatic sea-level change, whereas impact researchers focus on relative sea-level change.

3.6.2. Baseline Conditions

Based on historical tide gauge records and allowing for land movements, eustatic sea level has risen at an estimated rate of 1.0–2.0 mm yr⁻¹ during the past century (TAR WGI Chapter 11). This rate of sea-level rise is consistent with recent satellite altimeter data (Nerem *et al.*, 1997), which directly measures eustatic variations in sea level. Tide gauge records are the main source of information on relative sea level; records are archived by the Permanent Service for Mean Sea Level (PSMSL) (Spencer and Woodworth, 1993). These records exhibit variations in interannual and multi-decadal variability (e.g., Delcroix, 1998; Bell *et al.*, 1999; Nerem, 1999). The land surface forming the coastline at any point may be subsiding, static, or rising. Subsidence can be caused by tectonic movements, isostatic subsidence, compaction of sediments, or extraction of groundwater, oil, and/or gas. Uplift, as a result of postglacial isostatic rebound or tectonic processes, reduces or reverses relative sea-level rise. To allow for these influences, Douglas (1997) recommends that tide gauge records be at least 50 years in length before they are used to establish long-term trends or a nonstationary baseline.

Most studies of vulnerability to sea-level rise use the mean sea level at a reference date. For instance, studies employing the IPCC Common Methodology (WCC 1993, 1994) use the level in 1990 (Nicholls, 1995; Bijlsma, 1996). For more comprehensive assessments of coastal vulnerability, however, baseline time series of sea-level variability are required. These reflect tidal variations and the influences of water temperature, wind, air pressure, surface waves, and Rossby and Kelvin waves in combination with the effects of extreme weather events. Baseline information for coastal processes also may be necessary where the coastline is accreting, eroding, or changing in form as a result of previous environmental changes. Where an earlier climate or sea-level shift can be related directly to a response in coastal or adjacent marine processes, this may serve as a historical or palaeo-analog for assessment of future changes.

3.6.3. Global Average Sea-Level Rise

The major components of average global sea-level rise scenarios are thermal expansion, glaciers and small ice caps, the Greenland and Antarctic ice sheets, and surface and groundwater storage (Warrick *et al.*, 1996; TAR WGI Chapter 11). These phenomena usually are modeled separately. Using GCM output, the thermal component of sea-level rise has been estimated by Bryan (1996), Sokolov *et al.* (1998), and Jackett *et al.* (2000). Contributions from glaciers and ice sheets usually are estimated via mass-balance methods that use coupled atmosphere-ocean and atmosphere-ice relationships. Such studies include: for glaciers and the Greenland ice sheet, Gregory and Oerlemans (1998); for Greenland only, Van de Wal and Oerlemans (1997) and Smith (1998); for the Antarctic ice sheet, Smith *et al.* (1998); and for Greenland and Antarctica, Ohmura *et al.* (1996) and Thompson and Pollard (1997).

Simple models that integrate these separate components through their relationship with climate, such as the upwelling diffusion-energy balance model of Wigley and Raper (1992, 1993, 1995) used in Warrick *et al.* (1996), can be used to project a range of total sea-level rise. De Wolde *et al.* (1997) used a two-dimensional model to project a smaller range than in Warrick *et al.* (1996); the major differences were related to different model assumptions. Sokolov and Stone (1998) used a two-dimensional model to achieve a larger range. Some new estimates are presented in Section 3.8.2.

3.6.4. Regional Sea-Level Rise

Regional sea-level rise scenarios require estimates of regional sea-level rise integrated with estimates of local land movements. Currently there are too few model simulations to provide a range of regional changes in sea level, restricting most scenarios to using global mean values (de Wolde, 1999). An exception is Walsh *et al.* (1998), who produced scaled scenarios of regional sea-level rise for the Gold Coast of eastern Australia on the basis of a suite of runs from a single GCM. Because relative sea-level rise scenarios are needed for coastal impact studies,

local land movements also must be estimated. This requires long-term tide gauge records with associated ground- or satellite-based geodetic leveling. Geophysical models of isostatic effects, incorporating the continuing response of the Earth to ice-loading during the last glaciation, also provide estimates of long-term regional land movements (Peltier, 1998; Zwart *et al.*, 1999).

3.6.5. Scenarios Incorporating Variability

Most impacts on the coast and near coastal marine environments will result from extreme events affecting sea level, such as storm surges and wave set-up. The magnitude of extreme events at any particular time is influenced by tidal movements, storm severity, decadal-scale variability, and regional mean sea level. These phenomena are additive. Because it is impossible to provide projections of all of these phenomena with any confidence, many assessments of coastal impacts simply add projections of global average sea level to baseline records of short-term variability (e.g., Ali, 1996; McDonald and O'Connor, 1996; McInnes and Hubbert, 1996; Lorenzo and Teixiera, 1997). Moreover, several coastal processes also are stochastic, and locally specific scenarios may have to be constructed for these (e.g., Bray and Hooke, 1997).

3.6.6. Application of Scenarios

3.6.6.1. Simple Scenarios

Simple scenarios are based on one or several estimates of sea-level rise consistent with IPCC-projected ranges of global sea-level rise for a particular date. Usually a mid-range or upper estimate is chosen. The application of a eustatic scenario, where a relative scenario is required, discounts the impact of regional sea-level change and local land movements, although it is possible to add the latter explicitly where estimates exist (Gambolati *et al.*, 1999). Assessments that use simple scenarios usually test whether a coastal region is sensitive and/or vulnerable to a plausible upper limit of climate change (e.g., Zeidler, 1996; El Raey *et al.*, 1997; Olivo, 1997).

3.6.6.2. Projected Ranges

A range of global sea-level rise can be applied, bounded by its upper and lower extremes, for a particular date (e.g., Ali, 1996; Nicholls *et al.*, 1999). This will project a likely range of impacts but without any reference to the likelihood of that range or specific changes within that range (Section 2.5). The major disadvantage of this technique is the large range of uncertainty that is produced, making it difficult for policymakers and planners to decide on a concrete response.

3.6.6.3. Risk and Integrated Assessment

Risk assessment aims to produce meaningful outcomes under conditions of high uncertainty. For sea-level rise, two approaches

to risk assessment have been reported. The first approach is to construct a probability distribution for a single outcome. For example, Titus and Narayanan (1996) conclude that a sea-level rise of 10–65 cm by 2100 has an 80% probability of occurring; the 99th percentile was associated with a 104-cm rise. The second approach is to calculate the probability of exceedance above a given threshold identified as a hazard. Pittock and Jones (2000) suggest the use of critical thresholds, which link an unacceptable level of harm with a key climatic or climate-related variable. For coastal impacts, the critical threshold is then linked to a projected range of sea-level scenarios, through key climatic and marine variables, and its risk of exceedance calculated (Jones *et al.*, 1999).

IAMs attempt to represent the interaction of human activities with socioeconomic and biophysical systems on a global scale (see Section 3.3.2.3). In the TARGETS model (Rotmans and de Vries, 1997), various human activities that affect a succession of phenomena are simulated to produce scenarios of sea-level rise, which then lead to calculations of people and capital at risk in low-lying coastal regions (Hoekstra, 1997). The IMAGE 2 integrated model applies baseline scenarios of global environmental change (Alcamo *et al.*, 1996) to project several global outcomes, one of which is sea-level rise. Yohe and Schlesinger (1998) used a model of global economic activity to produce emissions profiles, which they then used to calculate temperature and sea-level changes and integrated with an economic damages model for the U.S. coastline. The scenarios of sea-level rise were probabilistically weighted from a sample of 280 to calculate the 10th and 90th percentiles and the median estimate, producing several ranges similar in magnitude to that of Titus and Narayanan (1996).

3.7. Representing Interactions in Scenarios and Ensuring Consistency

3.7.1. Introduction

There is great diversity in the scenarios adopted in impact assessments. This diversity is valuable in providing alternative views of the future, although it can hamper attempts to summarize and interpret likely impacts by introducing inconsistencies within or between studies. Moreover, there are certain key dependencies in climate change science that have resulted in time lags and inconsistencies in the application of scientific results between different research areas. This has been reflected in the IPCC process (see Table 3-6). Thus, although TAR WGI reviews recent projections of future climate, these results are not yet available to the impacts community to prepare and publish their analyses, on which the TAR WGII assessment is based. Instead, most impact studies have relied on earlier, more rudimentary climate projections. Similarly, the simplified assumptions used in climate model simulations about changes in radiative forcing of the climate from changing GHG and aerosol concentrations represent only a limited subset of plausible atmospheric conditions under a range of emissions scenarios reviewed by TAR WGIII.

Table 3-6: Approximate chronology of IPCC process in relation to GCM simulations, their adoption in impact studies, and the development of IPCC emissions scenarios. Abbreviations follow: AGCM = atmospheric GCM with simple ocean; AOGCM = coupled atmosphere-ocean GCM; GHG = greenhouse gas; IS92 = IPCC emissions scenarios published in 1992 (Leggett et al., 1992); SRES = Special Report on Emissions Scenarios (Nakicenovic et al., 2000).

Date	IPCC Process	Working Group I GCM Simulations	Working Group II GCM-Based Scenarios used in Impact Studies	Working Group III Emissions Scenarios
1988–1990	First Assessment Report (FAR), 1990	Equilibrium high-resolution AGCM	Equilibrium low-resolution 2 x CO ₂	Scenarios A-D (A = Business-as-Usual)
1991–1992	FAR Supplement, 1992	Transient AOGCM cold start GHG-only (Scenario A emissions)	Equilibrium low-resolution 2 x CO ₂	IS92a-f
1993–1996	Second Assessment Report (SAR), 1996	Transient AOGCM warm-start GHG + aerosol (0.5 or 1% per year emissions)	Equilibrium low/high-resolution; transient cold-start	IS92a-f (modified)
1997–1998	Regional Impacts Special Report, 1998	Transient AOGCM ensemble/multi-century control	Equilibrium low/high-resolution; transient cold-start/warm-start	IS92a-f (modified)
1999–2001	Third Assessment Report (TAR), 2001	Transient AOGCM CO ₂ -stabilization; SRES-forced	Transient warm-start; multi-century control and ensembles	SRES; stabilization

Creation of comprehensive scenarios that encompass the full complexity of global change processes and their interactions (including feedbacks and synergies) represents a formidable scientific challenge. This section addresses some components of this complexity. First it treats generally accepted biogeochemical processes; second, it addresses emerging climate-system processes; and third, it reviews rarely considered interactions between anthropogenic and natural driving forces. Finally, the importance of comprehensiveness and compatibility in scenario development is discussed.

3.7.2. Representing Processes and Interactions in Scenarios

3.7.2.1. Generally Considered Interactions

Emissions of greenhouse gases have increased their atmospheric concentrations, which alter the radiative properties of the atmosphere and can change the climate (see TAR WGI Chapters 3–8). Determination of atmospheric concentrations from emissions is not straightforward; it involves the use of models that represent biogeochemical cycles and chemical processes in the atmosphere (Harvey et al., 1997; TAR WGI Chapters 3–5). Several atmosphere-ocean interactions are considered in defining the future transient response of the climate system (Sarmiento et al., 1998; TAR WGI Chapter 8). For the purposes of scenario development, CO₂ occupies a special role, as a greenhouse gas (IPCC, 1996a) and by directly affecting carbon fluxes through CO₂ fertilization and enhanced

water-use efficiency (see Section 3.4.2). These direct responses are well known from experimentation (Kirschbaum et al., 1996). Biospheric carbon storage is further strongly influenced by climate, land use, and the transient response of vegetation. All of these interactions define the final CO₂ concentrations in the atmosphere and subsequent levels of climate change (see Table 3-7).

The early simple climate models that were used in the IPCC's First and Second Assessment Reports all emphasized the importance of CO₂ fertilization but few other biogeochemical interactions (Harvey et al., 1997). Inclusion of more realistic responses of the carbon cycle in climate scenarios still is an evolving research area (Walker et al., 1999), but most interactions now are adequately represented.

3.7.2.2. Less Considered Interactions

Interactions between land, vegetation, and the atmosphere have been studied extensively in deforestation and desertification model experiments (Charney et al., 1977; Bonan et al., 1992; Zhang et al., 1996; Hahmann and Dickinson, 1997). Changes in surface characteristics such as snow/ice and surface albedo and surface roughness length modify energy, water, and gas fluxes and affect atmospheric dynamics. These interactions occur at various scales (Hayden, 1998), but although their importance is well appreciated (Eltahir and Gong, 1996; Manzi and Planton, 1996; Lean and Rountree, 1997; Zeng, 1998) they still generally are ignored in scenario development.

Climate modeling studies (e.g., Henderson-Sellers *et al.*, 1995; Thompson and Pollard, 1995; Sellers *et al.*, 1996) suggest an additional warming of about 0.5°C after deforestation on top of the radiative effects of GHG, but these effects are not necessarily additive on regional scales. Betts *et al.* (1997) concur that vegetation feedbacks can be significant for climate on regional scales. More recent studies, however, tend to predict smaller changes, partly as a result of the inclusion of more interactions such as the cloud radiative feedback. Field experiments show large changes in surface hydrology and micrometeorological conditions at deforested sites (Gash *et al.*, 1996). On the other hand, observations have not provided direct evidence of changes in overall climate in the Amazon basin (Chu *et al.*, 1994) or in Sahel surface albedo (Nicholson *et al.*, 1998), but the available data series are too short to be conclusive.

Palaeoclimatic reconstructions, using empirical data and model results, provide better opportunities to study vegetation-atmosphere interactions. Climate models that incorporate dynamic vegetation responses simulate larger vegetation shifts for changed past climates than expected by the orbitally forced climate effect alone. For example, an additional 200–300 km poleward displacement of forests simulated for 6,000 ky BP in North America was triggered by changes in surface albedo (Kutzbach *et al.*, 1996; Texier *et al.*, 1997; Ganopolski *et al.*, 1998). However, these shifts are not observed in all model experiments (e.g., Broström *et al.*, 1998). Other modeling results suggest that oceans also play a prominent role (Hewitt and Mitchell, 1998). Thus, vegetation-ocean-climate interaction seems to be important in defining regional climate change responses.

Most vegetation models used in scenario development are equilibrium models (i.e., for a given climate they predict a fixed vegetation distribution). The latest dynamic vegetation models attempt to include plant physiology, biogeochemistry, and land surface hydrology (e.g., Goudriaan *et al.*, 1999), and some explicitly treat vegetation structure and succession. Foley

et al. (1998) coupled one such model to a GCM and found that the most climatically sensitive zones were the desert/grassland and forest/tundra ecotones. These zones also tend to be exposed to large disturbances and natural climate variability (Schimel *et al.*, 1997b). In another model experiment, Zeng and Neelin (1999) found that interannual and inter-decadal climate variability helps to keep the African savannah region from getting either too dry or too wet, through nonlinear vegetation-atmosphere interactions. Few of these models contain simulations of disturbances, such as fire regimes (Crutzen and Goldammer, 1993; Kasischke and Stocks, 2000), which rapidly alter vegetation patterns and influence vegetation responses. Unfortunately, hardly any of these insights are included routinely in scenario development.

3.7.2.3. Rarely Considered Interactions

Most scenarios emphasize systemic interactions within nonhuman components of the climate system. These interactions are relatively well studied. The response of society to changes in the climate system is much less well studied. Land-use and land-cover change is an exception, but its treatment in climate scenarios still is far from ideal (see Section 3.3). The difficulty of including such interactions in scenario development is that many are not precisely specified and act indirectly. For example, warmer climates would change heating and cooling requirements of buildings. Such effects frequently are listed as impacts but are not factored in as adjustments to energy use and thus emission levels. Another example is population migration, which can be treated as an impact of environmental or socioeconomic change while also serving as a scenario of demographic change affecting future regional vulnerability (Döös, 1997).

A model that accounts for such societal interactions with the climate system is TARGETS (Rotmans and de Vries, 1997), which evolved from the WORLD model of Meadows *et al.*

Table 3-7: Illustration of importance of some different feedback processes. Values are for the year 2100, obtained from a baseline scenario implemented in the IMAGE-2 integrated assessment model (adapted from Alcamo *et al.*, 1998a). The no-feedbacks case excludes CO₂ fertilization and accelerated ice melt and includes an intermediate adaptation level of vegetation.

Simulation	[CO ₂] (ppm)	Net Ecosystem Productivity (Pg a ⁻¹) ^a	Temperature Change (°C)	Sea-Level Rise (cm)	Vegetation Shift (%) ^b
All feedbacks	737	6.5	2.8	43	41
No CO ₂ fertilization	928	0.1	3.6	52	39
Vegetation adapts immediately	724	7.0	3.1	45	40
No adaptation of vegetation	762	5.3	3.2	46	41
No land-use change	690	6.9	2.9	41	39
No feedbacks	937	0.0	3.5	29	45
No land-use/no feedbacks	889	0.2	3.4	28	45
Range	690–937	0.0–7.0	2.8–3.6	28–52	39–45

^a 1 Pg a⁻¹ = 10¹⁵ grams per year.

^b Percentage of vegetated area for which climate change induces a change of vegetation class.

(1992). TARGETS is a highly aggregated model (only two regions and few resource classes) with simple relationships between population, economic development, and resource use; between environmental conditions and population/health/wealth; and between emissions, concentrations, climate, and impacts. The model generates globally averaged emissions and climate change scenarios. The strength of the model is that different interactions—including controversial ones, such as the effects of climate change on food availability and health and their interactions with population—can be explored easily, but its use for developing scenarios for impact assessment is limited.

3.7.3. Tools Capable of Addressing Interactions

Most climate scenarios for impact assessments were developed by using outputs from AOGCMs (Hulme and Brown, 1998). Often these results are scaled toward the desired emission levels with simple climate models (Hulme *et al.*, 1995; Harvey *et al.*, 1997; see Section 3.8.3). In this simple approach, most interactions are neglected.

The only models that can be used to develop more consistent scenarios that incorporate most of the important interactions are IAMs (see Section 3.3.2.3). IAMs have been developed with different levels of complexity, from extremely simple to highly complex (Harvey *et al.*, 1997). Different interactions are included, although no single model provides a fully comprehensive treatment. The models are most commonly used for emission scenario development and mitigation policy assessment (Schimel *et al.*, 1997a; Alcamo *et al.*, 1998a; Pepper *et al.*, 1998). All simulate a causal chain (e.g., human activities, emissions, climate change, sea-level rise, and other impacts). Emissions, climate change, impact, and mitigation scenarios derived from these models have been published (Schimel *et al.*, 1997a; Leemans *et al.*, 1998; Pepper *et al.*, 1998) and collected

in several databases (Alcamo *et al.*, 1995; Nakicenovic *et al.*, 2000). Unfortunately, it is not always clear which interactions are explicitly included in individual IAMs. This reduces the comparability of individual IAM-derived scenarios and thus their utility.

Depending on assumed interactions during scenario development, a wide range of estimates of climate change and its impacts is possible (see Table 3-7). However, within this range certain responses are more likely than others. To define appropriate and realistic levels of interactions, expert judgment and sensitivity experiments with models could be very valuable (van der Sluijs, 1997). Innovative, objective, and systematic approaches have to be developed to evaluate underlying scenario assumptions and to validate the scenario results. This is still an immature area of scenario development.

3.7.4. Problems of Compatibility between Scenarios

One difficulty faced by authors in attempting to summarize and synthesize the results of impact studies for previous IPCC assessments (i.e., IPCC, 1996b, 1998) has been a lack of consistency in projections. Different climate projections have been adopted in different studies, in different regions (or within the same region), and in different sectors. Moreover, even where the same climate projections are assumed, they might not be applied in the same way in different impact studies. Finally, some studies also are inconsistent in their methods of projecting changes in climate alongside concurrent changes in related socioeconomic and environmental conditions.

For example, GHG concentrations often are transformed into CO₂-equivalent concentrations to determine radiative forcing levels and climate change. The GCM community often presents climate change simulations as “doubled CO₂” anomalies.

Box 3-2. The Global Impact of Climate Change on Five Sectors (Parry and Livermore, 1999)

In this assessment, the prospective effects of unmitigated climate change during the 21st century are estimated at a global scale in five sectoral studies (see Table 3-8). Each study has different scenario requirements, though some are common to several studies. For example, the ecosystems study estimates potential biomass on the basis of scenarios of climate, CO₂ concentration, and nitrogen deposition, but it ignores future land-cover and land-use changes that would be expected regardless of climate change. In contrast, the study on food security examines the effects on crop productivity of the same scenarios of climate (though for fewer variables) and CO₂ concentration; it too ignores likely land-cover and land-use changes and does not consider effects of nitrogen deposition, although it adopts a range of socioeconomic and technological scenarios to evaluate the number of persons at risk from hunger.

Notably, across all of the studies the scenarios adopted are designed to be mutually consistent. For instance, the population and GDP scenarios are those adopted in constructing the IS92a emissions scenario (Leggett *et al.*, 1992). An approximation of the IS92a emissions scenario is used to force the HadCM2 and HadCM3 GCMs that were employed to construct the climate and sea-level scenarios (Hulme *et al.*, 1999b). Other scenarios are chosen to be broadly consistent with these assumptions. The scenarios are required as inputs to global impact models, and results from these are described elsewhere in this report. Finally, it also should be noted that although these studies are compatible and consistent, they are not integrated across sectors. For example, climate-induced changes in water resources for irrigation are not accounted for in estimates of future food security.

Depending on the scenario, however, 5–40% of the forcing is caused by non-CO₂ GHGs (30% in 1990). The doubled-CO₂ scenarios often are interpreted as CO₂ only (e.g., Cramer *et al.*, 1997); others add an explicit distinction between CO₂ and non-CO₂ gases (e.g., Downing *et al.*, 1999). In determining the impacts of direct CO₂ effects and climate change, this can easily lead to inconsistencies. Similar discrepancies exist for other types of interactions.

Finally, it is a significant challenge to integrate climate or sea-level rise scenarios, with a time horizon of decades to hundreds of years, with nonclimatic scenarios of social, economic, and technological systems that can change rapidly over a time scale of years. For instance, it is difficult to devise credible socioeconomic scenarios that extend beyond the lifetime of current infrastructure and institutions. Moreover, social/economic actors who need to be involved in the scenario development process (e.g., business, governments) often find long time horizons difficult to contemplate. Box 3-2 illustrates a recent example of an attempt to harmonize climate change, sea level, atmospheric composition, and socioeconomic scenarios in a multi-sectoral global impact assessment.

3.8. Scenarios of the 21st Century

This section summarizes recent developments that are likely to affect the construction of scenarios over the coming few years. One of these developments is construction of the new SRES emission scenarios. Some features of these scenarios and their implications for atmospheric composition, global climate, and sea level are described below. In addition, a brief review of possible regional climate changes during the 21st century is presented, followed by discussions of stabilization scenarios and changes in climate variability and extreme events—key issues in constructing scenarios for policy-relevant impact and adaptation assessments.

3.8.1. SRES Storylines and Emissions Scenarios

Development of the SRES scenarios (Nakicenovic *et al.*, 2000) is outlined in Section 3.2.4.1. The 40 scenarios, 35 of which are fully quantified, are based on four different narrative storylines and associated scenario families. Each storyline describes a different world evolving through the 21st century, and each

Table 3-8: Summary of scenarios adopted in an assessment of global impacts on five sectors (Parry and Livermore, 1999).

^d Nicholls *et al.* (1999) and see Chapters 6, 7, and 19.

^e Martens *et al.* (1999) and see Chapters 8 and 18.

may lead to quite different GHG emissions trajectories. Four of the scenarios are designated as “markers,” each characterizing one of four “scenario families”; two additional scenarios illustrate alternative energy developments in one of the families. The storylines and scenario families are as follows:

- *A1*: A future world of very rapid economic growth, global population that peaks mid-century and declines thereafter, and rapid introduction of new and more efficient technologies. Major underlying themes are economic and cultural convergence and capacity-building, with a substantial reduction in regional differences in per capita income. The A1 scenario family develops into three groups that describe alternative directions of technological change in the energy system: fossil-intensive (A1FI), nonfossil energy sources (A1T), and a balance across all sources (A1B).
- *A2*: A differentiated world. The underlying theme is self-reliance and preservation of local identities. Fertility patterns across regions converge very slowly, resulting in continuously increasing population. Economic development is primarily regionally orientated, and per capita economic growth and technological change are more fragmented and slower than other storylines.
- *B1*: A convergent world with rapid change in economic structures toward a service and information economy, reductions in material intensity, and introduction of clean technologies. The emphasis is on global solutions to economic, social, and environmental sustainability, including improving equity, but without additional climate change policies.
- *B2*: A world in which the emphasis is on local solutions to economic, social, and environmental sustainability. This is a world with continuously increasing global population at a lower rate than in scenario A2, intermediate levels of economic development, and less rapid and more diverse technological change than in the A1 and B1 storylines. Although this scenario also is orientated toward environmental protection and social equity, it focuses on the local and regional levels.

Measures of global population, economic development (expressed in annual GDP), and equity (per capita income ratio) for 2050 and 2100 that are implied under the SRES scenarios are shown in Table 3-9, alongside the IS92a scenario and estimates for the present day. Attempts are underway to “downscale” aspects of these global scenarios for use in regional impact assessment (e.g., Lorenzoni *et al.*, 2000).

3.8.2. Implications of SRES Scenarios for Atmospheric Composition and Global Climate

Estimates of atmospheric composition resulting from the SRES emissions scenarios are presented in TAR WGI Chapters 3–5. Information on CO₂ and ground-level O₃ concentrations is given in Tables 3-2 and 3-9. More detailed regional estimates

of pollutant concentrations and deposition of acidifying compounds based on these scenarios also are beginning to emerge (e.g., Mayerhofer *et al.*, 2000; see Section 3.4).

To interpret the possible range of global temperature and sea-level response to the SRES scenarios, estimates have been made with simple models for all 35 of the quantified SRES scenarios (Table 3-9; see also TAR WGI Chapters 9 and 11). Estimates of global warming from 1990 to 2100 give a range of 1.4–5.8°C—somewhat higher than the 0.7–3.5°C of the SAR. The main reason for this increase is that the levels of radiative forcing in the SRES scenarios are higher than in the IS92a-f scenarios, primarily because of lower sulfate aerosol emissions, especially after 2050. The temperature response also is calculated differently; rather than using the conventional idealized, equilibrium climate sensitivity range of 1.5–4.5°C (IPCC, 1996a), the simple model is tuned to the effective climate sensitivities of a sample of individual AOGCMs (see TAR WGI Chapter 9 for details). Sea-level rise between 1990 and 2100 is estimated to be 9–88 cm, which also accounts for uncertainties in ice-melt parameters (see TAR WGI Chapter 11).

3.8.3. Implications of SRES Scenarios for Regional Mean Climate

3.8.3.1. Regional Information from AOGCMs

Estimates of regional climate change to 2100 based on AOGCM experiments are described in TAR WGI Chapters 9 and 10. The results of nine AOGCMs run with the A2 and B2 SRES scenarios⁵ display many similarities with previous runs that assume IS92a-type emissions, although there also are some regional differences (see below). Overall, rates of warming are expected to be greater than the global average over most land areas and most pronounced at high latitudes in winter. As warming proceeds, northern hemisphere snow cover and sea-ice extent will be reduced. Models indicate warming below the global average in the North Atlantic and circumpolar southern ocean regions, as well as in southern and southeast Asia and southern South America in June–August. Globally there will be increases in average water vapor and precipitation. Regionally, December–February precipitation is expected to increase over the northern extratropics and Antarctica and over tropical Africa. Models also agree on a decrease in precipitation over Central America and little change in southeast Asia. Precipitation in June–August is projected to increase in high northern latitudes, Antarctica, and south Asia; change little in southeast Asia; and decrease in Central America, Australia, southern Africa, and the Mediterranean region.

The main differences between the SRES-based and IS92-based runs concern greater disagreement in the SRES runs on the magnitude of warming in some tropical and southern hemisphere regions and differing intermodel agreement on the

⁵Preliminary marker emissions scenarios released in 1998 for use in climate modeling (Nakicenovic *et al.*, 2000).

magnitude of precipitation change in a few regions, possibly as a result of aerosol effects. However, there are no cases in which the SRES and IS92a results indicate precipitation changes of opposite direction (see TAR WGI Chapter 10).

3.8.3.2. Regional Climate Characterizations

Only a limited number of AOGCM results based on the SRES emissions scenarios have been released and analyzed to date (i.e.,

results for the A2 and B2 scenarios), and none were available for the impact studies assessed in this report. In the meantime, alternative approaches have been used to gain an impression of possible regional changes in climate across a wider range of emissions scenarios. One method uses results from existing AOGCM simulations and scales the pattern of modeled regional climate change up or down according to the range of global temperature changes estimated by simple climate models for different emissions scenarios or assumptions about climate sensitivity (Santer *et al.*, 1990; Mitchell *et al.*, 1999;

Table 3-9: Some aspects of the SRES emissions scenarios and their implications for CO₂ concentration, global temperature and sea-level rise by 2050 and 2100 compared to the IS92a emissions scenario (Leggett *et al.*, 1992). Data in columns 2–4 are taken from Nakicenovic *et al.* (2000). Calculations in columns 6–7 are relative to 1990. ΔT is change in mean annual temperature averaged across simple climate model runs emulating results of seven AOGCMs with average climate sensitivity of 2.8°C (Chapter 9, TAR WGI). CO₂ concentrations were estimated by using the same model runs (data from S.C.B. Raper, Chapter 9, TAR WGI). Sea-level rise estimates are based on temperature changes (Chapter 11, TAR WGI). SRES-min and SRES-max are minimum and maximum estimates across all 40 SRES scenarios (35 fully quantified scenarios for CO₂, ΔT, and sea level). High and low estimates of CO₂ concentration and temperature change account for uncertainties in climate sensitivity (across the range 1.7–4.2°C). Sea-level rise range also accounts for uncertainties in model parameters for land ice, permafrost, and sediment deposition. Note that scenario values are mutually consistent along all rows except for SRES-min and SRES-max.

Emissions Scenario	Global Population (billions)	Global GDP ^a (10 ¹² US\$ a ⁻¹)	Per Capita Income Ratio ^b	CO ₂ Concentration ^c (ppm)	Global ΔT (°C)	Global Sea-Level Rise (cm)

^a Gross domestic product (1990 US\$ trillion yr⁻¹).

^b Ratio of developed countries and economies in transition (Annex I) to developing countries (Non-Annex I).

^c Modeled values are not the same as those presented by TAR WGI, Appendix II, which are based on simulations using two different carbon cycle models for the six illustrative SRES emissions scenarios. Both models produce very similar results to the model applied here for a mid-range climate sensitivity; discrepancies in the high and low estimates are attributable to differences in the modeled climate-carbon cycle feedback.

^d Modeled range across the six illustrative SRES scenarios.

^e Observed 1999 value (Chapter 3, WG I TAR).

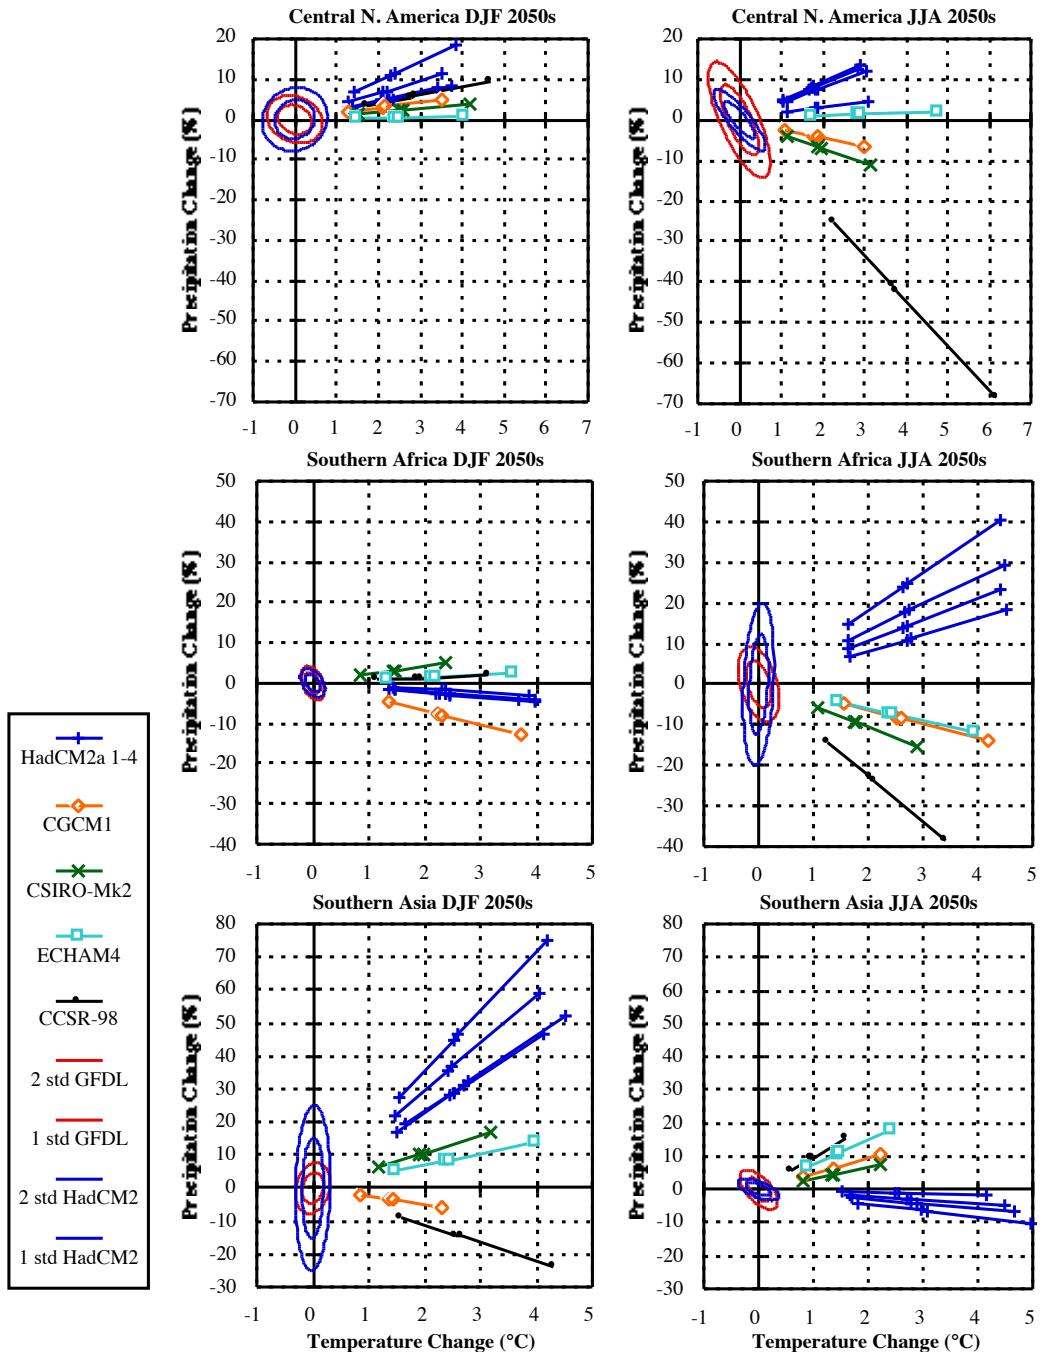

Figure 3-2: Scaled outputs of mean December–February (left) and June–August (right) temperature and precipitation change by the 2050s relative to 1961–1990 over land grid boxes representing Central North America (top), Southern Africa (middle), and Southern Asia (bottom) from eight simulations with five AOGCMs (experiments b, c, e, h, and a four-member ensemble from t; see Table 3-5). Simulations assume forcing by greenhouse gases but not aerosols, and are standardized according to the climate sensitivity of each AOGCM. Lines connect four points for each simulation, all in the same order from the origin: B1-low, B2-mid, A1-mid, A2-high. Each point represents the standardized regional changes in climate from the AOGCM, linearly scaled according to the global warming estimated with a simple climate model for one of four preliminary SRES marker emissions scenarios (B1, B2, A1, and A2) and a value of the climate sensitivity (low = 1.5°C ; mid = 2.5°C , and high = 4.5°C). Also plotted are ± 1 and ± 2 standard deviation ellipses from the 1400-year HadCM2 and 1000-year GFDL unforced simulations, which are used to indicate natural multi-decadal variability and are orientated according to the correlation between modeled 30-year mean temperature and precipitation. Results from two other AOGCMs did not extend to the 2050s (Carter *et al.*, 2000).

see also detailed discussion in TAR WGI Chapter 13). This “pattern-scaling” method has been employed by Carter *et al.* (2000), using results from simulations with seven AOGCMs, all assuming a radiative forcing approximating the IS92a emissions scenario (for GHGs but excluding aerosols) scaled across a range of global temperature changes estimated by using a simple climate model for the four preliminary marker SRES emissions scenarios.

Regional-scale summary graphs of scaled temperature and precipitation changes were constructed for 32 world regions, at subcontinental scale, chosen to represent the regions being assessed by Working Group II (Carter *et al.*, 2000). Examples of individual plots are shown in Figure 3-2. Changes are plotted alongside estimates of “natural” multi-decadal variability of temperature and precipitation, extracted from two multi-century unforced AOGCM simulations. The graphs thus provide a quick assessment of the likely uncertainty range *and* significance of each AOGCM projection; they also show the extent to which different AOGCMs agree or disagree with regard to regional response to a given magnitude of global warming. Although a preliminary comparison of these results with SRES AOGCM runs (which also include aerosol forcing) suggests broad agreement on regional temperature and precipitation changes, more rigorous comparison remains to be carried out, offering a useful test of the pattern-scaling method.

3.8.4. Stabilization Scenarios

The SRES scenarios assume no climate policy intervention, but nations already are engaged in negotiations to reduce emissions of GHGs. Targets for stabilization of GHG concentrations in the atmosphere are being investigated by scientists and policymakers. TAR WGIII Chapter 2 reviews more than 120 mitigation scenarios, most of which aim to stabilize emissions of CO₂ at some target level. Simple climate models, as well as some AOGCMs, have been used to estimate the climate and sea-level response to stabilization (see Harvey *et al.*, 1997; TAR WGI Chapters 9 and 11). Relative to most reference emissions scenarios (e.g., the SRES scenarios), stabilization scenarios reduce global warming, especially beyond 2100. However, even for the lowest stabilization targets considered (450 ppm), based on long simulations by AOGCMs, the climate system and oceans may continue to respond for many centuries after stabilization of atmospheric concentrations of GHGs. Furthermore, because of regional variations in the time lag of response, regional patterns of climate change might be quite different from the unmitigated case (Whetton *et al.*, 1998).

3.8.5. Scenarios of Changes in Climate Variability and Extreme Events

It is demonstrated throughout this report that changes in climatic variability and extremes often play a dominant role in climate change impacts. Moreover, the magnitude and frequency of extreme events can change rapidly with only relatively small

changes in climatic averages (see Section 3.5.4.6). However, climate modelers have more confidence in estimates of changes in averages than in changes in variability and extremes (see TAR WGI Chapters 8–10 and 13). Thus, impact assessors need to look carefully at the extent to which changes in variability and extremes are covered implicitly by changes in averages; when this is not the case, they must incorporate possible changes in these phenomena into scenarios. Table 3-10 summarizes projected changes in several types of extreme climate events and their likelihood taken from TAR WGI Technical Summary (see Table 1-1 for a typology of extremes). Table 3-10 also provides representative examples, drawn from different sectors and regions, of impacts that would be expected with high confidence, conditional on the occurrence of a given change in climate extremes. All of this information is reported in other chapters in this report.

3.9. State of the Science and Future Needs for Scenario Development

This chapter outlines the current practice of scenario development for climate impact, vulnerability, and adaptation assessment. Methods of scenario construction and application are evolving rapidly, so it is useful to identify which aspects are well developed and which aspects still are deficient.

3.9.1. Well-Developed Features

Some features of scenario development and application are well established and tested:

- Extensive monitoring efforts and continued development of global and regional databases has improved the quality and consistency of baseline observational data required for some scenario exercises, even in some data-sparse regions.
- Many impact studies apply incremental scenarios to explore the sensitivity of an exposure unit to a range of climate futures; studies seldom rely exclusively on a single, model-based scenario.
- Estimates of long-term mean global changes are available and widely applied for a limited number of variables (e.g., population, economic development, CO₂ concentration, global mean temperature), based on projections produced by specialized international organizations or the use of simple models.
- A growing volume of information now is available to enable scientists to construct regional scenarios of many features of global change, even though uncertainties in most projections remain high. A notable example is the IPCC-DDC, which was established in 1998 to facilitate the timely distribution of a consistent set of up-to-date projections of changes in climate and related environmental and socioeconomic factors for use in climate impact and adaptation assessment. Some of the studies reported in this volume use scenarios derived from information held in the DDC (see, e.g., Table 3-5).

Table 3-10: Examples of impacts resulting from projected changes in extreme climate events.

Projected Changes during the 21st Century in Extreme Climate Phenomena and their Likelihood^a	Representative Examples of Projected Impacts^b (all high confidence of occurrence in some areas^c)
Simple Extremes	
Higher maximum temperatures; more hot days and heat waves ^d over nearly all land areas (<i>Very Likely</i> ^a)	<ul style="list-style-type: none"> Increased incidence of death and serious illness in older age groups and urban poor Increased heat stress in livestock and wildlife Shift in tourist destinations Increased risk of damage to a number of crops Increased electric cooling demand and reduced energy supply reliability
Higher (increasing) minimum temperatures; fewer cold days, frost days, and cold waves ^d over nearly all land areas (<i>Very Likely</i> ^a)	<ul style="list-style-type: none"> Decreased cold-related human morbidity and mortality Decreased risk of damage to a number of crops, and increased risk to others Extended range and activity of some pest and disease vectors Reduced heating energy demand
More intense precipitation events (<i>Very Likely</i> ^a over many areas)	<ul style="list-style-type: none"> Increased flood, landslide, avalanche, and mudslide damage Increased soil erosion Increased flood runoff could increase recharge of some floodplain aquifers Increased pressure on government and private flood insurance systems and disaster relief
Complex Extremes	
Increased summer drying over most mid-latitude continental interiors and associated risk of drought (<i>Likely</i> ^a)	<ul style="list-style-type: none"> Decreased crop yields Increased damage to building foundations caused by ground shrinkage Decreased water resource quantity and quality Increased risk of forest fire
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities (<i>Likely</i> ^a over some areas) ^e	<ul style="list-style-type: none"> Increased risks to human life, risk of infectious disease epidemics, and many other risks Increased coastal erosion and damage to coastal buildings and infrastructure Increased damage to coastal ecosystems such as coral reefs and mangroves
Intensified droughts and floods associated with El Niño events in many different regions (<i>Likely</i> ^a) (see also under droughts and intense precipitation events)	<ul style="list-style-type: none"> Decreased agricultural and rangeland productivity in drought- and flood-prone regions Decreased hydro-power potential in drought-prone regions
Increased Asian summer monsoon precipitation variability (<i>Likely</i> ^a)	<ul style="list-style-type: none"> Increase in flood and drought magnitude and damages in temperate and tropical Asia
Increased intensity of mid-latitude storms (little agreement between current models) ^d	<ul style="list-style-type: none"> Increased risks to human life and health Increased property and infrastructure losses Increased damage to coastal ecosystems

^aLikelihood refers to judgmental estimates of confidence used by TAR WGI: *very likely* (90-99% chance); *likely* (66-90% chance). Unless otherwise stated, information on climate phenomena is taken from the Summary for Policymakers, TAR WGI.

^bThese impacts can be lessened by appropriate response measures.

^cBased on information from chapters in this report; high confidence refers to probabilities between 67 and 95% as described in Footnote 6 of TAR WGII, Summary for Policymakers.

^dInformation from TAR WGI, Technical Summary, Section F.5.

^eChanges in regional distribution of tropical cyclones are possible but have not been established.

3.9.2. Deficiencies in Knowledge and Future Needs

There are many shortcomings of current scenario development, but there also are promising new methods that may address these problems and require further attention. These include:

- Future socioeconomic, environmental, and land-use changes have not been represented satisfactorily in many recent impact studies and need to be integrated into the process of scenario development.
- Many impact studies fail to consider adequately uncertainties embedded in the scenarios they adopt. New techniques are emerging to explore the role of scenarios, conditional probabilities, and conditional forecasts in providing policy-relevant advice in impact assessments in an environment of high uncertainty.
- There is a mismatch between the time and space scales at which scenario information commonly is provided and the resolution at which it is required for impact assessments. Methods of obtaining higher resolution scenarios of global change from broad-scale projections are being actively developed and refined. However, in some regions of the world the coverage and availability of baseline global change data are still poor, which has hampered efforts at scenario development.
- Most global change scenarios consider long-term and broad-scale changes in mean conditions. Scenarios of changes in variability and the frequency of extreme events (climatic or nonclimatic) seldom are constructed because it is difficult to simulate such events and because they are complicated to formulate and explain. More research is required into methods of representing variability change in scenarios.
- Scenarios for impact studies lag new developments in climate modeling. There is a need to reduce this time lag to deliver up-to-date scenarios for impact assessment (e.g., constructing regional climate and sea-level scenarios by using outputs from AOGCM simulations that are based on SRES emissions scenarios).
- Few comprehensive scenarios have been developed to date for examining the consequences of stabilizing GHG concentrations at different concentrations, in line with Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC).
- Climate change mitigation conventionally has been treated separately from impacts and adaptation, except in some studies that use IAMs. However, these two methods of responding to climate change are inextricably linked, and this linkage should be reflected in scenarios. Efforts to develop the SRES scenarios with well-elaborated narratives and improved appreciation of important interactions in the climate system seem likely to generate greater consistency among scenarios.
- Few scenarios directly address adaptation, but existing scenario methods could be refined to do so (e.g., by combining scenarios of climate change with decision

support and similar systems being used to foster adaptation under current climate variability).

- Improved guidance material and training is required in the construction of integrated global change scenarios (see, e.g., IPCC-TGCIA, 1999; Hulme *et al.*, 2000), especially concerning the development of nonclimatic scenarios.

EXECUTIVE SUMMARY

- There are apparent trends in streamflow volume—both increases and decreases—in many regions. These trends cannot all be definitively attributed to changes in regional temperature or precipitation. However, widespread accelerated glacier retreat and shifts in streamflow timing in many areas from spring to winter are more likely to be associated with climate change.
 - The effect of climate change on streamflow and groundwater recharge varies regionally and between scenarios, largely following projected changes in precipitation. In some parts of the world, the direction of change is consistent between scenarios, although the magnitude is not. In other parts of the world, the direction of change is uncertain.
 - Peak streamflow is likely to move from spring to winter in many areas where snowfall currently is an important component of the water balance.
 - Glacier retreat is likely to continue, and many small glaciers may disappear.
 - Water quality is likely generally to be degraded by higher water temperature, but this may be offset regionally by increased flows. Lower flows will enhance degradation of water quality.
 - Flood magnitude and frequency are likely to increase in most regions, and low flows are likely to decrease in many regions.
 - Demand for water generally is increasing as a result of population growth and economic development, but it is falling in some countries. Climate change is unlikely to have a large effect on municipal and industrial demands but may substantially affect irrigation withdrawals.
 - The impact of climate change on water resources depends not only on changes in the volume, timing, and quality of streamflow and recharge but also on system characteristics, changing pressures on the system, how the management of the system evolves, and what adaptations to climate change are implemented. Nonclimatic changes may have a greater impact on water resources than climate change.
 - Unmanaged systems are likely to be most vulnerable to climate change.
 - Climate change challenges existing water resources management practices by adding additional uncertainty. Integrated water resources management will enhance the potential for adaptation to change.
 - Adaptive capacity (specifically, the ability to implement integrated water resources management), however, is distributed very unevenly across the world.
-

4.1. Introduction and Scope

This chapter assesses our understanding of the implications of climate change for the hydrological cycle, water resources, and their management. Since the beginnings of concern over the possible consequences of global warming, it has been widely recognized that changes in the cycling of water between land, sea, and air could have very significant impacts across many sectors of the economy, society, and the environment. The characteristics of many terrestrial ecosystems, for example, are heavily influenced by water availability and, in the case of instream ecosystems and wetlands, by the quantity and quality of water in rivers and aquifers. Water is fundamental to human life and many activities—most obviously agriculture but also industry, power generation, transportation, and waste management—and the availability of clean water often is a constraint on economic development. Consequently, there have been a great many studies into the potential effects of climate change on hydrology (focusing on cycling of water) and water resources (focusing on human and environmental use of water). The majority of these studies have concentrated on possible changes in the water balance; they have looked, for example, at changes in streamflow through the year. A smaller number of studies have looked at the impacts of these changes for water resources—such as the reliability of a water supply reservoir or the risk of flooding—and even fewer explicitly have considered possible adaptation strategies. This chapter summarizes key findings of research that has been conducted and published, but it concentrates on assessing opportunities and constraints on adaptation to climate change within the water sector. This assessment is based not only on the few studies that have looked explicitly at climate change but also on considerable experience within different parts of the water sector in adapting to changing circumstances in general.

This chapter first summarizes the state of knowledge of climate change impacts on hydrology and water resources (Section 4.2), before assessing effects on the hydrological cycle and water balance on the land (Section 4.3). Section 4.4 examines potential changes in water use resulting from climate change, and Section 4.5 assesses published work on the impacts of climate change for some water resource management systems. Section 4.6 explores the potential for adaptation within the water sector. The final two sections (Sections 4.7 and 4.8) consider several integrative issues as well as science and information requirements. The implications of climate change on freshwater ecosystems are reviewed in Chapter 5, although it is important to emphasize here that water management is increasingly concerned with reconciling human and environmental demands on the water resource. The hydrological system also affects climate, of course. This is covered in the Working Group I contribution to the Third Assessment Report (TAR); the present chapter concentrates on the impact of climate on hydrology and water resources.

At the outset, it is important to emphasize that climate change is just one of many pressures facing the hydrological system and water resources. Changing land-use and land-management

practices (such as the use of agrochemicals) are altering the hydrological system, often leading to deterioration in the resource baseline. Changing demands generally are increasing pressures on available resources, although per capita demand is falling in some countries. The objectives and procedures of water management are changing too: In many countries, there is an increasing move toward “sustainable” water management and increasing concern for the needs of the water environment. For example, the Dublin Statement, agreed at the International Conference on Water and the Environment in 1992, urges sustainable use of water resources, aimed at ensuring that neither the quantity nor the quality of available resources are degraded. Key water resources stresses now and over the next few decades (Falkenmark, 1999) relate to access to safe drinking water, water for growing food, overexploitation of water resources and consequent environmental degradation, and deterioration in water quality. The magnitude and significance of these stresses varies between countries. The late 1990s saw the development of several global initiatives to tackle water-related problems: The UN Commission on Sustainable Development published the “Comprehensive Assessment of the Freshwater Resources of the World” (WMO, 1997), and the World Water Council asked the World Commission for Water to produce a vision for a “water-secure world” (Cosgrove and Rijbersman, 2000). A series of periodical reports on global water issues was initiated (Gleick, 1998). The impacts of climate change, and adaptation to climate change, must be considered in the context of these other pressures and changes in the water sector.

4.2 State of Knowledge of Climate Change Impacts on Hydrology and Water Resources: Progress since the Second Assessment Report

4.2.1 Introduction

Over the past decade—and increasingly since the publication of the Second Assessment Report (SAR) (Arnell *et al.*, 1996; Kaczmarek, 1996)—there have been many studies into climate change effects on hydrology and water resources (see the online bibliography described by Chalecki and Gleick, 1999), some coordinated into national programs of research (as in the U.S. National Assessment) and some undertaken on behalf of water management agencies. There are still many gaps and unknowns, however. The bulk of this chapter assesses current understanding of the impacts of climate change on water resources and implications for adaptation. This section highlights significant developments in three key areas since the SAR: methodological advances, increasing recognition of the effect of climate variability, and early attempts at adaptation to climate change.

4.2.2 Estimating the Impacts of Climate Change

The impacts of climate change on hydrology usually are estimated by defining scenarios for changes in climatic inputs to a hydrological model from the output of general circulation models

(GCMs). The three key developments here are constructing scenarios that are suitable for hydrological impact assessments, developing and using realistic hydrological models, and understanding better the linkages and feedbacks between climate and hydrological systems.

The heart of the scenario “problem” lies in the scale mismatch between global climate models (data generally provided on a monthly time step at a spatial resolution of several tens of thousands of square kilometers) and catchment hydrological models (which require data on at least daily scales and at a resolution of perhaps a few square kilometers). A variety of “downscaling” techniques have been developed (Wilby and Wigley, 1997) and used in hydrological studies. These techniques range from simple interpolation of climate model output (as used in the U.S. National Assessment; Felzer and Heard, 1999), through the use of empirical/statistical relationships between catchment and regional climate (e.g., Crane and Hewitson, 1998; Wilby *et al.*, 1998, 1999), to the use of nested regional climate models (e.g., Christensen and Christensen, 1998); all, however, depend on the quality of simulation of the driving global model, and the relative costs and benefits of each approach have yet to be ascertained. Studies also have looked at techniques for generating stochastically climate data at the catchment scale (Wilby *et al.*, 1998, 1999). In principle, it is possible to explore the effects of changing temporal patterns with stochastic climate data, but in practice the credibility of such assessments will be strongly influenced by the ability of the stochastic model to simulate present temporal patterns realistically.

Considerable effort has been expended on developing improved hydrological models for estimating the effects of climate change. Improved models have been developed to simulate water quantity and quality, with a focus on realistic representation of the physical processes involved. These models often have been developed to be of general applicability, with no locally calibrated parameters, and are increasingly using remotely sensed data as input. Although different hydrological models can give different values of streamflow for a given input (as shown, for example, by Boorman and Sefton, 1997; Arnell, 1999a), the greatest uncertainties in the effects of climate on streamflow arise from uncertainties in climate change scenarios, as long as a conceptually sound hydrological model is used. In estimating impacts on groundwater recharge, water quality, or flooding, however, translation of climate into response is less well understood, and additional uncertainty is introduced. In this area, there have been some reductions in uncertainty since the SAR as models have been improved and more studies conducted (see Sections 4.3.8 and 4.3.10). The actual impacts on water resources—such as water supply, power generation, navigation, and so forth—depend not only on the estimated hydrological change but also on changes in demand for the resource and assumed responses of water resources managers. Since the SAR, there have been a few studies that have summarized potential response strategies and assessed how water managers might respond in practice (see Section 4.6).

There also have been considerable advances since the SAR in the understanding of relationships between hydrological processes at the land surface and processes within the atmosphere above. These advances have come about largely through major field measurement and modeling projects in different geographical environments [including the First ISLSCP Field Experiment (FIFE), LAMBADA, HAPEX-Sahel, and NOPEX; see www.gewex.com], coordinated research programs (such as those through the International Geosphere-Biosphere Programme (IGBP; see www.igbp.se) and large-scale coupled hydrology-climate modeling projects [including GEWEX Continental-Scale International Project (GCIP), Baltic Sea Experiment (BALTEX), and GEWEX Asian Monsoon Experiment (GAME); see www.gewex.com/projects.html]. The ultimate aim of such studies often is to lead to improved assessments of the hydrological effects of climate change through the use of coupled climate-hydrology models; thus far, however, the benefits to impact assessments have been indirect, through improvements to the parameterizations of climate models. A few studies have used coupled climate-hydrology models to forecast streamflow (e.g., Miller and Kim, 1996), and some have begun to use them to estimate effects of changing climate on streamflow (e.g., Miller and Kim, 2000).

4.2.3. Increased Awareness of the Effect of Climatic Variability on Hydrology and Water Resources

Since the SAR, many studies have explored linkages between recognizable patterns of climatic variability—particularly El Niño and the North Atlantic Oscillation—and hydrological behavior, in an attempt to explain variations in hydrological characteristics over time. These studies in North America (McCabe, 1996; Piechota *et al.*, 1997; Vogel *et al.*, 1997; Olsen *et al.*, 1999), South America (Marengo, 1995; Compagnucci and Vargas, 1998), Australasia (Chiew *et al.*, 1998), Europe (e.g., Shorthouse and Arnell, 1997), and southern Africa (Shulze, 1997) have emphasized variability not just from year to year but also from decade to decade, although patterns of variability vary considerably from region to region. Most studies focus on the past few decades with recorded hydrological data, but an increasing number of studies have reconstructed considerably longer records from various proxy data sources (e.g., Isdale *et al.*, 1998; Cleaveland, 2000). Such research is extremely valuable because it helps in interpretation of observed hydrological changes over time (particularly attribution of change to global warming), provides a context for assessment of future change, and opens up possibilities for seasonal flow prediction (e.g., Piechota *et al.*, 1998) hence more efficient adaptation to climatic variability. It also emphasizes that the hydrological “baseline” cannot be assumed to be constant, even in the absence of climate change.

4.2.4. Adaptation to Climate Change in the Water Sector

Water management is based on minimization of risk and adaptation to changing circumstances (usually taking the form

of altered demands). A wide range of adaptation techniques has been developed and applied in the water sector over decades. One widely used classification distinguishes between increasing capacity (e.g., building reservoirs or structural flood defenses), changing operating rules for existing structures and systems, managing demand, and changing institutional practices. The first two often are termed “supply-side” strategies, whereas the latter two are “demand-side.” Over the past few years, there has been a considerable increase in interest in demand-side techniques. International agencies such as the World Bank (World Bank, 1993) and initiatives such as the Global Water Partnership are promoting new ways of managing and pricing water resources to manage resources more effectively (Kindler, 2000).

This work is going on largely independently of climate change, but changes in water management practices will have a very significant impact on how climate change affects the water sector. Water managers in some countries are beginning to consider climate change explicitly, although the methodologies for doing so are not yet well defined and vary between and within countries depending on the institutional arrangements for long-term water resources planning. In the UK, for example, water supply companies were required by regulators in 1997 to “consider” climate change in estimating their future resource, hence investment, projections (Subak, 2000). In the United States, the American Water Works Association urged water agencies to explore the vulnerability of their systems to plausible climate changes (AWWA, 1997).

Clearly, however, the ability of water management agencies to alter management practices in general or to incorporate climate change varies considerably between countries. This issue is discussed further in Section 4.6.

4.3. Effects on the Hydrological Cycle

4.3.1. Introduction

This section summarizes the potential effects of climate change on the components of the water balance and their variability over time.

4.3.2. Precipitation

Precipitation is the main driver of variability in the water balance over space and time, and changes in precipitation have very important implications for hydrology and water resources. Hydrological variability over time in a catchment is influenced by variations in precipitation over daily, seasonal, annual, and decadal time scales. Flood frequency is affected by changes in the year-to-year variability in precipitation and by changes in short-term rainfall properties (such as storm rainfall intensity). The frequency of low or drought flows is affected primarily by changes in the seasonal distribution of

precipitation, year-to-year variability, and the occurrence of prolonged droughts.

TAR WGI Section 2.5 summarizes studies into trends in precipitation. There are different trends in different parts of the world, with a general increase in Northern Hemisphere mid- and high latitudes (particularly in autumn and winter) and a decrease in the tropics and subtropics in both hemispheres. There is evidence that the frequency of extreme rainfall has increased in the United States (Karl and Knight, 1998) and in the UK (Osborn *et al.*, 2000); in both countries, a greater proportion of precipitation is falling in large events than in earlier decades.

Current climate models simulate a climate change-induced increase in annual precipitation in high and mid-latitudes and most equatorial regions but a general decrease in the subtropics (Carter and Hulme, 1999), although across large parts of the world the changes associated with global warming are small compared to those resulting from natural multi-decadal variability, even by the 2080s. Changes in seasonal precipitation are even more spatially variable and depend on changes in the climatology of a region. In general, the largest percentage precipitation changes *over land* are found in high latitudes, some equatorial regions, and southeast Asia, although there are large differences between climate models.

Until recently, very few projections of possible changes in year-to-year variability as simulated by climate models have been published, reflecting both the (until recently) short model runs available and the recognition that climate models do not necessarily reproduce observed patterns of climatic variability. Recent developments, however, include the increasing ability of some global climate models to reproduce features such as El Niño (e.g., Meehl and Washington, 1996) and open up the possibility that it may be feasible to estimate changes in year-to-year variability. Recent scenarios for the UK, derived from HadCM2 experiments, indicate an increase in the relative variability of seasonal and annual rainfall totals resulting from global warming (Hulme and Jenkins, 1998).

Potential changes in intense rainfall frequency are difficult to infer from global climate models, largely because of coarse spatial resolution. However, there are indications (e.g., Hennessy *et al.*, 1997; McGuffie *et al.*, 1999) that the frequency of heavy rainfall events generally is likely to increase with global warming. Confidence in this assertion depends on the confidence with which global climate models are held. More generally, uncertainty in GCM projections of precipitation largely determines the uncertainty in estimated impacts on hydrological systems and water resources.

Increasing temperatures mean that a smaller proportion of precipitation may fall as snow. In areas where snowfall currently is marginal, snow may cease to occur—with consequent, very significant, implications (discussed below) for hydrological regimes. This projection is considerably less uncertain than possible changes in the magnitude of precipitation.

4.3.3. Evaporation

Evaporation from the land surface includes evaporation from open water, soil, shallow groundwater, and water stored on vegetation, along with transpiration through plants. The rate of evaporation from the land surface is driven essentially by meteorological controls, mediated by the characteristics of vegetation and soils, and constrained by the amount of water available. Climate change has the potential to affect all of these factors—in a combined way that is not yet clearly understood—with different components of evaporation affected differently.

The primary meteorological controls on evaporation from a well-watered surface (often known as potential evaporation) are the amount of energy available (characterized by net radiation), the moisture content of the air (humidity—a function of water vapor content and air temperature), and the rate of movement of air across the surface (a function of windspeed). Increasing temperature generally results in an increase in potential evaporation, largely because the water-holding capacity of air is increased. Changes in other meteorological controls may exaggerate or offset the rise in temperature, and it is possible that increased water vapor content and lower net radiation could lead to lower evaporative demands. The relative importance of different meteorological controls, however, varies geographically. In dry regions, for example, potential evaporation is driven by energy and is not constrained by atmospheric moisture contents, so changes in humidity are relatively unimportant. In humid regions, however, atmospheric moisture content is a major limitation to evaporation, so changes in humidity have a very large effect on the rate of evaporation.

Several studies have assessed the effect of changes in meteorological controls on evaporation (e.g., Chattopadhyay and Hulme, 1997), using models of the evaporation process, and the effect of climate change has been shown to depend on baseline climate (and the relative importance of the different controls) and the amount of change. Chattopadhyay and Hulme (1997) calculated increases in potential evaporation across India from GCM simulations of climate; they found that projected increases in potential evaporation were related largely to increases in the vapor pressure deficit resulting from higher temperature. It is important to emphasize, however, that different evaporation calculation equations give different estimates of absolute evaporation rates and sensitivity to change. Therefore, it can be very difficult to compare results from different studies. Equations that do not consider explicitly *all* meteorological controls may give very misleading estimates of change.

Vegetation cover, type, and properties play a very important role in evaporation. Interception of precipitation is very much influenced by vegetation type (as indexed by the canopy storage capacity), and different vegetation types have different rates of transpiration. Moreover, different vegetation types produce different amounts of turbulence above the canopy; the greater the turbulence, the greater the evaporation. A change in catchment vegetation—directly or indirectly as a result of climate change—therefore may affect the catchment water balance

(there is a huge hydrological literature on the effects of changing catchment vegetation). Several studies have assessed changes in biome type under climate change (e.g., Friend *et al.*, 1997), but the hydrological effects of such changes—and, indeed, changes in agricultural land use—have not yet been explored.

Although transpiration from plants through their stomata is driven by energy, atmospheric moisture, and turbulence, plants exert a degree of control over transpiration, particularly when water is limiting. Stomatal conductance in many plants falls as the vapor pressure deficit close to the leaf increases, temperature rises, or less water becomes available to the roots—and transpiration therefore falls. Superimposed on this short-term variation in stomatal conductance is the effect of atmospheric carbon dioxide (CO_2) concentrations. Increased CO_2 concentrations reduce stomatal conductance in C_3 plants (which include virtually all woody plants and temperate grasses and crops), although experimental studies show that the effects vary considerably between species and depend on nutrient and water status. Plant water-use efficiency (WUE, or water use per unit of biomass) therefore may increase substantially (Morison, 1987), implying a reduction in transpiration. However, higher CO_2 concentrations also may be associated with increased plant growth, compensating for increased WUE, and plants also may acclimatize to higher CO_2 concentrations. There have been considerably fewer studies into total plant water use than into stomatal conductance, and most empirical evidence to date is at the plant scale; it is difficult to generalize to the catchment or regional scale (Field *et al.*, 1995; Gifford *et al.*, 1996; Amthor, 1999). Free-air CO_2 enrichment (FACE) experiments, however, have allowed extrapolation at least to the 20-m plot scale. Experiments with cotton, for example (Hunsaker *et al.*, 1994), showed no detectable change in water use per unit land area when CO_2 concentrations were increased to 550 ppmv; the 40% increase in biomass offset increased WUE. Experiments with wheat, however, indicated that increased growth did not offset increased WUE, and evaporation declined by approximately 7% (although still less than implied by the change in stomatal conductance; Kimball *et al.*, 1999). Some model studies (e.g., Field *et al.*, 1995, for forest; Bunce *et al.*, 1997, for alfalfa and grass; Cao and Woodward, 1998, at the global scale) suggest that the net direct effect of increased CO_2 concentrations at the catchment scale will be small (Korner, 1996), but others (e.g., Pollard and Thompson, 1995; Dickinson *et al.*, 1997; Sellers *et al.*, 1997; Raupach, 1998, as discussed by Kimball *et al.*, 1999) indicate that stomata have more control on regional evaporation. There clearly is a large degree of uncertainty over the effects of CO_2 enrichment on catchment-scale evaporation, but it is apparent that reductions in stomatal conductance do not necessarily translate into reductions in catchment-scale evaporation.

The *actual* rate of evaporation is constrained by water availability. A reduction in summer soil water, for example, could lead to a reduction in the rate of evaporation from a catchment despite an increase in evaporative demands. Arnell (1996) estimated for a sample of UK catchments that the rate of actual evaporation would increase by a smaller percentage than the atmospheric demand for evaporation, with the greatest

difference in the “driest” catchments, where water limitations are greatest.

4.3.4. Soil Moisture

The amount of water stored in the soil is fundamentally important to agriculture and is an influence on the rate of actual evaporation, groundwater recharge, and generation of runoff. Soil moisture contents are directly simulated by global climate models, albeit over a very coarse spatial resolution, and outputs from these models give an indication of possible directions of change. Gregory *et al.* (1997), for example, show with the HadCM2 climate model that a rise in greenhouse gas (GHG) concentrations is associated with reduced soil moisture in Northern Hemisphere mid-latitude summers. This was the result of higher winter and spring evaporation, caused by higher temperatures and reduced snow cover, and lower rainfall inputs during summer.

The local effects of climate change on soil moisture, however, will vary not only with the degree of climate change but also with soil characteristics. The water-holding capacity of soil will affect possible changes in soil moisture deficits; the lower the capacity, the greater the sensitivity to climate change. Climate change also may affect soil characteristics, perhaps through changes in waterlogging or cracking, which in turn may affect soil moisture storage properties. Infiltration capacity and water-holding capacity of many soils are influenced by the frequency and intensity of freezing. Boix-Fayos *et al.* (1998), for example, show that infiltration and water-holding capacity of soils on limestone are greater with increased frost activity and infer that increased temperatures could lead to increased surface or shallow runoff. Komescu *et al.* (1998) assess the implications of climate change for soil moisture availability in southeast Turkey, finding substantial reductions in availability during summer.

4.3.5. Groundwater Recharge and Resources

Groundwater is the major source of water across much of the world, particularly in rural areas in arid and semi-arid regions, but there has been very little research on the potential effects of climate change. This section therefore can be regarded as presenting a series of hypotheses.

Aquifers generally are replenished by effective rainfall, rivers, and lakes. This water may reach the aquifer rapidly, through macro-pores or fissures, or more slowly by infiltrating through soils and permeable rocks overlying the aquifer. A change in the amount of effective rainfall will alter recharge, but so will a change in the duration of the recharge season. Increased winter rainfall—as projected under most scenarios for mid-latitudes—generally is likely to result in increased groundwater recharge. However, higher evaporation may mean that soil deficits persist for longer and commence earlier, offsetting an increase in total effective rainfall. Various types of aquifer will be recharged differently. The main types are unconfined and

confined aquifers. An unconfined aquifer is recharged directly by local rainfall, rivers, and lakes, and the rate of recharge will be influenced by the permeability of overlying rocks and soils. Some examples of the effect of climate change on recharge into unconfined aquifers have been described in France, Kenya, Tanzania, Texas, New York, and Caribbean islands. Bouraoui *et al.* (1999) simulated substantial reductions in groundwater recharge near Grenoble, France, almost entirely as a result of increases in evaporation during the recharge season. Macro-pore and fissure recharge is most common in porous and aggregated forest soils and less common in poorly structured soils. It also occurs where the underlying geology is highly fractured or is characterized by numerous sinkholes. Such recharge can be very important in some semi-arid areas (e.g., the Wajir region of Kenya; Mailu, 1993). In principle, “rapid” recharge can occur whenever it rains, so where recharge is dominated by this process it will be affected more by changes in rainfall amount than by the seasonal cycle of soil moisture variability. Sandstrom (1995) modeled recharge to an aquifer in central Tanzania and showed that a 15% reduction in rainfall—with no change in temperature—resulted in a 40–50% reduction in recharge; he infers that small changes in rainfall could lead to large changes in recharge and hence groundwater resources. Loaiciga *et al.* (1998) explored the effect of a range of climate change scenarios on groundwater levels in the Edwards Balcones Fault Zone aquifer in Texas, a heavily exploited aquifer largely fed by streamflow seepage. They show that, under six of the seven GCM-based scenarios used, groundwater levels and springflows would reduce substantially as a result of lower streamflow. However, they use 2xCO₂ scenarios that represent changes in temperature that are considerably greater than those projected even by the 2080s under current scenarios (Carter and Hulme, 1999), so the study considerably overstates the effect of climate change in the next few decades.

Shallow unconfined aquifers along floodplains, which are most common in semi-arid and arid environments, are recharged by seasonal streamflows and can be depleted directly by evaporation. Changes in recharge therefore will be determined by changes in the duration of flow of these streams—which may locally increase or decrease—and the permeability of the overlying beds, but increased evaporative demands would tend to lead to lower groundwater storage. In semi-arid areas of Kenya, flood aquifers have been improved by construction of subsurface weirs across the river valleys, forming subsurface dams from which water is tapped by shallow wells. The thick layer of sands substantially reduces the impact of evaporation. The wells have become perennial water supply sources even during the prolonged droughts (Mailu, 1988, 1992).

Sea-level rise will cause saline intrusion into coastal aquifers, with the amount of intrusion depending on local groundwater gradients. Shallow coastal aquifers are at greatest risk (on Long Island, New York, for example). Groundwater in low-lying islands therefore is very sensitive to change. In the atolls of the Pacific Ocean, water supply is sensitive to precipitation patterns and changes in storm tracks (Salinger *et al.*, 1995). A reduction

in precipitation coupled with sea-level rise would not only cause a diminution of the harvestable volume of water; it also would reduce the size of the narrow freshwater lense (Amadore *et al.*, 1996). For many small island states, such as some Caribbean islands, seawater intrusion into freshwater aquifers has been observed as a result of overpumping of aquifers. Any sea-level rise would worsen the situation.

It will be noted from the foregoing that unconfined aquifers are sensitive to local climate change, abstraction, and seawater intrusion. However, quantification of recharge is complicated by the characteristics of the aquifers themselves as well as overlying rocks and soils.

A confined aquifer, on the other hand, is characterized by an overlying bed that is impermeable, and local rainfall does not influence the aquifer. It is normally recharged from lakes, rivers, and rainfall that may occur at distances ranging from a few kilometers to thousands of kilometers. Recharge rates also vary from a few days to decades. The Bahariya Oasis and other groundwater aquifers in the Egyptian Desert, for example, are recharged at the Nubian Sandstone outcrops in Sudan; such aquifers may not be seriously affected by seasonal or interannual rainfall or temperature of the local area.

Attempts have been made to calculate the rate of recharge by using carbon-14 isotopes and other modeling techniques. This has been possible for aquifers that are recharged from short distances and after short durations. However, recharge that takes place from long distances and after decades or centuries has been problematic to calculate with accuracy, making estimation of the impacts of climate change difficult. The medium through which recharge takes place often is poorly known and very heterogeneous, again challenging recharge modeling. In general, there is a need to intensify research on modeling techniques, aquifer characteristics, recharge rates, and seawater intrusion, as well as monitoring of groundwater abstractions. This research will provide a sound basis for assessment of the impacts of climate change and sea-level rise on recharge and groundwater resources.

4.3.6. River Flows

By far the greatest number of hydrological studies into the effects of climate change have concentrated on potential changes on streamflow and runoff. The distinction between "streamflow" and "runoff" can be vague, but in general terms streamflow is water within a river channel, usually expressed as a rate of flow past a point—typically in $m^3 s^{-1}$ —whereas runoff is the amount of precipitation that does not evaporate, usually expressed as an equivalent depth of water across the area of the catchment. A simple link between the two is that runoff can be regarded as streamflow divided by catchment area, although in dry areas this does not necessarily hold because runoff generated in one part of the catchment may infiltrate before reaching a channel and becoming streamflow. Over short durations, the amount of water leaving a catchment

outlet usually is expressed as streamflow; over durations of a month or more, it usually is expressed as runoff. In some countries, "runoff" implies surface runoff only (or, more precisely, rapid response to an input of precipitation) and does not include the contribution of discharge from groundwater to flow, but this is a narrow definition of the term.

This section first considers recent trends in streamflow/runoff and then summarizes research into the potential effects of future climate change.

4.3.6.1. Trends in Observed Streamflow

Since the SAR, there have been many notable hydrological events—including floods and droughts—and therefore many studies into possible trends in hydrological data. Table 4-1 summarizes some of these studies and their main results.

In general, the patterns found are consistent with those identified for precipitation: Runoff tends to increase where precipitation has increased and decrease where it has fallen over the past few years. Flows have increased in recent years in many parts of the United States, for example, with the greatest increases in low flows (Lins and Slack, 1999). Variations in flow from year to year have been found to be much more strongly related to precipitation changes than to temperature changes (e.g., Krasovskia, 1995; Risbey and Entekhabi, 1996). There are some more subtle patterns, however. In large parts of eastern Europe, European Russia, central Canada (Westmacott and Burn, 1997), and California (Dettinger and Cayan, 1995), a major—and unprecedented—shift in streamflow from spring to winter has been associated not only with a change in precipitation totals but more particularly with a rise in temperature: Precipitation has fallen as rain, rather than snow, and therefore has reached rivers more rapidly than before. In cold regions, such as northern Siberia and northern Canada, a recent increase in temperature has had little effect on flow timing because precipitation continues to fall as snow (Shiklomanov, 1994; Shiklomanov *et al.*, 2000).

However, it is very difficult to identify trends in hydrological data, for several reasons. Records tend to be short, and many data sets come from catchments with a long history of human intervention. Variability over time in hydrological behavior is very high, particularly in drier environments, and detection of any signal is difficult. Variability arising from low-frequency climatic rhythms is increasingly recognized (Section 4.2), and researchers looking for trends need to correct for these patterns. Finally, land-use and other changes are continuing in many catchments, with effects that may outweigh any climatic trends. Changnon and Demissie (1996), for example, show that human-induced changes mask the effects of climatic variability in a sample of midwest U.S. catchments. Even if a trend is identified, it may be difficult to attribute it to global warming because of other changes that are continuing in a catchment. A widespread lack of data, particularly from many developing

Table 4-1: Recent studies into trends in river flows.

Study Area	Data Set	Key Conclusions	Reference(s)
<i>Global</i>	– 161 gauges in 108 major world rivers, data to 1990	– Reducing trend in Sahel region but weak increasing trend in western Europe and North America; increasing relative variability from year to year in several arid and semi-arid regions	– Yoshino (1999)
<i>Russia</i>			
– European Russia and western Siberia	– 80 major basins, records from 60 to 110 years	– Increase in winter, summer, and autumn runoff since mid-1970s; decrease in spring flows	– Georgiyevsky <i>et al.</i> (1995, 1996, 1997); Shiklomanov and Georgiyevsky (2001)
– European former Soviet Union	– 196 small basins, records up to 60 years	– Increase in winter, summer, and autumn runoff since mid-1970s; decrease in spring flows	– Georgiyevsky <i>et al.</i> (1996)
<i>Baltic Region</i>			
– Scandinavia		– Increase in winter, summer and autumn runoff since mid-1970s; decrease in spring flows	– Bergstrom and Carlsson (1993)
– Baltic states		– Increase in winter, summer and autumn runoff since mid-1970s; decrease in spring flows	– Tarend (1998)
<i>Cold Regions</i>			
– Yenesei, Siberia	– Major river basin	– Little change in runoff or timing	– Shiklomanov (1994)
– Mackenzie, Canada	– Major river basin	– Little change in runoff or timing	– Shiklomanov <i>et al.</i> (2000)
<i>North America</i>			
– United States	– 206 catchments	– 26 catchments with significant trends: half increasing and half decreasing	– Lins and Slack (1999)
– California	– Major river basins	– Increasing concentration of streamflow in winter as a result of reduction in snow	– Dettinger and Cayan (1995); Gleick and Chalecki (1999)
– Mississippi basin	– Flood flows in major basins	– Large and significant increases in flood magnitudes at many gauges	– Olsen <i>et al.</i> (1999)
– West-central Canada	– Churchill-Nelson river basin	– Snowmelt peaks earlier; decreasing runoff in south of region, increase in north	– Westmacott and Burn (1997)
<i>South America</i>			
– Colombia	– Major river basins	– Decrease since 1970s	– Marengo (1995)
– Northwest Amazon	– Major river basins	– Increase since 1970s	– Marengo <i>et al.</i> (1998)
– SE South America	– Major river basins	– Increase since 1960s	– Genta <i>et al.</i> (1998)
– Andes	– Major river basins	– Increase north of 40°S, decrease to the south	– Waylen <i>et al.</i> (2000)
<i>Europe</i>			
– UK	– Flood flows in many basins	– No clear statistical trend	– Robson <i>et al.</i> (1998)
<i>Africa</i>			
– Sahelian region	– Major river basins	– Decrease since 1970s	– Sircoulon (1990)
<i>Asia</i>			
– Xinjiang region, China	– Major river basins	– Spring runoff increase since 1980 from glacier melt	– Ye <i>et al.</i> (1999)
<i>Australasia</i>			
– Australia	– Major basins	– Decrease since mid-1970s	– Thomas and Bates (1997)

countries, and consistent data analysis makes it impossible to obtain a representative picture of recent patterns and trends in hydrological behavior. Monitoring stations are continuing to be closed in many countries. Reconstructions of long records, stretching back centuries, are needed to understand the characteristics of natural decadal-scale variability in streamflow.

4.3.6.2. Effects of Climate Change on River Flows

By far the majority of studies into the effects of climate change on river flows have used GCMs to define changes in climate that

are applied to observed climate input data to create perturbed data series. These perturbed data are then fed through a hydrological model and the resulting changes in river flows assessed. Since the SAR, there have been several global-scale assessments and a large number of catchment-scale studies. Confidence in these results is largely a function of confidence in climate change scenarios *at the catchment scale*, although Boorman and Sefton (1997) show that the use of a physically unrealistic hydrological model could lead to misleading results.

Arnell (1999b) used a macro-scale hydrological model to simulate streamflow across the world at a spatial resolution of $0.5^\circ \times 0.5^\circ$,

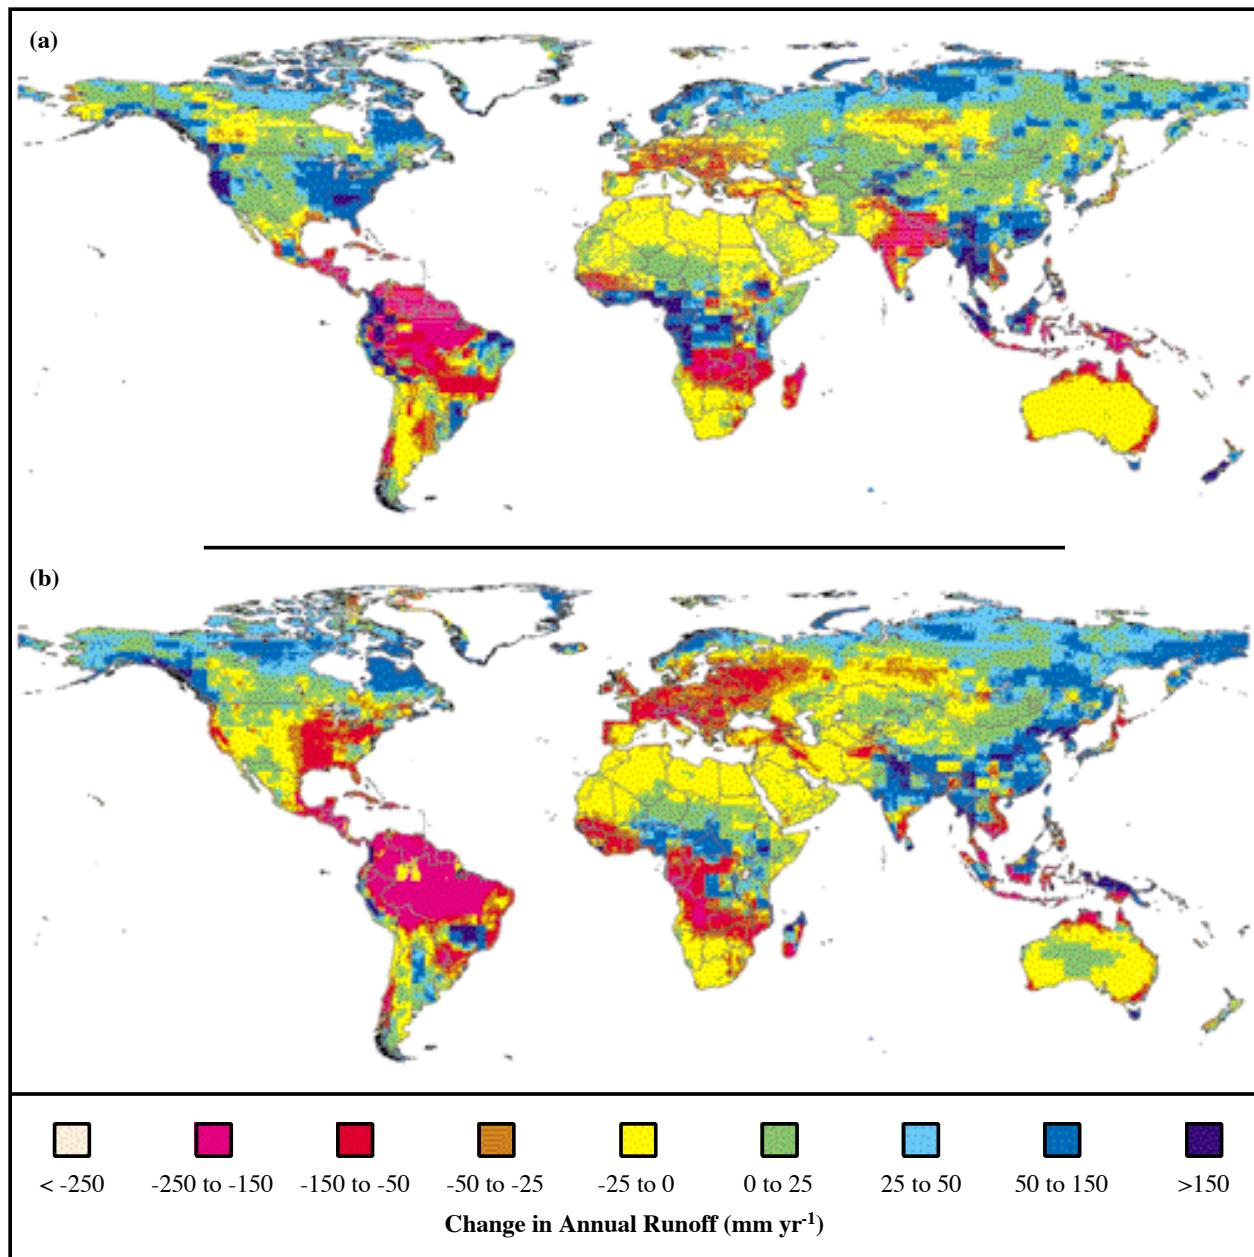

Figure 4-1: Change in average annual runoff by 2050 under HadCM2 ensemble mean (a) and HadCM3 (b) (Arnell, 1999b).

under the 1961–1990 baseline climate and under several scenarios derived from HadCM2 and HadCM3 experiments. Figure 4-1 shows the absolute change in annual runoff by the 2050s under the HadCM2 and HadCM3 scenarios: Both have an increase in effective CO₂ concentrations of 1% yr⁻¹. The patterns of change are broadly similar to the change in annual precipitation—increases in high latitudes and many equatorial regions but decreases in mid-latitudes and some subtropical regions—but the general increase in evaporation means that some areas that see an increase in precipitation will experience a reduction in runoff. Alcamo *et al.* (1997) also simulated the effects of different climate change scenarios on global river flows, showing broadly similar patterns to those in Figure 4-1.

Rather than assess each individual study, this section simply tabulates catchment-scale studies published since the SAR and draws some general conclusions. As in the SAR, the use of different scenarios hinders quantitative spatial comparisons. Table 4-2 summarizes the studies published since the SAR, by continent. All of the studies used a hydrological model to estimate the effects of climate scenarios, and all used scenarios based on GCM output. The table does not include sensitivity studies (showing the effects of, for example, increasing precipitation by 10%) or explore the hydrological implications of past climates. Although such studies provide extremely valuable insights into the sensitivity of hydrological systems to changes in climate, they are not assessments of the potential effects of future global warming.

It is clear from Table 4-2 that there are clear spatial variations in the numbers and types of studies undertaken to date; relatively few studies have been published in Africa, Latin America, and southeast Asia. A general conclusion, consistent across many studies, is that the effects of a given climate change scenario vary with catchment physical and land-cover properties and that small headwater streams may be particularly sensitive to change—as shown in northwestern Ontario, for example, by Schindler *et al.* (1996).

4.3.6.2.1. Cold and cool temperate climates

These areas are characterized by precipitation during winter falling as snow and include mountainous and low-lying regions. A major proportion of annual streamflow is formed by snow melting in spring. These areas include large parts of North America, northern and eastern Europe, most of Russia, northern China, and much of central Asia. The most important climate change effect in these regions is a change in the timing of streamflow through the year. A smaller proportion of precipitation during winter falls as snow, so there is proportionately more runoff in winter and, as there is less snow to melt, less runoff during spring. Increased temperatures, in effect, reduce the size of the natural reservoir storing water during winter. In very cold climates (such as in Siberia and northern Russia), there is little change in the timing of streamflow because winter precipitation continues to fall as snow with higher temperatures.

The largest effects are in the most “marginal” snow-dominated regime areas.

The effects of climate change on the magnitude of annual runoff and flows through the year are much less consistent than the effect on streamflow timing because they depend not on the temperature increase but on the change in precipitation. In general, precipitation increases in high-latitude areas under most scenarios, but in lower latitudes precipitation may decrease. Kazcmarek *et al.* (1997), for example, show a decrease in annual runoff in Poland under a Geophysical Fluid Dynamics Laboratory (GFDL)-based scenario (by around 20% by the 2050s) but an increase under a Goddard Institute for Space Studies (GISS) scenario (by as much as 20%); in both cases, the season of maximum flow shifts from spring to winter.

Similar patterns are found for rivers in mountainous regions or draining from mountains. The Rhine and Danube, for example, would both see a reduction in spring flows and an increase in winter runoff (Grabs, 1997; Starosolszky and Gauzer, 1998), as would rivers draining east and west from the Rocky Mountains in North America.

4.3.6.2.2. Mild temperate climates

Hydrological regimes in these regions are dominated by the seasonal cycles of rainfall and evaporation; snowfall and snowmelt are not important. Here, climate change tends to affect

the magnitude of flows in different seasons—by an amount that depends on the change in rainfall—and may lead to an exaggerated seasonal cycle, but it generally does not affect the timing of flows through the year. In the UK, for example, most scenarios result in an increase in winter runoff and, particularly in the south, a decrease in summer runoff (Arnell and Reynard, 1996); similar patterns are found across most of western Europe under most scenarios (Arnell, 1999a). Low flows tend to occur during summer, and changes in low-flow frequency are closely related to changes in the balance between summer rainfall and summer evaporation. Across most mid-latitude temperate regions, summer rainfall would decline with global warming, leading to a reduction in low flows.

The detailed effect of a given change in climate, however, depends to a large extent on the geological characteristics of the catchment. Studies in the UK (Arnell and Reynard, 1996) and Belgium (Gellens and Roulin, 1998) have indicated that in catchments with considerable groundwater, changes in summer flows are largely a function of the change not in summer rainfall but in rainfall during the winter recharge season.

4.3.6.2.3. Arid and semi-arid regions

River flows in arid and semi-arid regions are very sensitive to changes in rainfall: A given percentage change in rainfall can produce a considerably larger percentage change in runoff. There have been relatively few studies in such regions since the SAR, but work has been done in southern Africa (Schulze, 1997), Australia (Bates *et al.*, 1996), northern China (Ying and Huang, 1996), and southern Russia (Georgiyevsky *et al.*, 1996; Shiklomanov, 1998).

4.3.6.2.4. Humid tropical regions

Runoff regimes in these regions are very much influenced by the timing and duration of the rainy season or seasons. Climate change therefore may affect river flows not only through a change in the magnitude of rainfall but also through possible changes in the onset or duration of rainy seasons (such as those caused by monsoon).

4.3.7. Lakes

Lakes are particularly vulnerable to changes in climate parameters. Variations in air temperature, precipitation, and other meteorological components directly cause changes in evaporation, water balance, lake level, ice events, hydrochemical and hydrobiological regimes, and the entire lake ecosystem. Under some climatic conditions, lakes may disappear entirely. There are many different types of lakes, classified according to lake formation and origin, the amount of water exchange, hydrochemistry, and so forth.

An important distinction is drawn between closed (endorheic) lakes, with no outflow, and exorheic lakes, which are drained

by outflowing rivers. Endorheic lakes are very dependent on the balance of inflows and evaporation and are very sensitive to change in either (whether driven by climate change, climatic variability, or human interventions). This also means that they are very important indicators of climate change and can provide records of past hydroclimatic variability over a large area (e.g., Kilkus, 1998; Obolkin and Potemkin, 1998). Small endorheic lakes are most vulnerable to a change in climate; there are indications that even relatively small changes in inputs can produce large fluctuations in water level (and salinity) in small closed lakes in western North America (Laird *et al.*, 1996).

The largest endorheic lakes in the world are the Caspian and Aral Seas, Lake Balkash, Lake Chad, Lake Titicaca, and the Great Salt Lake. Some of the largest east African lakes, including Lakes Tanganyika and Malawi, also can be regarded as practically endorheic. Changes in inflows to such lakes can have very substantial effects: The Aral Sea, for example, has been significantly reduced by increased abstractions of irrigation water upstream, the Great Salt Lake in the United States has increased in size in recent years as a result of increased precipitation in its catchment, and Qinghai Lake in China has shrunk following a fall in catchment precipitation. Many endorheic lake systems include significant internal thresholds, beyond which change may be very different. Lake Balkash, for example, currently consists of a saline part and a fresh part, connected by a narrow strait. Several rivers discharge into the fresh part, preventing salinization of the entire lake. A reduction in freshwater inflows, however, would change the lake regime and possibly lead to salinization of the freshwater part; this would effectively destroy the major source of water for a large area.

Exorheic lakes also may be sensitive to changes in the amount of inflow and the volume of evaporation. Evidence from Lake Victoria (east Africa), for example, indicates that lake levels may be increased for several years following a short-duration increase in precipitation and inflows. There also may be significant thresholds involving rapid shifts from open to closed lake conditions. Progressive southward expansion of Lake Winnipeg under postglacial isostatic tilting was suppressed by a warm dry climate in the mid-Holocene, when the north basin of the lake became closed (endorheic) and the south

basin was dry (Lewis *et al.*, 1998). A trend of progressively moister climates within the past 5,000 years caused a return from closed to open (overflowing) lake conditions in the north basin and rapid flooding of the south basin about 1,000 years later. Other examples include Lake Manitoba, which was dry during the warm mid-Holocene (Teller and Last, 1982). Computations of sustainable lake area under equilibrium water balance (after Bengtsson and Malm, 1997) indicate that a return to dry conditions comparable to the mid-Holocene climate could cause this 24,400-km² lake draining a vast area from the Rocky Mountains east almost to Lake Superior to become endorheic again (Lewis *et al.*, 1998).

Climate change also is likely to have an effect on lake water quality, through changes in water temperature and the extent and duration of ice cover. These effects are considered in Section 4.3.10.

4.3.8. Changes in Flood Frequency

Although a change in flood risk is frequently cited as one of the potential effects of climate change, relatively few studies since the early 1990s (e.g., Nash and Gleick, 1993; Jeton *et al.*, 1996) have looked explicitly at possible changes in high flows. This largely reflects difficulties in defining credible scenarios for change in the large rainfall (or snowmelt) events that trigger flooding. Global climate models currently cannot simulate with accuracy short-duration, high-intensity, localized heavy rainfall, and a change in mean monthly rainfall may not be representative of a change in short-duration rainfall.

A few studies, however, have tried to estimate possible changes in flood frequencies, largely by assuming that changes in monthly rainfall also apply to “flood-producing” rainfall. In addition, some have looked at the possible additional effects of changes in rainfall intensity. Reynard *et al.* (1998), for example, estimated the change in the magnitude of different return period floods in the Thames and Severn catchments, assuming first that all rainfall amounts change by the same proportion and then that only “heavy” rainfall increases. Table 4-3 summarizes the changes in flood magnitudes in the Thames and Severn by

Table 4-3: Percentage change in magnitude of peak floods in Severn and Thames catchments by the 2050s (Reynard *et al.*, 1998).

Catchment	Return Period				
	2-Year	5-Year	10-Year	20-Year	50-Year
Thames					
– GGx-x ^a	10	12	13	14	15
– GGx-s ^b	12	13	14	15	16
Severn					
– GGx-x ^a	13	15	16	17	20
– GGx-s ^b	15	17	18	19	21

^a GGx-x = HadCM2 ensemble mean scenario with proportional change in rainfall.

^b GGx-s = HadCM2 ensemble mean scenario with change in storm rainfall only.

the 2050s: Flood risk increases because winter rainfall increases, and in these relatively large catchments it is the total volume of rainfall over several days, not the peak intensity of rainfall, that is important. Schreider *et al.* (1996) in Australia assessed change in flood risk by assuming that all rainfall amounts change by the same proportion. They found an increase in flood magnitudes under their wettest scenarios—even though annual runoff totals did not increase—but a decline in flood frequency under their driest scenarios.

Panagoulia and Dimou (1997) examined possible changes in flood frequency in the Acheloos basin in central Greece. Floods in this catchment derive from snowmelt, and an increase in winter precipitation—as indicated under the scenarios used—results in more frequent flood events of longer duration. The frequency and duration of small floods was most affected. Saethun *et al.* (1998) explored the effect of fixed increases in temperature and precipitation in 25 catchments in the Nordic region. They show that higher temperatures and higher precipitation increases flood magnitudes in parts of the region where floods tended to be generated from heavy rainfall in autumn but decrease flood magnitudes where floods are generated by spring snowmelt. In some cases, the peak flood season shifts from spring to autumn. This conclusion also is likely to apply in other environments where snow and rain floods both occur.

Mirza *et al.* (1998) investigated the effects of changes in precipitation resulting from global warming on future flooding in Bangladesh. Standardized precipitation change scenarios from four GCMs were used for the analysis. The most extreme scenario showed that for a 2°C rise in global mean temperature, the average flood discharge for the Ganges, Brahmaputra, and Meghna could be as much as 15, 6, and 19% higher, respectively.

4.3.9. Changes in Hydrological Drought Frequency

Droughts are considerably more difficult to define in quantitative terms than floods. Droughts may be expressed in terms of rainfall deficits, soil moisture deficits, lack of flow in a river, low groundwater levels, or low reservoir levels; different definitions are used in different sectors. A “hydrological” drought occurs when river or groundwater levels are low, and a “water resources” drought occurs when low river, groundwater, or reservoir levels impact water use. Low river flows in summer may not necessarily create a water resources drought, for example, if reservoirs are full after winter; conversely, a short-lived summer flood may not end a water resources drought caused by a prolonged lack of reservoir inflows. Water resources droughts therefore depend not only on the climatic and hydrological inputs but critically on the characteristics of the water resource system and how droughts are managed. This section focuses on hydrological drought, particularly on low river flows. Different studies have used different indices of low river flows, including the magnitude of minimum flows, the frequency at which flows fall below some threshold, the duration of flow below a threshold, and the cumulative difference between actual flows and some defined threshold.

At the global scale, Arnell (1999b) explored the change in the minimum annual total runoff with a return period of 10 years under several scenarios, based on HadCM2 and HadCM3 GCMs. He shows that the pattern of this measure of “low flow” (which is relatively crude) changes in a similar way to average annual runoff (as shown in Figure 4-1) but that the percentage changes tend to be larger. Arnell (1999a) mapped a different index of low flow across Europe—the average summed difference between streamflow and the flow exceeded 95% of the time, while flows are below this threshold—under four scenarios. The results suggest a reduction in the magnitude of low flows under most scenarios across much of western Europe, as a result of lower flows during summer, but an amelioration of low flows in the east because of increased winter flows. In these regions, however, the season of lowest flows tends to shift from the current winter low-flow season toward summer.

Döll *et al.* (1999) also modeled global runoff at a spatial resolution of 0.5°x0.5°, not only for average climatic conditions but also for typical dry years. The annual runoff exceeded in 9 years out of 10 (the 10-year return period “drought” runoff) was derived for each of more than 1,000 river basins covering the whole globe. Then the impact of climate change on these runoff values was computed by scaling observed temperature and precipitation in the 1-in-10 dry years with climate scenarios of two different GCMs (Chapter 3), ECHAM4/OPYC3 and GFDL-R15. Climate variability was assumed to remain constant. For the same GHG emission scenario, IS92a, the two GCMs compute quite different temperature and more so precipitation changes. With the GFDL scenario, runoff in 2025 and 2075 is simulated to be higher in most river basins than with the ECHAM scenario. The 1-in-10 dry year runoff is computed to decrease between the present time (1961–1990 climate) and 2075 by more than 10% on 19% (ECHAM) or 13% (GFDL) of the global land area (Table 4-4) and to increase by more than 50% on 22% (ECHAM) or 49% (GFDL) of the global land area. These results underline the high sensitivity of computed future runoff changes to GCM calculations.

Table 4-4: Computed change of 1-in-10 dry year runoff under emission scenario IS92a between the present time (1961–90) and 2075: Influence of climate scenarios computed by two GCMs (Döll *et al.*, 1999).

Change in Runoff between Present and 2075 (%, decrease negative)	Fraction of Global Land Area, where Runoff will have Changed (%), using Climate Scenarios of MPI GFDL	
	MPI	GFDL
Increase by more than 200%	8.4	14.4
+50 to +200	13.4	34.9
+10 to + 50	39.5	24.0
-10 to +10	19.9	14.0
-50 to -10	12.1	10.1
Decrease by more than 50%	6.7	2.5

There have been several other studies into changes in low flow indicators at the catchment scale. Gellens and Roulin (1998), for example, simulated changes in low flows in several Belgian catchments under a range of GCM-based scenarios. They show how the same scenario could produce rather different changes in different catchments, depending largely on the catchment geological conditions. Catchments with large amounts of groundwater storage tend to have higher summer flows under the climate change scenarios considered because additional winter rainfall tends to lead to greater groundwater recharge (the extra rainfall offsets the shorter recharge season). Low flows in catchments with little storage tend to be reduced because these catchments do not feel the benefits of increased winter recharge. Arnell and Reynard (1996) found similar results in the UK. The effect of climate change on low flow magnitudes and frequency therefore can be considered to be very significantly affected by catchment geology (and, indeed, storage capacity in general). Dvorak *et al.* (1997) also showed how changes in low flow measures tend to be proportionately greater than changes in annual, seasonal, or monthly flows.

4.3.10. Water Quality

Water in rivers, aquifers, and lakes naturally contains many dissolved materials, depending on atmospheric inputs, geological conditions, and climate. These materials define the water's chemical characteristics. Its biological characteristics are defined by the flora and fauna within the water body, and temperature, sediment load, and color are important physical characteristics. Water "quality" is a function of chemical, physical, and biological characteristics but is a value-laden term because it implies quality in relation to some standard. Different uses of water have different standards. Pollution can be broadly defined as deterioration of some aspect of the chemical, physical, or biological characteristics of water (its "quality") to such an extent that it impacts some use of that water or ecosystems within the water. Major water pollutants include organic material, which causes oxygen deficiency in water bodies; nutrients, which cause excessive growth of algae in lakes and coastal areas—known as eutrophication (leading to algal blooms, which may be toxic and consume large amounts of oxygen when decaying); and toxic heavy metals and organic compounds. The severity of water pollution is governed by the intensity of pollutants and the assimilation capacity of receiving water bodies—which depends on the physical, chemical, and biological characteristics of streamflow—but not all pollutants can be degraded, however.

Chemical river water quality is a function of the chemical load applied to the river, water temperature, and the volume of flow. The load is determined by catchment geological and land-use characteristics, as well as by human activities in the catchment: Agriculture, industry, and public water use also may result in the input of "polluting" substances. Agricultural inputs are most likely to be affected by climate change because a changing climate might alter agricultural practices. A changing climate

also may alter chemical processes in the soil, including chemical weathering (White and Blum, 1995). Avila *et al.* (1996) simulated a substantial increase in base cation weathering rates in Spain when temperature and precipitation increased (although if precipitation were reduced, the effects of the higher temperature were offset). This, in turn, resulted in an increase in concentrations of base cations such as calcium, sodium, and potassium and an increase in streamwater alkalinity. Warmer, drier conditions, for example, promote mineralization of organic nitrogen (Murdoch *et al.*, 2000) and thus increase the potential supply to the river or groundwater. Load also is influenced by the processes by which water reaches the river channel. Nitrates, for example, frequently are flushed into rivers in intense storms following prolonged dry periods.

River water temperature depends not only on atmospheric temperature but also on wind and solar radiation (Orlob *et al.*, 1996). River water temperature will increase by a slightly lesser amount than air temperature (Pilgrim *et al.*, 1998), with the smallest increases in catchments with large contributions from groundwater. Biological and chemical processes in river water are dependent on water temperature: Higher temperatures alone would lead to increases in concentrations of some chemical species but decreases in others. Dissolved oxygen concentrations are lower in warmer water, and higher temperatures also would encourage the growth of algal blooms, which consume oxygen on decomposition.

Streamwater quality, however, also will be affected by streamflow volumes, affecting both concentrations and total loads. Carmichael *et al.* (1996), for example, show how higher temperatures and lower summer flows could combine in the Nitra River, Slovakia, to produce substantial reductions in dissolved oxygen concentrations. Research in Finland (Frisk *et al.*, 1997; Kallio *et al.*, 1997) indicates that changes in stream water quality, in terms of eutrophication and nutrient transport, are very dependent on changes in streamflow. For a given level of inputs, a reduction in streamflow might lead to increases in peak concentrations of certain chemical compounds. Cruise *et al.* (1999) simulated increased concentrations of nitrate in the southeast United States, for example, but the total amount transported from a catchment might decrease. Hanratty and Stefan (1998) simulated reductions in nitrate and phosphate loads in a small Minnesota catchment, largely as a result of reductions in runoff. Alexander *et al.* (1996) suggest that nutrient loadings to receiving coastal zones would vary primarily with streamflow volume. Increased streamflow draining toward the Atlantic coast of the United States under many scenarios, for example, would lead to increased nutrient loadings. An increased frequency of heavy rainfall would adversely affect water quality by increasing pollutant loads flushed into rivers and possibly by causing overflows of sewers and waste storage facilities. Polluting material also may be washed into rivers and lakes following inundation of waste sites and other facilities located on floodplains.

Water temperature in lakes responds to climate change in more complicated ways because thermal stratification is formed in

summer, as well as in colder regions in winter. Meyer *et al.* (1999) evaluated the effect of climate change on thermal stratification by simulation for hypothetical lakes. They show that lakes in subtropic zones (about latitude 30 to 45°) and in subpolar zones (latitude 65 to 80°) are subject to greater relative changes in thermal stratification patterns than mid-latitude or equatorial lakes and that deep lakes are more sensitive than shallow lakes in the subtropic zones. Hostetler and Small (1999) simulated potential impacts on hypothetical shallow and deep lakes across North America, showing widespread increases in lake water temperature slightly below the increase in air temperature in the scenarios used. The greatest increases were in lakes that were simulated to experience substantial reductions in the duration of ice cover; the boundary of ice-free conditions shifted northward by 10° of latitude or more (1,000 km). Fang and Stefan (1997) show by simulation that winter stratification in cold regions would be weakened and the anoxic zone would disappear. Observations during droughts in the boreal region of northwestern Ontario show that lower inflows and higher temperatures produce a deepening of the thermocline (Schindler *et al.*, 1996).

The consequences of these direct changes to water quality of polluted water bodies may be profound, as summarized by Varis and Somlyody (1996) for lakes. Increases in temperature would deteriorate water quality in most polluted water bodies by increasing oxygen-consuming biological activities and decreasing the saturation concentration of dissolved oxygen. Hassan *et al.* (1998a,b) employed a downscaled climate model combined with GCM output to predict future stratification for Suwa Lake, Japan, on a daily basis, as well as for the prolonged summer stratification period. They predict increased growth of phytoplankton and reduced dissolved oxygen concentrations at different depths in the lake. Analysis of past observations in Lake Biwa in Japan (Fushimi, 1999) suggests that dissolved oxygen concentrations also tend to reduce when air (and lake water) temperature is higher.

Water quality in many rivers, lakes, and aquifers, however, is heavily dependent on direct and indirect human activities. Land-use and agricultural practices have a very significant effect on water quality, as do management actions to control point and nonpoint source pollution and treat wastewaters discharged into the environment. In such water bodies, future water quality will be very dependent on future human activities, including water management policies, and the direct effect of climate change may be very small in relative terms (Hanratty and Stefan, 1998). Considerable effort is being expended in developed and developing countries to improve water quality (Sections 4.5 and 4.6), and these efforts will have very significant implications for the impact of climate change on water quality.

Confidence in estimates of change in water quality is determined partly by climate change scenarios (and their effects on streamflow), but additional uncertainty is added by current lack of detailed understanding of some of the process interactions involved.

4.3.11. Glaciers and Small Ice Caps

Valley glaciers and small ice caps represent storages of water over long time scales. Many rivers are supported by glacier melt, which maintains flows through the summer season. The state of a glacier is characterized by the relationship between the rate of accumulation of ice (from winter snowfall) and the rate of ablation or melt. Most, but not all, valley glaciers and small ice caps have been in general retreat since the end of the Little Ice Age, between 100 and 300 years ago—for example, in Switzerland (Greene *et al.*, 1999), Alaska (Rabus and Echelmeyer, 1998), the Canadian Rockies (Schindler, 2001), east Africa (Kaser and Noggler, 1991), South America (Ames and Hastenrath, 1996; see also Chapter 14), the arid region of northwest China (Liu *et al.*, 1999), and tropical areas as a whole (Kaser, 1999). Temperature appears to be the primary control (Greene *et al.*, 1999), and rates of retreat generally are accelerating (Haeberli *et al.*, 1999). The World Glacier Monitoring Service (see <http://www.geo.unizh.ch/wgms>) monitors glacier mass balances and publishes annual reports on glacier fluctuations.

The effect of future climate change on valley glaciers and small ice caps depends on the extent to which higher temperatures are offset by increased winter accumulation. At the global scale, Gregory and Oerlemans (1998) simulate a general decline in valley glacier mass (and consequent rise in sea level), indicating that the effects of higher temperatures generally are more significant than those of additional winter accumulation. Model studies of individual glaciers have shown general retreat with global warming. Wallinga and van de Wal (1998) and Haeberli and Beniston (1998), for example, both simulated retreat in Alpine glaciers with higher temperatures and changes in winter accumulation. Davidovich and Ananicheva's (1996) simulation results show retreat of Alaskan glaciers but also a substantial increase in mass exchange (and therefore rate of movement) as a result of increased winter accumulation.

Oerlemans *et al.* (1998) simulated the mass balance of 12 valley glaciers and small ice sheets distributed across the world. They found that most scenarios result in retreat (again showing that temperature changes are more important than precipitation changes) but showed that it was very difficult to generalize results because the rate of change depends very much on glacier hypsometry (i.e., variation in altitude across the glacier). Their simulations also show that, in the absence of a change in precipitation, a rise in temperature of 0.4°C per decade would virtually eliminate all of their study glaciers by 2100, but a rise of 0.1°C per decade would “only” lead to a reduction in glacier volume of 10–20%.

Tropical glaciers are particularly exposed to global warming. Kaser *et al.* (1996) show that the equilibrium line altitude (ELA)—the line separating the accumulation zone from the ablation zone—of a tropical glacier is relatively more sensitive to changes in air temperature than that of a mid-latitude glacier. This is because of the lack of seasonality in tropical temperatures and the fact that ablation is significant year-round. To illustrate, a 1°C rise in temperature during half of the year only will have

a direct impact on total ablation, annual mass balance, and ELA of a tropical glacier. In the case of a mid-latitude glacier, this increase may occur during winter when temperatures may be well below freezing over much (if not all) of the glacier. As a result, there may be no significant change in ablation or position of the ELA, even though the annual temperature will have increased.

Glacier retreat has implications for downstream river flows. In rivers fed by glaciers, summer flows are supported by glacier melt (with the glacier contribution depending on the size of the glacier relative to basin area, as well as the rate of annual melt). If the glacier is in equilibrium, the amount of precipitation stored in winter is matched by melt during summer. However, as the glacier melts as a result of global warming, flows would be expected to increase during summer—as water is released from long-term storage—which may compensate for a reduction in precipitation. As the glacier gets smaller and the volume of melt reduces, summer flows will no longer be supported and will decline to below present levels. The duration of the period of increased flows will depend on glacier size and the rate at which the glacier melts; the smaller the glacier, the shorter lived the increase in flows and the sooner the onset of the reduction in summer flows.

4.3.12. River Channel Form and Stability

Patterns of river channel erosion and sedimentation are determined largely by variations in streamflow over time—in particular, the frequency of floods. There is considerable literature on past changes in streamflow—caused by human influences or natural climatic variability—and associated river channel changes (Rumsby and Mackin, 1994) but very little on possible future channel changes. This largely reflects a lack of numerical models to simulate erosion and sedimentation processes; assessments of possible future channel changes that have been made have been inferred from past changes. In northern England, for example, Rumsby and Mackin (1994) show that periods with large numbers of large floods are characterized by channel incision, whereas periods with few floods were characterized by lateral reworking and sediment transfer. Increased flooding in the future therefore could be associated with increased channel erosion.

The density of the drainage network reflects the signature of climate on topography. Moglen *et al.* (1998) show that drainage density is sensitive to climate change but also that the direction of change in density depends not only on climate change but also on the current climate regime.

Hanratty and Stefan (1998) simulated streamflow and sediment yield in a small catchment in Minnesota. The scenario they used produced a reduction in sediment yield, largely as a result of reduced soil erosion, but their confidence in the model results was low. In fact, the lack of physically based models of river channel form and sediment transport means that the confidence in estimates of the effect of climate change on river channels is low in general.

4.3.13. Climate Change and Climatic Variability

Even in the absence of a human-induced climate change, hydrological behavior will vary not only from year to year but also from decade to decade (see Section 4.2). Hulme *et al.* (1999) simulated streamflow across Europe under four climate change scenarios for the 2050s (based on four different simulations from the HadCM2 climate model) and seven scenarios representing different 30-year climates extracted from a long run of the HadCM2 model with no GHG forcing. They show that natural multi-decadal (30-year) variability in average annual runoff is high across most of Europe and that this natural variability in runoff in mid-latitude Europe is greater than the simulated signal of climate change. In northern and southern Europe, the magnitude of climate change by the 2050s is greater than the magnitude of natural variability. However, the spatial patterns of climate change and climatic variability are very different, with a much more coherent (usually north-south) pattern in the climate change signal. Nevertheless, the results indicate that, for individual catchments in certain areas, the magnitude of climate change effects on some indicators of streamflow may be smaller than natural climatic variability for several decades, whereas in other areas, the climate change signal will be larger than past experience.

4.4. Effects on Water Withdrawals

4.4.1. Introduction

The consequences of climate change for water resources depend not only on possible changes in the resource base—as indicated in Section 4.3—but also on changes in the *demand*, both human and environmental, for that resource. This section assesses the potential effects of climate change on water withdrawals and use, placing these effects in the context of the many nonclimatic influences that are driving demand.

It must be noted that “demand” in its economic sense means willingness to pay for a particular service or commodity and is a function of many variables—particularly price, income (for households), output (for industries or agriculture), family composition, education levels, and so forth. The usefulness of the demand function is found in the ability to predict the effects of changes in causal variables and in measurement of the demanding party’s “willingness to pay” as a measure of gross benefits to the demanding party of various quantities. This willingness to pay is measured as the area under the demand function in the price-quantity plane. The quantities *actually* purchased (the quantities of water withdrawn or used) over time are the result of the interaction of factors affecting demand as defined above and conditions of supply (or availability). Thus, for example, the fact that the quantity purchased over time increases could be the result of falling costs of supply (a shift in the supply curve) rather than an increase in demand (shift in the demand curve). In this section, the term “demand” often is used as a synonym for “requirements;” this reflects usage of the term in large parts of the water sector.

Demands can be classified along two dimensions: instream or offstream, and consumptive or nonconsumptive. Instream demands use water within the river channel (or lake) and do not involve withdrawal. Examples include ecosystem uses, navigation, hydropower generation, recreation, and use of the water course for waste assimilation. Offstream demands extract water from the river channel, lake, or aquifer. They include domestic, industrial, and agricultural demands, as well as extractions for industrial and power station cooling. These demands can be consumptive or nonconsumptive. Consumptive demands “use” the water so it cannot be entirely returned to the river; nonconsumptive demands return the water to the river, although it may be returned to a different catchment or at a different quality. The primary consumptive demands are for irrigation and some types of industrial cooling (where the water is evaporated to the atmosphere rather than returned to the river).

4.4.2. World Water Use

Figure 4-2 shows estimated total water withdrawals, by sector, from 1900 to 1998 (Shiklomanov, 1998; Shiklomanov *et al.*, 2000). Agricultural use—primarily for irrigation—is by far the largest proportion, accounting in 1995 for 67% of all withdrawals and 79% of all water consumed. Municipal, or domestic, use represents only about 9% of withdrawals. There are large differences, of course, between continents, with the greatest absolute volume of irrigation withdrawals in Asia.

Over the past few years there have been many projections of future water withdrawals; virtually all have overestimated the actual rate of increase (Shiklomanov, 1998). Figure 4-2 also shows projected total global water withdrawals estimates made for the UN Comprehensive Assessment of the Freshwater Resources of the World (Raskin *et al.*, 1997). The central projection represents a “Conventional Development Scenario” (CDS), with “best-guess” estimates of future population growth, economic development, and water-use intensity. The upper and lower lines represent high and low cases, where the

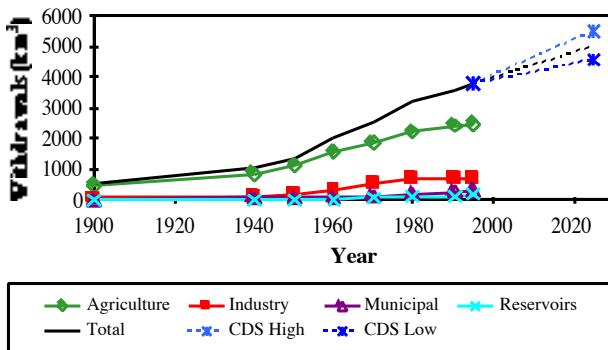

Figure 4-2: Global water withdrawals, 1900–1995, with projected future total withdrawals to 2025 [data from Shiklomanov *et al.*, 2000 (after Raskin *et al.*, 1997)].

assumed rates of growth are altered. Under the core CDS, global water withdrawals would increase by about 35% over 1995 values by 2025, with low and high estimates of 23 and 49%, respectively. The greatest rates of growth are projected to be in Africa and the Middle East, with the lowest growth in developed economies. These projections are very dependent not only on the assumed rate of population growth but also on the different assumed rates of water usage. They do not take potential climate change into account.

The amount of municipal water withdrawals is dependent on the number of urban dwellers, the level of development (related to the availability of a piped distribution network and sewage systems, amongst other things), income levels, and price where actually applied to water. Per capita withdrawals in many developed countries are falling, and this may more than offset an increasing population: Total municipal withdrawals in the United States, for example, are falling largely as a result of increasing prices, conservation education provided by water utilities, and increasing use of water-efficient appliances. However, municipal withdrawals in developing countries can be expected to increase with living standards; under the CDS, per capita withdrawals in these countries are projected to rise toward those in more economically developed countries. Rapid urbanization in developing countries is expected to lead to very substantial increases in total municipal water withdrawals.

The industrial sector currently accounts for approximately 20% of current withdrawals. This water is used primarily either in processing (food processing or heavy industry) or for cooling; the relative proportions vary between countries. Future industrial water use is expected to rise substantially as industrial development continues, but the increase probably will be less than the increase in industrial production as water is used with greater efficiency (using less per unit of production, for example, or relocating power generation plants to coastal areas to use seawater for cooling). Under the CDS, total industrial water use increases; this increase is concentrated largely in Asia and Latin America (Raskin *et al.*, 1997).

The amount of water used for agriculture is dependent primarily on the level of irrigation development, the pricing of water, and the reliability of supply. Future irrigation uses are a function of the rate of expansion of irrigated land, irrigation efficiency, and pricing practices. Efficiency is projected to improve—partly as a result of changes in the cost of water and partly as a result of technological developments—but this may be more than offset by increases in the area under irrigation. The amount of increase, however, is very uncertain; it depends on, among other things, assumed rates of population growth (increasing demand) and assumed changes in world agricultural markets. Previous estimates of future water use have tended to overestimate the rate of increase because the rate of expansion of irrigated land has been overestimated (Shiklomanov, 1998). The expanded use of pricing to reflect water scarcity is being strongly promoted by international organizations and will affect the quantities used. However, many regions that historically have been dependent on rainfall are using

supplemental irrigation—a factor that will increase irrigation use.

Estimates of future water withdrawals are notoriously uncertain, largely reflecting uncertainties in the future rate of population and economic growth. There is an analogy here with GHG emissions scenarios. Also important, however, are possible changes in the way water is priced. Much agricultural water, for example, currently is heavily subsidized, and a shift toward a more “economic” price for water is likely to have a very significant effect on use. The World Bank and other economic development agencies are pushing for major reforms in the way water is priced and sold, as well as the use of water markets as an efficient way of reallocating existing supplies and motivating efficiency.

4.4.3. Sensitivity of Demand to Climate Change

Climate change is another potential influence on the demand for water. Municipal demand is related to climate to a certain extent. Shiklomanov (1998) notes different rates of use in different climate zones, although in making comparisons between cities it is difficult to account for variation in nonclimatic controls. The sensitivity of municipal demand to climate change is likely to be very dependent on the uses to which the water is put. The most sensitive areas are increased personal washing and—more importantly in some cultures—increased use of water in the garden and particularly on the lawn. Studies in the UK (Herrington, 1996) suggest that a rise in temperature of about 1.1°C by 2025 would lead to an increase in average per capita domestic demand of approximately 5%—in addition to nonclimatic trends—but would result in a larger percentage increase in peak demands (demands for garden watering may be highly concentrated). Boland (1997) estimated the effects of climate change on municipal demand in Washington, D.C., under a range of different water conservation policies. Table 4-5

Table 4-5: Percentage change in average summer water use from 1990 by 2030: Washington, D.C. (Boland, 1997).^a

	Policy 1 ^b	Policy 2 ^c	Policy 3 ^d
No change in climate	+100	+61	+45
<i>Additional Change over Baseline Climate</i>			
GISS A scenario	+8	+8	+8
GISS B scenario	-13	-13	-13
GFDL scenario	+15	+15	+15
Max Planck scenario	+17	+16	+17
Hadley Centre scenario	+19	+19	+19

^a See original paper for scenario definitions.

^b Policy 1 = 1990 measures.

^c Policy 2 = Policy 1 plus increased recycling, public education, and altered plumbing regulations.

^d Policy 3 = Policy 2 plus 50% real increase in water tariffs.

summarizes percentage change in summer water use under the range of scenarios considered. Boland (1997) concludes that the effect of climate change is “small” relative to economic development and the effect of different water conservation policies.

Industrial use for processing purposes is insensitive to climate change; it is conditioned by technologies and modes of use. Demands for cooling water, however, may be affected by climate change. Increased water temperatures will reduce the efficiency of cooling, perhaps necessitating increased abstraction (or, of course, changes in cooling technologies to make them more efficient).

Agricultural demand, particularly for irrigation water, is considerably more sensitive to climate change. There are two potential effects. First, a change in field-level climate may alter the need for and timing of irrigation: Increased dryness may lead to increased demands, but demands could be reduced if soil moisture content rises at critical times of the year. Döll and Siebert (1999) applied a global irrigation water-use model with a spatial resolution of 0.5°x0.5° to assess the impact of climate change on net irrigation requirements per unit irrigated area, with a climate change scenario based on the ECHAM4 GCM. Figure 4-3 shows the relative change of net irrigation requirements between the present time (1961–1990) and 2025 in all areas equipped for irrigation in 1995. Under this scenario—and similarly under the corresponding HadCM3 scenario—net irrigation requirements per unit irrigated area generally would decrease across much of the Middle East and northern Africa as a result of increased precipitation, whereas most irrigated areas in India would require more water. The extra irrigation requirements per unit area in most parts of China would be small; the HadCM3 scenario leads to a greater increase in northern China. Other climate models would give different indications of regional changes in irrigation requirements. On the global scale, increases and decreases in net irrigation requirements largely cancel, and there is less difference between different climate models; under two scenarios considered by Döll and Siebert (2001), global net irrigation requirements would increase, relative to the situation without climate change, by 3.5–5% by 2025 and 6–8% by 2075. Actual changes in withdrawals would be dependent on changes in the efficiency of irrigation water use.

The second potential effect of climate change on irrigation demand is through increasing atmospheric CO₂ concentrations (Chapter 5). Higher CO₂ concentrations lower plant stomatal conductance, hence increase WUE; but as indicated in Section 4.3.3, this may be offset to a large extent by increased plant growth.

Hatch *et al.*(1999) assessed irrigation water requirements in Georgia, USA, using a climate change scenario derived from HadCM2. This scenario produced increased rainfall in most seasons, which, together with a shorter growing season and the assumed effect of CO₂ enrichment, resulted in a *decrease* in irrigation demand, ranging from just 1% by 2030 for soybean

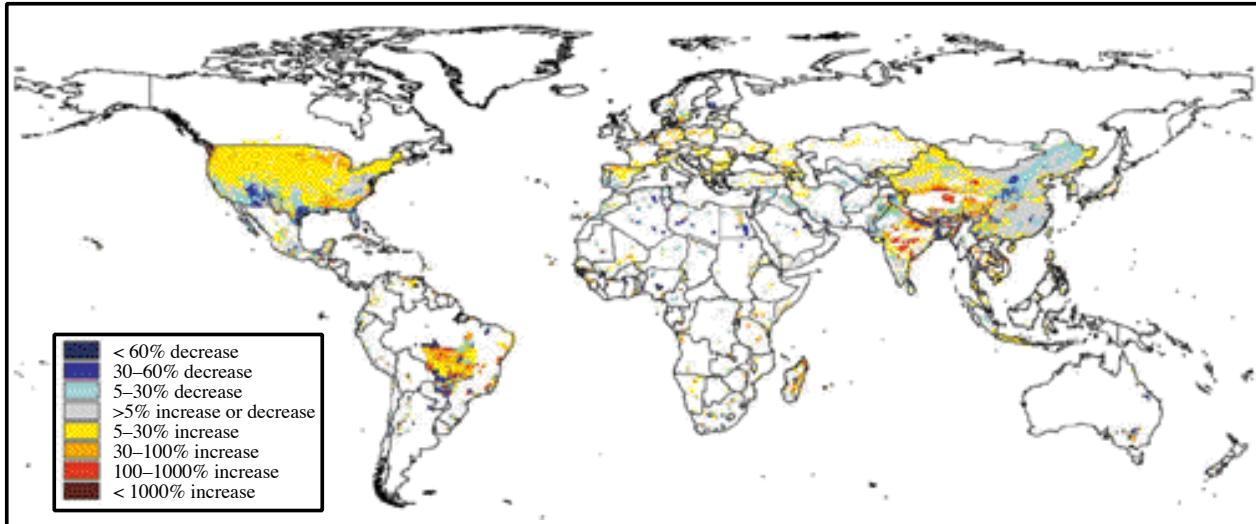

Figure 4-3: Relative change of annual net irrigation requirement between present time (1961–1990) and 2025 as a result of climate change (MPI climate scenario; areas equipped for irrigation in 1995 shown) (Döll and Siebert, 2001).

to as much as 20% by 2030 for corn. Along the Gulf Coast of the United States, however, the same scenario implies an increase in irrigation demands (Ritschard *et al.*, 1999). Strzepek *et al.* (1999) also simulated decreases in irrigation requirements across the U.S. cornbelt under two of three scenarios (with the decrease depending on assumed irrigation use efficiency) but an increase under the third scenario. These three studies together indicate considerable uncertainty in estimated future irrigation withdrawals.

4.5. Impacts on Water Resources and Hazards

4.5.1. Introduction

The preceding sections have assessed the potential effect of climate change on river flows, groundwater recharge and other biophysical components of the water resource base, and demands for that resource. The consequences, or impacts, of such changes on risk or resource reliability depend not only on the biophysical changes in streamflow, recharge, sea-level rise, and water quality but also on the characteristics of the water management system. This section considers what possible changes in hydrology and demand will mean for water supply, flood risk, power generation, navigation, pollution control, recreation, habitats, and ecosystems services *in the absence of planned adaptation to climate change*. In practice, of course, the *actual* impacts of climate change will be rather different because water managers will make incremental or autonomous adaptations to change—albeit on the basis of imperfect knowledge—and the impact of change will be a function of adaptation costs and residual impacts. However, very few studies have incorporated deliberate adaptation strategies (Alexandrov, 1998, is one), and studies that do not consider adaptation provide a base case for assessing the magnitude of the climate change “problem.” More significant, some studies

have not accounted for nonclimatic changes in the way water resources are managed or systems are operated and have applied the future climate to the present management system. This is unrealistic, but the extent of adaptation by many water managers is uncertain. It is important to assess the effect of climate change by, say, the 2050s in the context of the water management system that would exist by then in the absence of climate change—considering, for example, changes in demand or legislative requirements.

The sensitivity of a water resource system to climate change is a function of several physical features and, importantly, societal characteristics. Physical features that are associated with maximum sensitivity include:

- A current hydrological and climatic regime that is marginal for agriculture and livestock
- Highly seasonal hydrology as a result of either seasonal precipitation or dependence on snowmelt
- High rates of sedimentation of reservoir storage
- Topography and land-use patterns that promote soil erosion and flash flooding conditions
- Lack of variety in climatic conditions across the territory of the national state, leading to inability to relocate activities in response to climate change.

Societal characteristics that maximize susceptibility to climate change include:

- Poverty and low income levels, which prevent long-term planning and provisioning at the household level
- Lack of water control infrastructures
- Lack of maintenance and deterioration of existing infrastructure
- Lack of human capital skills for system planning and management

- Lack of appropriate, empowered institutions
- Absence of appropriate land-use planning
- High population densities and other factors that inhibit population mobility
- Increasing demand for water because of rapid population growth
- Conservative attitudes toward risk [unwillingness to live with some risks as a tradeoff against more goods and services (risk aversion)]
- Lack of formal links among the various parties involved in water management.

This section first considers the global-scale implications of climate change on broad measures of water resources then assesses in more detail potential impacts on defined systems.

4.5.2. Impacts of Climate Change on Water Resources: A Global Perspective

There are several indicators of water resource stress, including the amount of water available per person and the ratio of volume of water withdrawn to volume of water potentially available. When withdrawals are greater than 20% of total renewable resources, water stress often is a limiting factor on development (Falkenmark and Lindh, 1976); withdrawals of 40% or more represents high stress. Similarly, water stress may be a problem if a country or region has less than 1,700 m³ yr⁻¹ of water per capita (Falkenmark and Lindh, 1976). Simple numerical indices, however, give only partial indications of water resources pressures in a country or region because the consequences of “water stress” depend on how the water is managed.

At the global scale, assessments of water stress usually are made by country because that is the unit at which water-use data generally are available. In 1990, approximately one-third of the world’s population lived in countries using more than 20% of their water resources, and by 2025 about 60% of a larger total would be living in such stressed countries, in the absence of climate change (WMO, 1997), largely because population growth. Arnell (1999b, 2000) estimates the effect of a number of climate change scenarios on national water resource availability and compares this with estimated future demands for water (increasing following the CDS outlined in Section 4.4). Table 4-6 shows the numbers of people living in countries using more than 20% of their water resources in 2025 and 2050 and in

which the amount of resources decreases by more than 10% as a result of climate change. There is considerable variability between scenarios, essentially reflecting how resources change in populous countries, but by the 2020s the table indicates that about 0.5 billion people could see increased water resources stress as a result of climate change. Significant geographic variations are hidden in Table 4-6. Under most of the scenarios considered, climate change increases stresses in many countries in southern and western Africa and the Middle East, whereas it ameliorates stresses in parts of Asia. Alcamo *et al.* (1997) found broadly similar results.

Figure 4-4 shows water resources per capita in 1990 and 2050 for a set of countries, as listed in Table 14-3 of the WGII contribution to the SAR, showing resources per capita in 2050 without climate change (long line) and under eight climate change scenarios (short lines) (Arnell, 2000). There are some differences with the earlier table because of the use of updated data sets, but similar conclusions can be drawn. Climate change tends to have a small effect relative to population growth, and the range of magnitudes of effect between scenarios also is little changed; the effects are still uncertain. For most of the example countries, climate change may result in either an increase or a decrease, although for some the climate change signal is more consistent (reductions in South Africa, Cyprus, and Turkey, for example, and increases in China). Note that these figures represent national averages, and different parts of each country may be differently affected.

Table 4-7 gives an indication of the potential effect of stabilizing GHG concentrations on the total number of people living in water-stressed countries adversely affected by climate change (Arnell *et al.*, 2001). The results are conditional on the climate model used and the stabilization scenario, but this study—using just the HadCM2 climate model—suggests that by the 2050s the “weaker” stabilization target has little effect on the total number of impacted people, and although the “stronger” target reduces the impact of climate change, it does not eliminate it. The changes by the 2020s are very much affected by climatic variability between the various GCM runs.

4.5.3. Catchment and System Case Studies

Although there have been many assessments of the effect of climate change on river flows and (to a much lesser extent)

Table 4-6: Number of people living in water-stressed countries that are adversely affected by climate change, under a “business-as-usual” emissions scenario (IS92a) (Arnell, 2000).

	Total Population (millions)	Population in Water-Stressed Countries ^a (millions)	Number of People (millions) in Water-Stressed Countries with Increase in Water Scarcity

Blue diamonds represent 1990; long pink bars 2050 with no climate change; and short black bars 2050 under different climate change scenarios.

groundwater recharge, there have been few published quantitative studies into impacts on real water resource systems. Table 4-8 lists studies published in particular aspects of the water sector. Rather than summarize a large number of studies—which use different scenarios and different methodologies—this section gives a description of a few particularly comprehensive studies.

Perhaps the most comprehensive set of studies conducted to date was published by Lettenmaier *et al.* (1999). This study looked at potential climate change impacts on six dimensions of water resource (power generation, municipal water supply, recreation, flood defense, navigation, and environmental flow regulation) in six major U.S. basins, using realistic models of the water system operation and scenarios for possible future nonclimatic changes in demands and objectives (not all the six dimensions were assessed in each basin). Table 4-9 summarizes the results, showing changes in a range of indicators (which varied between basins) by 2050 under three climate change scenarios and a varying number of operational and demand scenarios. The results clearly show considerable variability between scenarios and catchments; they also show that climate

change might produce water resources benefits. The results also indicate that, in most sectors and basins, the impacts of different demand and operational assumptions by 2050 are greater than, or of similar magnitude to, the potential impacts of climate change.

Kaczmarek *et al.* (1996) assessed the impact of climate change on the water supply system in the Warta River basin in Poland, looking at two climate change scenarios in the context of increasing demand for water (particularly from irrigation). In the absence of climate change, they show that there would be supply problems in part of the system by 2050, simply because of the increase in demand. Under one of the scenarios, inflows to supply reservoirs would increase sufficiently to prevent supply problems; under the other scenario, the risk of shortage would increase substantially (the probability of an annual deficit of 10% would increase from 4 to ~25%, for example). Kaczmarek *et al.* (1996) also looked at the feasibility of one adaptation option—transferring water from one reservoir to another—and showed how it could lessen the likelihood of shortage.

Table 4-7: Effect of stabilization of CO_2 concentrations on numbers of people living in water-stressed countries adversely affected by climate change (Arnell *et al.*, 2001). Climate change under each emissions scenario is simulated with HadCM2 general circulation model; other climate models could give different indications of the effect of stabilization.

The River Rhine is a very important transport route within Europe. Grabs (1997) considered the effect of two climate change scenarios on navigation opportunities, having translated climate into streamflow by using a catchment water balance model. Table 4-10 summarizes the results: Under one of the scenarios, there would be little obvious effect on navigation opportunities, but under the other movement could be curtailed, particularly by the middle of the 21st century.

The vast majority of the impact assessments in Table 4-8 describe the effects of climate change on the reliability of an existing system. Very few explore the costs of these impacts, primarily because of difficulties in deciding the basis for calculation. Are the costs of climate change equal to the cost of

continuing to provide the current standard of service? Are the costs of services foregone (in terms of extra flood damages or reduced use of water), or are they incurred in providing services at a new economically-optimum level? In other words, estimates of the cost of climate change must consider explicitly the measures used to adapt to that change, and the economic costs of climate change will depend on the adaptation strategies adopted. Carmichael *et al.* (1996) present one of the few studies that has tried to cost the implications of climate change. They investigated the treatment costs necessary to maintain a given water quality standard (expressed in terms of dissolved oxygen content) in a river in Slovakia and calculated the least costly treatment under the present hydrological regime and under one scenario for the 2020s. They showed that costs would be little

different if the aim were to meet a 4 ppm dissolved oxygen target under average summer conditions but would rise by a factor of about 14 (at current prices) if the aim were to meet the same target under low-flow conditions, even taking a least-cost approach.

Aggregated estimates of the cost of impacts of climate change on water resources have been prepared for Spain, the UK, and the United States. Ayala-Carcedo and Iglesias-Lopez (2000) estimate that the reduction in water supplies under one scenario would cost nearly US\$17 billion (2000 values) between 2000 and 2060, or about US\$280 million yr⁻¹ in terms of increased expenditure to maintain supplies and lost agricultural production. A study in the UK estimated the costs of climate change for water supply and flood protection (ERM, 2000). Table 4-11 shows the costs (converted to US\$) involved in making up shortfalls of 5, 10, and 20% in the supply or demand across Britain, under several different types of approaches (see Section 4.6.2). The study assumes that the same change in water availability occurred across all of Britain—which probably overstates the costs because many parts of Britain are projected to have increased runoff—and estimated costs on the basis of standardized costs per unit of water. The study does not consider the feasibility of each of the potential adaptations. The cost of demand management measures increases substantially for large reductions in demand because more expensive technologies are needed. Note that a 5% reduction in demand represents just more than half the water of a 5% increase in supply; reducing domestic demand by 20% has a similar effect to increasing supply by 10%. The ERM study assumes that annual riverine flood damages would increase, because of increased flooding, by about US\$80–170 million yr⁻¹ over the next 30 years (compared to a current figure of about US\$450 million), and the average annual cost of building structural works to prevent this extra flooding would be about US\$40 million.

There have been two sets of estimates of the aggregate cost of climate change for water resources in the United States, using different approaches. Hurd *et al.* (1999) examined four river basins under nine climate change scenarios (defining fixed changes in temperature and precipitation) and extrapolated to the United States as a whole. Their study uses detailed economic and hydrological modeling and suggests that the largest costs would arise through maintaining water quality at 1995 standards—US\$5.68 billion yr⁻¹ (1994 US\$) by 2060 with a temperature increase of 2.5°C and a 7% increase in precipitation—and through lost hydropower production (US\$2.75 billion yr⁻¹ by 2060, under the same scenario). Costs of maintaining public water supplies would be small, and although loss of irrigation water would impact agricultural users, changed cropping and irrigation patterns would mean that the economic losses to agriculture would be less than US\$0.94 billion yr⁻¹ by 2060. However, this study extrapolates from the four study catchments to the entire United States by assuming that the same climate change would apply across the whole country.

Frederick and Schwarz (1999) take a different approach, looking at 18 major water resource regions and 99 assessment subregions, with two climate change scenarios for the 2030s based on climate model simulations. Water scarcity indices were developed for each assessment subregion, comparing scarcities under “desired streamflow conditions” and “critical streamflow conditions” on the demand side with “mean streamflows” and “dry-condition streamflows” on the supply side. These indices played a key role in determining the costs of meeting various streamflow targets. A supply-demand balance in each region is achieved through supply- and demand-side measures, each of which has an assumed unit cost. Three strategies were defined for each region: “environmental,” focusing on protecting the environment; “efficient,” maintaining supplies to users; and “institutional,” placing limits on

Table 4-9: Impact of climate change scenarios by 2050 on various water resource indices in six U.S. basins (Lettenmaier *et al.*, 1999).^a

^a See original paper for detailed summary of scenarios used.

changes in environmental indicators and the area of irrigation. The total national cost of climate change was determined under each strategy by aggregating least-cost measures in each subregion. Table 4-12 summarizes the estimated national costs under the three strategies and two scenarios. The costs are considerably greater under the drier CGCM1 scenario than under the wetter HadCM2 scenario (which, in fact, implies a benefit), and they vary with management strategy. Costs under the drier scenario are considerably higher than those estimated by Hurd *et al.* (1999), reflecting partly the different approaches used and partly the spatial variability in the effect of climate change considered by Frederick and Schwarz (1999).

4.5.4. Impacts of Climate Change on Water Resources: An Overview

This section explores the global-scale implications of climate change for water resources stress and summarizes a few studies into climate change impacts on several real-world water management systems. However, few published studies consider impacts in quantitative terms on real-world systems; most published studies infer changes in water resources from changes in streamflow.

It is very difficult to draw quantitative conclusions about the impacts of climate change, for several reasons. Different studies

Table 4-10: Effect of climate change on navigation opportunities on River Rhine (Grabs, 1997).

have used different methodologies and different scenarios, but, most important, different systems respond very differently to climate change. It is possible, however, to make some qualitative generalizations:

- In systems with large reservoir capacity, changes in resource reliability may be proportionately smaller than changes in river flows.
- The potential impacts of climate change must be considered in the context of other changes that affect water management. Few studies have explicitly compared climate change with other pressures, but in many environments it is likely that over a time horizon of less than 20 years, climate change impacts will be very small relative to other pressures. This will depend on the system.
- The implications of climate change are likely to be greatest in systems that currently are highly stressed.

By far the majority of studies of the impact of climate change on water resources have concentrated on human aspects of the water environment. Only a very few (e.g., Eheart *et al.*, 1999;

Meyer *et al.*, 1999) have considered impacts on the aquatic environment. Some of these studies are considered in Chapter 5, but it must be remembered that water resources systems in many parts of the world increasingly are being managed to maintain instream and wetland ecosystems. This either increases effective water demand or decreases water availability.

Confidence in estimated quantitative impacts of climate change on water resources generally is low, reflecting initial confidence in climate change scenarios and low confidence in estimates of future pressures on water resources (as a result of factors such as changes in demand or legislative requirements). However, techniques for estimating the impacts of a given scenario are now well established.

4.6. Adaptation Options and Management Implications

4.6.1. Introduction

The preceding sections have assessed the possible effects of climate change on the water resource base and on the demand for water, as well as the potential impacts on water users. Most published studies have looked at impacts in the absence of planned adaptation to climate change, and the few studies that have tried to cost impacts have had to make assumptions about adaptation. This section assesses opportunities in the water sector for adapting to climate change and explores any constraints which may exist.

Water management has always adapted to change (especially following extreme events or in response to increased demand), and climate change is just one of the pressures facing water managers. Other pressures include increasing demands for water resources or protection against hazard, changing water management objectives (which recently have included increasing

Table 4-11: Estimated national average annual costs (US\$ million) of impacts of climate change on water resources and riverine flooding, UK, over next 30 years (ERM, 2000).

	5% reduction in supply by 2030	10% reduction in supply by 2030	20% reduction in supply by 2030

recognition of the importance of meeting environmental needs as well as those of offstream demands), changing water management technologies, and altered legislative environments.

It is important to distinguish between development of adaptive options for meeting changing demands and resources and assessment of the abilities of a given water management agency (interpreted broadly) actually to adapt to climate change. Over the years, a wide range of adaptive techniques has been developed, largely in response to the need to meet increased demands. Broad distinctions can be drawn among “supply-side” adaptive techniques (changing structures, operating rules, and institutional arrangements) and “demand-side” techniques (which change the demand for water or protection against risk and include institutional changes as well). Examples of supply-side adaptations include increasing flood defenses, building weirs and locks to manage water levels for navigation, and modifying or extending infrastructure to collect and distribute water to consumers. Demand-side techniques include water demand management (such as encouraging water-efficient irrigation and water pricing initiatives), changing water allocations (Miller *et al.*, 1997), and nonstructural flood management measures (such as land-use controls). Distinctions also can be drawn between anticipatory and reactive actions. The former are taken in advance of some change, the latter in response to a change. Reactive actions include short-term operational adaptations, such as temporary exploitation of new sources, and longer term measures. A major flood or drought, for example, often triggers a change in water management. However, although many adaptive options do exist, knowledge of these options and the expertise of officials to execute them may be limited in some situations.

The optimum extent of adaptation can be characterized in terms of the benefits and costs of adaptation. The extremes of adaptation are “no adaptation” and “adaptation sufficient to eliminate all effects” (which usually is not physically possible). The optimum level of adaptation minimizes the combined costs of adaptation and residual negative effects, with the most cost-effective steps taken first.

Water managers long have had access to many techniques for assessing options and implementing adaptive strategies. However, the techniques used have changed over time and vary between countries, and they are very much influenced by institutional arrangements in place in a country. Factors that affect adaptive capacity in a country include institutional

capacity, wealth, management philosophy (particularly management attitudes toward supply-side versus demand-side strategies, as well as “sustainable” management), planning time scale, and organizational arrangements (adaptation will be harder, for example, when there are many different “managers” involved or where water managers do not have sound professional guidance).

This section looks first at water management options, then at management techniques. It contends that water managers generally are aware of technical and institutional options—although for many reasons may not have access to all of them—and that climate change challenges management techniques for assessing and selecting options, rather than the technical and institutional options themselves.

4.6.2. Water Management Options

Table 4-13 summarizes some supply- and demand-side adaptive options, by water-use sector. Each option has a set of economic, environmental, and political advantages and disadvantages.

Most of these strategies are being adopted or considered in many countries in the face of increasing demands for water resources or protection against risk. In the UK, for example, water supply companies currently are pursuing the “twin track” of demand management and supply management in response to potential increases in demand for water (although there is a conflict between different parts of the water management system over the relative speeds with which the two tracks should be followed). These management strategies also are potentially feasible in the face of climate change. Nowhere, however, are water management actions being taken explicitly and solely to cope with climate change, although in an increasing number of countries climate change is being considered in assessing future resource management. In the UK, for example, climate change is one of the factors that must be considered by water supply companies in assessing their future resource requirements—although companies are highly unlikely to have new resources justified at present on climate change alone.

The continuing debate in water management (Easter *et al.*, 1998) is between the practicalities and costs of supply-side versus demand-side options, and this debate is being pursued independently of climate change. The tide is moving toward the use of demand-side options because they are regarded as being more environmentally sustainable, cost-effective, and flexible (Frederick, 1986; World Bank, 1993; Young *et al.*, 1994; Anderson and Hill, 1997). “Smart” combinations of supply-side and demand-side approaches are needed, although in many cases new supply-side infrastructure may be necessary. This is particularly the case in developing countries, where the challenge often is not to curb demand but to meet minimum human health-driven standards.

There do appear, however, to be numerous “no regret” policies that warrant immediate attention. In this context, a “no regret” policy is one that would generate net social benefits regardless

Table 4-13: Supply-side and demand-side adaptive options: some examples.

Supply-Side		Demand-Side	
Option	Comments	Option	Comments
<i>Municipal water supply</i>			
– Increase reservoir capacity	– Expensive; potential environmental impact	– Incentives to use less (e.g., through pricing)	– Possibly limited opportunity; needs institutional framework
– Extract more from rivers or groundwater	– Potential environmental impact	– Legally enforceable water use standards (e.g., for appliances)	– Potential political impact; usually cost-inefficient
– Alter system operating rules	– Possibly limited opportunity	– Increase use of grey water	– Potentially expensive
– Inter-basin transfer	– Expensive; potential environmental impact	– Reduce leakage	– Potentially expensive to reduce to very low levels, especially in old systems
– Desalination	– Expensive (high energy use)	– Development of non-water-based sanitation systems	– Possibly too technically advanced for wide application
– Seasonal forecasting	– Increasingly feasible		
<i>Irrigation</i>			
– Increase irrigation source capacity	– Expensive; potential environmental impact	– Increase irrigation-use efficiency	– By technology or through increasing prices
		– Increase drought-tolerant	– Genetic engineering is controversial
		– Change crop patterns	– Move to crops that need less or no irrigation
<i>Industrial and power station cooling</i>			
– Increase source capacity	– Expensive	– Increase water-use efficiency	– Possibly expensive to upgrade
– Use of low-grade water	– Increasingly used	– and water recycling	
<i>Hydropower generation</i>			
– Increase reservoir capacity	– Expensive; potential environmental impact	– Increase efficiency of turbines; encourage energy efficiency	– Possibly expensive to upgrade
– Seasonal forecasting	– May not be feasible		
<i>Navigation</i>			
– Build weirs and locks	– Expensive; potential environmental impact	– Alter ship size and frequency	– Smaller ships (more trips, thus increased costs and emissions)
– Increased dredging	– Potential environmental impact		
<i>Pollution control</i>			
– Enhance treatment works	– Potentially expensive	– Reduce volume of effluents to treat (e.g., by charging discharges)	
		– Catchment management to reduce polluting runoff	– Requires management of diffuse sources of pollution
<i>Flood management</i>			
– Increase flood protection (levees, reservoirs)	– Expensive; potential environmental impact	– Improve flood warning and dissemination	– Technical limitations in flash-flood areas, and unknown effectiveness
– Catchment source control to reduce peak discharges	– Most effective for small floods	– Curb floodplain development	– Potential major political problems

of whether there was climate change. Examples include elimination of subsidies to agriculture and floodplain occupancy and explicit recognition of environmental values in project design and evaluation. The effect of successful demand-side policies is to reduce the need for supply augmentation, although they may not prevent such needs entirely if changes are large. Such policy changes represent the minimum package of “anticipatory policy changes” in response to climate change.

4.6.3. Implications of Climate Change for Water Management Policy

Climate change exaggerates current pressures in water management—adding to the debate on sound management strategies—and adds a new component. This new component relates to uncertainty in climate change: How can water management efficiently adapt to climate change, given that the magnitude (or possibly even the direction) of change is not known? Conventionally, water resource managers assume that the future resource base will be the same as that of the past and therefore that estimates of indices such as average reservoir yield or probable maximum flood that are based on past data will apply in the future. There are two issues: assessing alternatives in the face of uncertainty and making decisions on the basis of this assessment.

Techniques for assessing alternatives include scenario analysis and risk analysis. Scenario analysis is central to climate change impact assessment, but it is not widely used in water resource assessment (although there are some very important exceptions, such as at the federal level in the United States). Scenario analysis, as in climate change impact assessment, tends to involve simulation of the effects of different scenarios, although in water resources assessment these tend to be different demand and operational scenarios rather than different climate scenarios. Stakhiv (1998) argues that if water managers already adopt a scenario-based approach, as at the federal level in the United States (Lins and Stakhiv, 1998), climate change therefore does not cause any additional *conceptual* challenges to water management: Climate change can be regarded simply as an extra type of scenario. However, the uncertain nature of climate change and the potential for nonlinearities in impact mean not only that the range of scenarios conventionally considered may

be too narrow but also that a larger number of scenarios must be evaluated. In practice, scenario-based approaches are used in few water management agencies, and adoption of scenario analysis would challenge conventional water management practices in many countries.

Risk analysis involves assessment of the risk of certain thresholds being crossed under different possible futures (Major, 1998). It generally involves stochastic simulation of hydrological data to develop a sampling distribution of possible futures. In principle, climate change can be incorporated into risk analysis by changing the underlying population from which data are generated according to climate change scenarios. Matalas (1997) discusses the role of stochastic simulation in the context of climate change and argues that given the wide range in futures that often is simulated by assuming a stationary climate, the operational assumption of stationarity may remain appropriate in the face of climate change in some regions. However, it is possible that climate change could generate futures outside those produced under stationarity, and it cannot be assumed that climate change can be ignored in all circumstances.

The second main issue is that of decisionmaking under uncertainty. This issue was widely investigated during the 1960s and 1970s, largely in the context of uncertainties about demands or the precise distribution of floods and droughts over the short and medium terms. Climate change has revived interest in decisionmaking under uncertainty, and several analyses of different techniques have been published (e.g., Fisher and Rubio, 1997; Frederick, 1997; Hobbs, 1997; Hobbs *et al.*, 1997; Luo and Caselton, 1997; Chao *et al.*, 1999). There still is considerable debate. Hobbs (1997), for example, concludes that Bayesian approaches involving allocation of probabilities to specific outcomes are more suitable than Dempster-Shafer reasoning (which requires the analyst to assign probabilities to ranges—perhaps overlapping—of outcomes), but Luo and Caselton (1997) conclude the reverse. Particularly significant is the issue of assigning probabilities to alternative possible futures. Hobbs *et al.* (1997) note unease among water planners in assigning subjective probabilities to different futures.

Planners of water resource and flood protection schemes conventionally cope with uncertainty by adding a safety factor to design estimates. This safety factor usually is defined arbitrarily.

Table 4-14: Headroom “score” characterizing effect of climate change on resource zone yield: an approach used in UK (UKWIR, 1998).

Range in Resource Zone Yield between Four Defined Scenarios ^a	Case 1: Two Scenarios Above and Two Below Mean	Case 2: Three Scenarios Below and One Above Mean	Case 3: Three Scenarios Above and One Below Mean
<15%	2	3	1
15–25%	4	6	2
25–35%	6	9	3
>35%	8	10	4

^aAs percentage of “best estimate” of yield.

As part of a review of water resource design practices in the UK, a more formal approach to calculation of this safety factor, or “headroom,” has been developed (UKWIR, 1998). This procedure identifies eight sources of supply-side uncertainty and three sources of demand-side uncertainty, each of which is given a score. The total score is summed and converted into a percentage value for the headroom allowance (with a maximum of 20%). Climate change is included as one of the supply-side uncertainties; its score depends on the range of estimates of supply-yield under four defined climate change scenarios (Table 4-14). Although this approach has many arbitrary elements, it does represent a systematic approach to the treatment of climate change uncertainties in water resources assessment.

Different aspects of the water sector have different planning horizons and infrastructure lifetimes. The parts of the water sector with long horizons and lifetimes need to take a different approach to climate change than parts with shorter lead times; one assessment and decision methodology will not be suitable for all managers.

4.6.4. Factors Affecting Adaptive Capacity

From the beginning of human attempts to shape the water environment to human benefit, water management has dealt with the variability of the native supply of water and the variability of demands for the use of water (Stakhiv, 1998). Great strides have been made in dealing with even extreme water regimes—particulary droughts—through interventions on the supply and demand sides (e.g., Stern and Easterling, 1999). Drought management planning is playing an increasing role in many water management agencies, lowering their susceptibility to drought impacts. Thus, in some ways the prospects of a change in the resource base—perhaps characterized by lower mean supplies and higher variability—represent only a sharpening of traditional challenges to water management. There are three important differences, however. First, future climate change is highly uncertain at spatial and temporal scales that are relevant to water management: All we know is that the future may not necessarily be like the recent past. Second, as noted above, the potential pervasiveness of these changes across large regions presents challenges that preclude some traditional steps of adaptation and requires innovative approaches that go beyond experience to date. Third, climate-induced effects may be nonlinear, carrying potential for surprises beyond those incorporated in traditional water management.

The ability to adapt to climate variability and climate change is affected by a range of institutional, technological, and cultural features at the international, national, regional, and local levels, in addition to specific dimensions of the change being experienced. Among the most important features are the following:

- 1) The capacity of water-related institutions, consisting of water agencies' authority to act, skilled personnel, the capability and authority to consider a wide range of alternatives (including but not limited to supply-side

and demand-side interventions) in adapting to changed conditions, the capability and authority to use multi-objective planning and evaluation procedures in the assessment of policy alternatives, procedures for conflict resolution, and incentives to undertake serious *ex post* analysis of policies and projects to learn what has really worked (OECD, 1985). For example, O'Connor *et al.* (1999) found in the Susquehanna River Basin, USA, that experienced full-time water managers are more likely to consider future scenarios in their planning than part-time managers.

- 2) The legal framework for water administration that always constrains, for better and for worse, the options that are open to water management. Naturally, laws change as needs change, but the changes are slow and greatly lag changing needs. In many countries, the legal framework for water management is moving toward increasing environmental protection (e.g., the European Union's habitats directive). Such a direction poses further constraints on options to address climate change, but if the move reflects an increasing concern with *sustainable* water management (however defined), opportunities for considering adaptation to climate change are increased.
- 3) The wealth of nations in terms of natural resources and ecosystems, human-made capital (especially in the form of water control systems), and human capital (including trained personnel) that determines what nations can “afford to commit” to adaptation. This should include the ability and willingness to transfer wealth among population groups and regions within a country and among nations. This is the major constraint on adaptation to climate change in poorer countries.
- 4) The state of technology and the framework for the dissemination (or monopolization) of technology, especially in the fields of bioengineering of drought- and salt-resistant varieties of plants and techniques for the desalination of seawater.
- 5) Mobility of human populations to change residential and work locations in response to severe climate events or climate change. This is a major factor in coastal and island areas. Mobility is severely hampered by population pressures, especially in tropical island settings.
- 6) The speed of climate change is crucial in determining the capabilities of societies to adapt and change water management practices. Speed of change and the *cumulative extent* of change affect the impacts on society in nonlinear fashions (Howe *et al.*, 1990; National Research Council, 1992).
- 7) The complexity of management arrangements also may be a factor in response. In principle, the fewer agencies involved in water management, the easier it will be to implement an adaptation strategy (although the structure within the agencies will be very important). If there are many stakeholders to involve—perhaps with conflicting requirements, management goals, and perceptions and each with some management control over part of the water system—it may be more difficult

- to adapt to changing circumstances. There is evidence that in some mature infrastructure systems, there may be substantial opportunities for increasing the resilience of water resource systems through institutional changes as well (Hansler and Major, 1999).
- 8) The ability of water managers to assess current resources and project future resources. This requires continuing collection of data and the ability to use scenarios with hydrological models to estimate possible future conditions.

Whether adaptation takes place or not may be heavily influenced by the occurrence of extreme events. Such events often are catalysts for change in management and may serve two roles. First, they may expose failings in the current water management system. Second, they may raise the perception among decision makers of the possibility of climate change—even if they cannot be attributed directly to climate change.

Recent experience with extreme events (e.g., the Chinese floods of 1998, the Rhine floods of 1996 and 1997, the eastern European floods of 1997 and 1998, and the Mozambique floods of 2000) shows that many societies are extremely exposed to loss and damage during extreme events, especially floods. At first, it may appear that this implies that existing adaptive techniques, as widely used by water managers, are not working as expected to minimize risk and loss (some loss will always be inevitable because no flood protection scheme can provide complete protection): Adaptation is not working. However, there is extensive evidence that social vulnerability to extreme events is serious and increasing (Munasinghe and Clark, 1995; Hewitt, 1997; Tobin and Montz, 1997; Haughton, 1998; La Red, 1999; Mileti, 1999) and that this exposure to hazards has been significantly increased by public and private development with insufficient regard for known hazards (Hewitt, 1997; Marsden, 1997; Pulwarty and Riebsame, 1997). In the United States there was more damage from hurricanes between 1990 and 1995 than there was between 1970 and 1990, after adjustments for inflation (Pielke, 1997), even though both periods had low hurricane frequency (Landsea *et al.*, 1996). Changnon *et al.* (1997) analyzed the dramatic increase in dollar losses of insured property in the United States, which reached US\$840 billion in the 1990–1994 period, and conclude that changes in weather and climate were not primary causes. Detailed meteorological analyses came to the same conclusion for flooding losses (Changnon, 1998; Karl and Knight, 1998).

Thus, societies' failure to adapt to extreme events *in the broadest sense* (i.e., by "allowing" risk-prone development) appears to have been largely responsible for increased damages, and that failure has not improved with time (Changnon and Changnon, 1998; Pielke and Landsea, 1998; Kunkel *et al.* 1999). It also appears that political decisions may have produced maladaptive results (Wiener, 1996; Hewitt, 1997; Mileti, 1999). In the United States, insurance has been a leading instrument for hazard awareness and post-event recovery. After 30 years of promotion, education, and subsidized premiums, only 20% of residents in floodplains were insured by the late

1990s (LeCompte and Gahagan, 1998; Pasterick, 1998). These failures to take advantage of insurance suggest that even wealthy societies adapt poorly to foreseeable hazards.

The residual damages of hazard events also are inequitably distributed across populations. This was shown clearly by studies of Hurricane Andrew in Florida (Peacock *et al.*, 1997), leading the director of the Pan American Health Organization to state that "those who lost the most had the least to lose" (PAHO, 1999). Hurricane Mitch devastated Central America in 1998, exhibiting the extreme vulnerability of that region (La Red, 1999; UNICEF, 1999). Among the responsible factors were lack of land-use planning, deforestation, and inappropriate consumption and production systems (Hewitt, 1997; Mileti, 1999; PAHO, 1999).

Thus, available evidence concerning the effectiveness of adaptation to meteorological and geologic hazards indicates poor levels of individual and social adaptation to hazards. This failing extends well beyond the water management sector as conventionally defined and can be argued to reflect weaknesses in development control, planning guidance, public education, and fiscal incentives. The foregoing examples indicate that having the ability to adapt to change is not the same as actually adapting to change: The tools often are not used, for a variety of reasons.

4.6.5. Adaptation to Climate Change in the Water Sector: an Overview

Water managers are accustomed to adapting to changing circumstances, many of which can be regarded as analogs of future climate change, and a wide range of adaptive options has been developed. Supply-side options are more familiar to most water managers, but demand-side options increasingly are being implemented. Water management is evolving continually, and this evolution will affect the impact of climate change in practice. For reasons noted above, climate change is likely to challenge existing water management practices, especially in countries with less experience in incorporating uncertainty into water planning. The generic issue is incorporation of climate change into the types of uncertainty traditionally treated in water planning.

Integrated water resources management (IWRM) (Bogardi and Nachtnebel, 1994; Kindler, 2000) increasingly is regarded as the most effective way to manage water resources in a changing environment with competing demands. IWRM essentially involves three major components: explicit consideration of *all* potential supply-side and demand-side actions, inclusion of all stakeholders in the decision process, and continual monitoring and review of the water resources situation. IWRM is an effective approach in the absence of climate change, and there already are many good reasons for it to be implemented. Adopting integrated water resources management will go a long way toward increasing the ability of water managers to adapt to climate change.

There are three final points to make:

- 1) “Upstream” adaptation may have implications for “downstream” uses. In other words, the impact of climate change on one user may be very much determined by the actions of other users in response to climate change. This emphasizes the need for basin-scale management.
- 2) The emphasis in this section has been on managed water systems. In many countries, particularly in rural parts of the developing world, water supply is “managed” at the household level, utilizing local water sources. There is a need to look at the implications of climate change in circumstances of this type in which investment in substantial infrastructure is unlikely.
- 3) Adaptation to climate change to reduce vulnerability in the water sector should involve far more than just water managers. Increasing social vulnerability to water stress (in terms of drought and flood) in many parts of the world reflects a wide range of pressures, many of which are outside the responsibility of water managers. Reducing vulnerability to climate change-induced flood and drought will require decisions about issues such as development and planning control, fiscal incentives (such as subsidized insurance or government disaster relief) to occupy (and continue to occupy after loss) hazard-prone land, and wealth enhancement.

4.7. Integration: Water and Other Sectors

4.7.1. The Nonclimate Context

The impact of climate change in the water sector is a function of biophysical changes in water quantity and composition, the use to which the water is put, and the way in which those uses are managed. The implications of climate change for water resources therefore must be considered in the context of the many other pressures on water resources and their management. These pressures—and management responses to them—are evolving rapidly, and the water management system (legal, infrastructural, and institutional) in the future may be very different in many countries from that at present. Considerable efforts are underway in many international agencies and organizations (e.g., Global Water Partnership, World Bank) to improve the way water is used and managed; these actions will have very significant consequences not only for economies, access to safe water, and the environment but also for the impacts of climate change. *Adaptation to climate change in the water sector must be considered in the context of these other changes*—and, of course, climate change must be considered as a factor in the development of improved management techniques.

4.7.2. Water and Other Related Sectors

Water is a fundamental component of many economic activities. The impact of climate change on the quality and quantity of

water therefore will be felt by such economic activities in one way or another. Examples of such linkages are given in the following subsections.

4.7.2.1. Ecosystems (TAR Chapter 5)

Changes in hydrological characteristics will lead to changes in aquatic and wetland ecosystems (as reviewed in Chapter 5)—as, indeed, may some of the actions taken by water managers to adapt to climate change. In practice, much water management increasingly focuses on ensuring that human use of water does not adversely impact the water environment, and maintaining and enhancing environmental quality is regarded as a legitimate management goal. Environmental demands, of course, will alter as climate changes.

Agriculture also will be affected by water availability, and actions taken by farmers in response to climate change may impact the water environment. For example, climate change may increase demands for irrigation from the agricultural sector, and if these extra needs are withdrawn from rivers or aquifers, there will be an effect on hydrological and ecological regimes: The “direct” effect of climate change on hydrological regimes and ecosystems may be enhanced. On the other hand, a lack of water resulting from climate change might mean that increased irrigation demands cannot be met, and changes in the water sector therefore are impacting directly on agricultural response to climate change. In addition, changes in agricultural land use resulting directly or indirectly from climate change may affect catchment water balance and water quality. These effects may be more substantial than the direct effects of climate change on hydrology.

4.7.2.2. Coastal and Marine Zones (TAR Chapter 6)

The ecology and morphology of river deltas reflect a balance between coastal and upstream processes. Changes in freshwater flow regimes will impact deltas, although the effects probably will be smaller than those of sea-level rise. Estuary characteristics also are affected by inflows from upstream, and the relative effects of sea-level rise and changes in river flows may be similar. Saline intrusion along estuaries, associated with higher sea levels and perhaps exacerbated by lower river flows, could threaten low-lying freshwater intakes, although adaptive options (relocation) are easy to implement. Saline intrusion into coastal aquifers also is a possibility, creating severe adaptation challenges in some settings—particularly low-lying islands such as atolls. Finally, rivers bring large quantities of nutrients and other materials to the coastal zone, and these fluxes are likely to be affected by changes in streamflow volumes in particular.

4.7.2.3. Settlements (TAR Chapter 7)

Provision of water to cities—especially the mega-cities emerging in some parts of the developing world—may become increasingly

problematic, with consequent effects on city growth and access to safe water. Altered river flows also may affect the ability of settlements to dispose of waste safely. Urban storm drainage is potentially very sensitive to changes in short-duration rainfall and is both expensive to install and difficult to upgrade. Finally, changes in flood flows imply changes in urban flood risk; indications are that the risk generally will increase.

The most vulnerable parts of the mega-cities are the informal settlements that do not have planned water distribution and sanitation systems. Rural populations also are exposed to climate change, and it is possible that their sensitivity to change may be greater: The urban population enjoys planned water supply systems that can adapt to changes of climate change better than unplanned systems in rural areas.

4.7.2.4. Financial Services (TAR Chapter 8)

The main linkage with the finance sector is through insurance and public disaster relief. Insurance against flood losses is available in some countries, and major flood events in these countries could challenge—at least temporarily—local and perhaps international insurers.

4.7.2.5. Health (TAR Chapter 9)

Changes in hydrological regimes have the potential to alter health risks. Most important are potential changes in access to safe drinking water, but that is likely to be more affected by factors other than climate change (such as provision of water distribution systems and improved sanitation). Water-borne diseases and water-related insect vector diseases are more sensitive to changes in hydrological patterns (e.g., Patz *et al.*, 1998; Checkley *et al.*, 2000). Floods have associated health problems, and climate change also has the potential to alter contamination of water supplies (through changes in flow pathways that lead to increased leaching of pollutants and through reduced flows that lead to increased concentrations) and contamination of shellfish and fish.

4.7.3. Water and Conflict

A change in water availability has the potential to induce conflict between different users (Biswas, 1994; Dellapena, 1999). These users may be in the same area—cities versus farmers, for example—or they may be in different parts of the river basin. Much has been written about the potential for international conflict (hot or cold) over water resources (e.g., Gleick, 1998); where there are disputes, the threat of climate change is likely to exacerbate, rather than ameliorate, matters because of uncertainty about the amount of future resources that it engenders. One major implication of climate change for agreements between competing users (within a region or upstream versus downstream) is that allocating rights in absolute terms may lead to further disputes in years to come

when the total absolute amount of water available may be different.

4.8. Science and Information Needs

4.8.1. Introduction

In the water sector, it is important to distinguish between the needs of those who wish to estimate the potential magnitude of climate change impacts on hydrology and water resources—to meet IPCC concerns, for example—and the more pragmatic needs of water managers who need to consider how best to adapt to climate change. The two sets of requirements are linked, but there are some important differences in emphasis.

4.8.2. Estimating Future Impacts of Climate Change

Some climate change analysts are essentially concerned with estimating what would actually happen under different climate futures: What are the impacts, for example, of continued growth of emissions of GHGs at 1% yr⁻¹, and what would be the impact of stabilizing CO₂ concentrations at, say, 550 ppmv by 2150? How do changes in variability affect the water environment? These impacts—and their costs—then could be compared with the impacts, costs, and benefits of mitigation. Such studies, in principle, could allow identification of “dangerous” levels of climate change. There also are important science questions concerning the processes by which climate change might impact the water environment. For example, how might flow pathways through soils change?

Such research questions need developments in the following areas:

- *Creation of credible climate change scenarios.* This involves improvements to GCMs so that they simulate present climate and its multi-decadal variability even better, development of conceptually sound downscaling techniques (in the absence of high-resolution global climate models), and characterization of potential changes in variability at time scales from daily to decadal. These requirements are common to all impact sectors and (with the exception of downscaling) are central to improving the understanding of climate change in the most general sense.
- *Characterization of natural climatic and hydrological variability.* Potential future climate changes resulting from increasing concentrations of GHGs need to be placed in context by appreciation of “natural” climatic and hydrological variability. Much needs to be learned about linkages between different components of the climate system in different parts of the world, which requires joint use of observational data (including remotely sensed data), palaeoclimatic data, and model simulations. Palaeoclimatic and palaeohydrological reconstructions can provide very useful information

- on the variability in “natural” hydrological systems, as well as insights into nonlinear relationships between climate forcing and hydrological response.
- *Improved hydrological models.* Particularly important is development and application of process-based models of hydrological processes that include realistic representations of processes that generate streamflow and recharge and determine water quality. Key issues include development of models that do not need catchment calibration (but may require remotely sensed inputs) to assess the effects of climate change in parts of the world with limited hydrological data and development of coupled climate-hydrology models (which also are important for the improvement of climate model performance and for seasonal forecasting). The international collaborative research efforts summarized in Section 4.2.2 are extremely important.
 - *Characterization of uncertainty.* How important are the different sources of uncertainty—in emissions, global climate response, and regional climate change—for estimated effects of climate change? Is downscaling cost-effective, given the wide range of changes in climate that might result from different emissions scenarios, for example? What can ensemble climate model experiments contribute? There has been little systematic analysis to date of the relative importance of different sources of uncertainty.
 - *Impacts on real-world water systems.* Section 4.5 notes that there have been relatively few published studies on the impacts of climate change on real-world water resources systems, and inferences about impacts generally have been made from estimates of changes in streamflow alone. This may give a very misleading impression of the actual impacts of change because the characteristics of the water management system are a very important buffer between hydrological effect and impact on users and the environment. Therefore, more studies into real-world systems are needed.
 - *Effects of adaptation.* Most impact studies have ignored adaptation by water managers, and in opposition it often is asserted that water managers will be able to adapt. However, how will managers make adaptation decisions in practice on the basis of incomplete information, and what would be the effects of inefficient adaptation on the impacts of climate change?

4.8.3. Adapting to Climate Change

Water managers are beginning to consider adapting to climate change. Some—but not all—water management plans and infrastructure have long lead times and long design lives. Improved understanding of the “science” of climate change impacts in the water sector is important but is not in itself enough to enable efficient adaptation. This is because it will never be feasible to base decisions on just one future climate scenario, particularly for time horizons greater than a decade.

This is partly a result of incomplete knowledge but largely because of inherent uncertainty in future emissions of GHGs. Therefore, water managers always will be dealing with a range of scenarios, and research aimed at enabling efficient adaptation consequently must focus largely on appropriate analytical and management tools to cope with uncertainty and change rather than on “improving” climate change science and scenarios *per se*. In some aspects of water management—particularly associated with water quality—scientific research into processes is fundamental to allowing efficient adaptation.

Efficient adaptation to climate change in the water sector requires effort in five main areas:

- *Data for monitoring.* Adaptive water management requires reliable data on which to make decisions, calibrate models, and develop projections for the future. These data should cover not just hydrological characteristics but also indicators of water use.
- *Understanding patterns of variability.* An understanding of patterns of variability—in particular, the stability of a “baseline” climate—is important for medium-term water management. It is increasingly recognized that even in the absence of climate change, the recent past may not be a reliable guide to the hydrological resource base of the near future.
- *Analytical tools.* Effective water management requires numerous tools to assess options and the future. These tools include scenario analysis and risk analysis, which are used in some parts of water management but currently are by no means widespread.
- *Decision tools.* Scenario and risk analysis provides information on possible futures and their consequences. They must be supplemented with tools such as Bayesian and other decisionmaking tools to make decisions on the basis of the information provided. Again, techniques for decisionmaking under uncertainty are not widely used in water management at present, and some of the approaches being used are not very sophisticated.
- *Management techniques.* These are the techniques that are actually implemented to meet management objectives. The broad spectrum of techniques (such as building a reservoir or managing demand) is well known, but there is a need for research into specific aspects of many demand-side approaches in particular, as well as into opportunities for seasonal flow forecasting and innovative water supply and treatment technologies (such as desalination). It also is necessary to undertake research to determine how to enhance the range of techniques considered by water managers.

Note that the above efforts are needed to improve water management even in the absence of climate change, and there is an overarching need to improve the exchange of information between hydrological science and water managers.

Water managers have long been accustomed to dealing with change, although until recently this has been primarily change

resulting from changes in demand and altered legislative or statutory requirements. Climate change does not in itself stimulate development of new adaptive strategies, but it encourages a more adaptive, incremental, risk-based approach to water management. More precisely, it provides further encouragement for a trend that already is gathering pace.

EXECUTIVE SUMMARY

Ecosystems are subject to many pressures (e.g., land-use change, resource demands, population changes); their extent and pattern of distribution is changing, and landscapes are becoming more fragmented. Climate change constitutes an additional pressure that could change or endanger ecosystems and the many goods and services they provide.

There now is a substantial core of observational and experimental studies demonstrating the link between climate and biological or physical processes in ecosystems (e.g., shifting range boundaries, flowering time or migration times, ice break-up on streams and rivers), most evident in high latitudes. Recent modeling studies continue to show the potential for significant disruption of ecosystems under climate change. Further development of simple correlative models that were available at the time of the Second Assessment Report (SAR) point to areas where ecosystem disruption and the potential for ecosystem migration are high. Observational data and newer dynamic vegetation models linked to transient climate models are refining the projections. However, the precise outcomes depend on processes that are too subtle to be fully captured by current models.

At the time of the SAR, the interaction between elevated carbon dioxide (CO_2), increasing temperatures, and soil moisture changes suggested a possible increase in plant productivity through increased water-use efficiency (WUE). Recent results suggest that the gains might be small under field conditions and could be further reduced by human management activities. Many ecosystems are sensitive to the frequency of El Niño-Southern Oscillation (ENSO) and other extreme events that result in changes in productivity and disturbance regimes (e.g., fires, pest and disease outbreak).

Agriculture

Most global and regional economic studies—with and without climate change—indicate that the downward trend in real commodity prices in the 20th century is likely to continue into the 21st century, although confidence in these predictions decreases farther into the future (see Section 5.3.1).

Impacts

- Experiments have shown that relative enhancement of productivity caused by elevated CO_2 usually is greater when temperature rises but may be less for crop yields at above-optimal temperatures (established but incomplete).

Although the beneficial effects of elevated CO_2 on the yield of crops are well established for the experimental conditions tested, this knowledge is incomplete for numerous tropical crop species and for crops grown under suboptimal conditions (low nutrients, weeds, pests and diseases). In experimental work, grain and forage quality declines with CO_2 enrichment and higher temperatures (high confidence) (see Sections 5.3.3, 5.4.3, and 5.5.3).

- Experimental evidence suggests that relative enhancement of productivity caused by elevated CO_2 usually is greater under drought conditions than in wet soil. Nevertheless, a climate change-induced reduction in summer soil moisture (see Table 3-10)—which may occur even in some cases of increased summer precipitation—would have detrimental effects on some of the major crops, especially in drought-prone regions (medium confidence).
- Soil properties and processes—including organic matter decomposition, leaching, and soil water regimes—will be influenced by temperature increase (high confidence). Soil erosion and degradation are likely to aggravate the detrimental effects of a rise in air temperature on crop yields. Climate change may increase erosion in some regions, through heavy rainfall and through increased windspeed (competing explanations) (see Section 5.3.3).
- Model simulations of wheat growth indicate that greater variation in temperature (change in frequency of extremes) under a changing climate reduces average grain yield. Moreover, recent research emphasizes the importance of understanding how variability interacts with changes in climate means in determining yields (established but incomplete) (see Section 5.3.4).
- Crop modeling studies that compare equilibrium scenarios with transient scenarios of climate change report significant yield differences. The few studies that include comparable transient and equilibrium climate change scenarios generally report greater yield loss with equilibrium climate change than with the equivalent transient climate change. Even these few studies are plagued with problems of inconsistency in methodologies, which make comparisons speculative at this time (see Section 5.3.4).

Adaptation and Vulnerability

- Prospects for adaptation of plant material to increased air temperature through traditional breeding and genetic modification appear promising (established but incomplete). More research on possible adaptation of crop species to elevated CO_2 is needed before more certain results can be presented (see Section 5.3.3).

- Simulations without adaptation suggest more consistent yield losses from climate change in tropical latitudes than temperate latitudes. Agronomic adaptation abates extreme yield losses at all latitudes, but yields tend to remain beneath baseline levels after adaptation more consistently in the tropics than in temperate latitudes (moderate confidence) (see Section 5.3.4).
- The ability of livestock producers to adapt their herds to the physiological stress of climate change is not known conclusively, in part because of a general lack of experimentation and simulations of livestock adaptation to climate change (see Section 5.3.3).
- Crop and livestock farmers who have sufficient access to capital and technologies are expected to adapt their farming systems to climate change (medium to low confidence) (see Section 5.3.4). Substantial shifts in their mix of crops and livestock production may be necessary, however, and considerable costs could be involved in this process—*inter alia*, in learning and gaining experience with different crops or if irrigation becomes necessary. In some cases, a lack of water resulting from climate change might mean that increased irrigation demands cannot be met (see Section 4.7.2). Although this conclusion is speculative because of lack of research, it is intuitive that the costs of adaptation should depend critically on the rate of climate change.
- Impacts of climate change on agriculture after adaptation are estimated to result in small percentage changes in global income; these changes tend to be positive for a moderate global warming, especially when the effects of CO₂ fertilization are taken into account (low confidence) (see Section 5.3.5).
- The effectiveness of adaptation in ameliorating the economic impacts of climate change across regions will depend critically on regional resource endowments. It appears that developed countries will fare better in adapting to climate change; developing countries and countries in transition, especially in the tropics and subtropics, will fare worse. This finding has particularly significant implications for the distribution of impacts within developing countries, as well as between more- and less-developed countries. These findings provide evidence to support the hypothesis advanced in the SAR that climate change is likely to have its greatest adverse impacts on areas where resource endowments are poorest and the ability of farmers to respond and adapt is most limited (medium confidence) (see Section 5.3.5).
- Degradation of soil and water resources is one of the major future challenges for global agriculture (see Section 5.3.2). These processes are likely to be intensified by adverse changes in temperature and precipitation. Land use and management have been shown to have a greater impact on soil conditions than the direct effects of climate change; thus, adaptation has the potential to significantly mitigate these impacts (see Section 5.3.4). A critical research need is to assess whether resource degradation will significantly increase the risks faced by vulnerable agricultural and rural populations (see Section 5.3.6).
- It is concluded with low confidence that a global temperature rise of greater than 2.5°C will result in rising commodity prices. Similarly, a global temperature rise of greater than 2.5°C increases by 80 million the absolute number of people at risk of hunger. It should be noted, however, that these hunger estimates are based on the assumption that food prices will rise with climate change, which is highly uncertain (see Section 5.3.6).

Wildlife

Recent estimates indicate that 25% of the world's mammals and 12% of birds are at significant risk of global extinction. Climate change is only one of a long list of pressures on wildlife. Other pressures include exploitation of animals, pollution and other biochemical poisonings, extreme climatic events, wildlife diseases, collisions with towers and other structures, anthropogenic barriers to dispersal, and war and other civil conflicts. Alone or in combination, these pressures will greatly increase species' vulnerabilities to rarity and extinction (high confidence). Habitat conversion and degradation affect nearly 89% of all threatened birds and 83% of all threatened mammals. About one-fifth of threatened mammals in Australia and the Americas and the world's birds are affected by introduced species.

Impacts, Adaptations, and Vulnerabilities

- Many animals already may be responding to local climatic changes. The types of changes already observed include poleward and elevational movement of ranges, changes in animal abundance, changes in body size, and shifts in the timing of events, such as earlier breeding in spring. Possible climatically associated shifts in animal ranges and densities have been noted on many continents and within each major taxonomic group of animals (see Table 5-3).
- Laboratory and field studies have demonstrated that climate plays a strong role in limiting species' ranges (high confidence). Even though only a small fraction of all species have been monitored long enough to detect significant trends, changes exhibited over the past few decades in the bulk of these species are consistent with local warming and expected physiological responses (medium confidence). However, possible *specific* changes in wildlife from climate change can be projected only with low confidence for most species because of many possible contributing factors, such as habitat destruction and introduction of exotic species. Some species clearly are responding to global change (see Section 5.4.3), and many more changes probably have gone undetected. Researchers are in the process of coupling these discernible changes with various biological theories regarding climate and species spatial and temporal patterns; through this process, we expect that reliable *general* projections can be and in fact are being made.
- Protecting threatened and endangered species requires measures that, in general, reverse the trend toward rarity. Without management, rapid climate change—in conjunction

- with other pressures—is likely to cause many species that currently are classified as critically endangered to become extinct and several labeled endangered or vulnerable to become much rarer, and thereby closer to extinction, in the 21st century (high confidence).
- Concern over species becoming rare or extinct is warranted because of the goods and services provided by ecosystems and the species themselves. Most of the goods and services provided by wildlife (e.g., pollination, natural pest control) are derived from their roles within systems. Other valuable services are provided by species contributing to ecosystem stability or to ecosystem health and productivity. The recreational value (e.g., sport hunting, wildlife viewing) of species is large in market and nonmarket terms. Species loss also could impact the cultural and religious practices of indigenous peoples around the world. Losses of species can lead to changes in the structure and function of affected ecosystems and loss of revenue and aesthetics. Understanding the role each species plays in ecosystem services is necessary to understand the risks and possible surprises associated with species loss. Without this information, the probability of surprises associated with species loss is high (medium confidence).
 - Humans may need to adapt not only in terms of wildlife conservation but also to replace lost ecological services normally provided by wildlife. It may be necessary to develop adaptations to losses to natural pest control, pollination, and seed dispersal. Although replacing providers of these services sometimes may be possible, the alternatives may be costly. Finding replacements for other services, such as contributions to nutrient cycling and ecosystem stability/biodiversity, are much harder to imagine. In many cases, such as the values of wildlife associated with subsistence hunting and cultural and religious ceremonies, any attempt at replacement may represent a net loss. In many countries, climate change impacts, such as reductions in wildlife populations, may have the greatest impact on the lowest income groups—those with the least ability to adapt if hunting opportunities decline.

Rangelands

Most rangelands in the world have been affected by human activity, and many are degraded in some way. Desertification tends to be associated with land degradation in rangelands; however, desertification combines many land degradation processes and can be exacerbated by climate change. Many of the rangelands of the world are affected by ENSO events and are sensitive to the frequency of these events, resulting in changes in productivity of these systems.

Impacts, Adaptations, and Vulnerabilities

- Based on observations and modeling studies, the effects of elevated CO₂ and climate change could result in increased plant productivity and thus an increase in soil carbon sequestration in many rangelands. However, some of the

gains in productivity would be offset by increases in temperatures and by human management activities (medium confidence).

- Modeling studies and observations suggest that plant production, species distribution, disturbance regimes (e.g., frequencies of fires, insect/pest outbreaks), grassland boundaries, and nonintensive animal production would be affected by potential changes in climate and land use. The impacts of climate change are likely to be minor compared to those of land degradation (high confidence).
- Irrigation in semi-arid climates is a major cause of secondary salinization. Elevated CO₂ may reduce the impacts of secondary salinization, although experimental work shows that any increase in temperature may negate these benefits and may even exacerbate problems of secondary salinity (medium confidence).
- In many parts of the world that are dominated by rangelands, lack of infrastructure and investment in resource management limits available options for adaptation and makes these areas more sensitive and vulnerable to the impacts of climate change (high confidence). Some adaptation options (e.g., integrated land management) could be implemented irrespective of technology and infrastructure. Other adaptation options could be implemented through active involvement of communities in the management of rangelands.

Forests and Woodlands

Loss in forest cover appears to have slowed in recent years relative to 1980–1995. However, fragmentation, unsustainable logging of mature forests, degradation, and development of infrastructure—all leading to losses of biomass—have occurred over significant areas in developing and developed countries (high confidence). Pressure from disturbances such as fires appears to be increasing around the world. Fire suppression in temperate managed and unmanaged forests with access to infrastructure and human capital has been largely successful, but regions with comparatively less infrastructure have been more susceptible to natural and human-caused fires. Deforestation will continue to be the dominant factor influencing land-use change in tropical regions. Timber harvests near roads and mills in tropical regions are likely to continue to fragment and damage natural forests (high confidence).

Non-wood forest products (NWFP) such as edible mushrooms, nuts, fruits, palm hearts, herbs, spices, gums, aromatic plants, game, fodder, rattan, medicinal and cosmetic products, resins, and the like make important contributions to household income, food security, national economies, and the environmental objectives of conservation of biodiversity.

Impacts, Adaptations, and Vulnerabilities

- Forest response to climate change and other pressures will alter future carbon storage in forests, but the global extent and direction of change is unknown.

- Recent experimental evidence suggests that the net balance between net primary productivity (NPP—usually assumed to increase with warming, but challenged by recent studies), heterotrophic respiration (often assumed to increase with warming, but also challenged by recent studies), and disturbance releases (often ignored, but shown to be important in boreal estimates of net biome productivity) is no longer as clear as stated in the SAR.
- Research reported since the SAR confirms the view that the largest and earliest impacts induced by climate change are likely to occur in boreal forests, where changes in weather-related disturbance regimes and nutrient cycling are primary controls on productivity (high confidence). The effect of these changes on NPP and carbon storage is uncertain.
- Since the SAR, free-air CO₂ enrichment (FACE) experiments suggest that tree growth rates may increase, litterfall and fine root increment may increase, and total NPP may increase, but these effects are expected to saturate because forest stands tend toward maximum carrying capacity, and plants may become acclimated to increased CO₂ levels (medium confidence).
- Questions of saturation of the CO₂ response can be addressed through longer term experiments on tree species grown under elevated CO₂ in open-top chambers under field conditions over several growing seasons. Results from these experiments show continued and consistent stimulation of photosynthesis and little evidence of long-term loss of sensitivity to CO₂; the relative effect on aboveground dry mass was highly variable and greater than indicated by seedling studies, and the annual increase in wood mass per unit of leaf area increased (high confidence).
- Contrary to the SAR, global timber market studies that include adaptation suggest that climate change will increase global timber supply and enhance existing market trends toward rising market share in developing countries. Consumers are likely to benefit from lower timber prices; producers may gain or lose, depending on regional changes in timber productivity and potential dieback effects. Studies that do not consider global market forces, timber prices, or adaptation predict that supply in boreal regions could decline (medium confidence).
- Industrial timber harvests are predicted to increase by 1–2% yr⁻¹. The area of industrial timber plantations is likely to continue to expand, and management in second-growth forests in temperate regions is likely to continue to intensify, taking pressure off natural forests for harvests (high confidence).
- At the regional and global scale, the extent and nature of adaptation will depend primarily on wood and non-wood product prices, the relative value of substitutes, the cost of management, and technology. On specific sites, changes in forest growth and productivity will constrain—and could limit—choices of adaptation strategies (high confidence). In markets, prices will mediate adaptation through land and product management. Adaptation in managed forests will include salvaging dead and dying timber and replanting with new species that are better suited to the new climate.

Lakes and Rivers

Capture, culture, and recreational fisheries are reported to land about 23 Mt yr⁻¹ of biomass, but the actual numbers probably are twice that. Fish species in freshwater total about 11,800. High levels of endemism are common for many different groups of freshwater organisms. In addition to climatic changes, lakes and rivers are impacted by pressures such as land and water use, pollution, capture and culture fisheries, water extraction, and hydrologic engineering structures such as dams, dykes, and channelization (well established). These pressures interact with pressures from climate change and vary in their impact even at local levels mediated through changes in hydrology (medium confidence).

Impacts, Adaptations, and Vulnerabilities

- A 150-year trend in 26 lakes and rivers in the northern hemisphere averaging 9 days later freeze and 10 days earlier ice breakup has resulted from a 1.8°C increase in air temperature (very high confidence).
- Empirical and simulation studies show that elevated water temperature increases summer anoxia in deep waters of stratified lakes (high confidence).
- There has been an observed poleward movement of southern and northern boundaries of fish distributions (high confidence).
- There is a loss of habitat for cold- and coolwater fishes and gain in habitat for warmwater fishes (high confidence).
- There are complex relations between warmer temperature, more episodic rainfall, and poleward movement of warm-water zooplanktivorous fishes, which may exacerbate eutrophication of lakes and rivers (medium confidence).
- Human activities to manage water flow may exacerbate the impact on lakes and rivers (medium confidence); for example, the increase in hydrologic engineering structures is likely to result in fewer free-flowing streams (medium confidence). Attempts to manage the poleward movement of fauna and flora, especially in lakes whose isolation is likely to slow down species from moving poleward, is likely to be contentious and produce frequent surprises and unexpected dynamics of freshwater communities (medium confidence).
- New opportunities may be provided for aquaculture of warmer water species in more poleward locations (medium confidence).
- As a class of ecosystems, inland waters are vulnerable to climatic change and other pressures, owing to their small size and position downstream from many human activities (high confidence). The most vulnerable elements include reduction and loss of lake and river ice (very high confidence), loss of habitat for coldwater fish (very high confidence), increases in extinctions and invasions of exotics (high confidence), and potential exacerbation of existing pollution problems such as eutrophication, toxics, acid rain, and ultraviolet-B (UV-B) radiation (medium confidence).

Inland Wetlands

Wetlands play an important role in maintaining biological diversity by providing a habitat for many plant and animal species, some of which are endemic or endangered. They also have significant scientific value that goes beyond their plant and animal communities. Peat-accumulating wetlands are important for global change because of the large carbon store accumulated over the millennia and the risk that this store would be released to the atmosphere in conditions modified by global change. Besides being carbon sinks, wetlands are sources of methane to the atmosphere.

We can state with high confidence that the pressures of climate change on habitat, biodiversity, and carbon sink on most wetland types will be largely indirect, operating through changes in water level. On peatlands underlain by permafrost, however, direct temperature impacts can be more important. Food and fiber production are ecosystem services that simultaneously form a pressure (land-use change) on other services (habitat, biodiversity, carbon sink).

Impacts, Adaptations, and Vulnerabilities

- A warmer, drier climate is not necessarily likely to lead to a large loss of stored peat for all peatland types (e.g., boreal peatlands), but there are competing explanations because feedback mechanisms between climate and peatland hydrology and the autogenic nature of peatland development are poorly understood.
- Peatlands underlain by permafrost are likely to become net carbon sources rather than sinks, mainly because of melting of permafrost and lowering of the water table (high confidence). Work in tussock and wet tundra has shown that these systems already may be net annual sources of 0.19 Gt C.
- Extensive seasonally inundated freshwater swamps, which are major biodiversity foci, could be displaced if predicted sea-level rises of 10–30 cm by 2030 occur (high confidence).
- In the southeast Asian region, droughts in recent years related to ENSO events have lowered local water tables and thus increased the severity of fires in tropical peatlands (high confidence).
- The effects of water-level drawdown after drainage for forestry indicate that the shift in species composition from wetland species to forest species only slightly affects plant species richness of individual sites; in regions dominated by forests, however, there would be a clear reduction in regional diversity as landscapes become homogenized after water-level drawdown (medium confidence).
- Most wetland processes are dependent on catchment-level hydrology. Thus, adaptations to projected climate change may be practically impossible. For degrading key habitats, small-scale restoration may be possible if sufficient water is available.
- Arctic and subarctic ombrotrophic bog communities on permafrost, together with more southern depressional wetlands with small catchment areas, are likely to be most

vulnerable to climate change. The increasing speed of peatland conversion and drainage in southeast Asia is likely to place these areas at a greatly increased risk of fires and affect the viability of tropical wetlands.

Arctic and Alpine Ecosystems

Observations show that high-latitude warming has occurred in the Arctic region since the 1960s. Precipitation and surface evaporation have increased at high latitudes. Permafrost temperatures have warmed in western North America by 2–4°C from 1940 and in Siberia by 0.6–0.7°C from 1970 to 1990, whereas permafrost cooled in northeastern Canada. These patterns roughly parallel recent trends in air temperature. Carbon flux measurements in Alaska suggest that the recent warming trend may have converted tundra from a net carbon sink to a source of as much as 0.7 Gt C yr⁻¹. During recent decades, the peak-to-trough amplitude in the seasonal cycle of atmospheric CO₂ concentrations has increased, and the phase has advanced at arctic and subarctic CO₂ observation stations north of 55°N. This change in carbon dynamics in the atmosphere probably reflects some combination of increased uptake during the first half of the growing season—which could explain the observed increase in biomass of some shrubs, increased winter efflux, and increased seasonality of carbon exchange associated with disturbance. This “inverse” approach generally has concluded that mid-northern latitudes were a net carbon sink during the 1980s and early 1990s. At high northern latitudes, these models give a wider range of estimates; some analyses point to a net and others to a sink.

Climatic changes observed in alpine areas generally have paralleled climatic patterns in surrounding regions, with the most pronounced warming at high latitudes, in the Alps, and in Asia and the least pronounced changes in tropical alpine regions. Precipitation generally has increased, with the most pronounced changes in winter, leading to increased snow depth. Regional trends in climate have led to shrinkage of alpine and subpolar glaciers equivalent to 0.25 ± 0.1 mm yr⁻¹ of sea-level change—or 16% of the sea-level rise in the past 100 years. Net mass reduction of the alpine glaciers has been most pronounced since 1980, when regional warming was greatest. Climatic warming observed in the Alps has been associated with upward movement of some plant taxa of 1–4 m per decade on mountaintops and the loss of some taxa that formerly were restricted to high elevations. In general, direct human impacts on alpine vegetation from grazing, tourism, and nitrogen deposition are so strong that climatic effects on the goods and services provided by alpine ecosystems are difficult to detect.

Impacts, Adaptations, and Vulnerabilities

- Projected climatic warming of 4–10°C by the end of the 21st century is likely to cause substantial increases in decomposition, nutrient release, and primary production (high confidence). Many of these changes in productivity

may be threshold effects; they also may be mediated by changes in species composition and therefore are likely to lag changes in climate by years, decades, or centuries (medium confidence).

- Important changes in diversity in the Arctic include changes in the abundance of caribou, waterfowl, and other subsistence resources (medium confidence).
- Tundra has a three- to six-fold higher winter albedo than boreal forest, but summer albedo and energy partitioning differ more strongly among ecosystems within either tundra or boreal forest than between these two biomes (high confidence). Changes in albedo and energy absorption during winter are likely to act as a positive feedback to regional warming.
- Disturbances such as fires are likely to change with changes in regional climate and affect biophysical properties (high confidence).
- In alpine areas, warming is likely to create a shortened snowmelt season, with rapid water release creating floods and later growing-season droughts, affecting productivity in these areas (medium confidence).
- Changes in goods and services in alpine ecosystems are likely to be dominated by changes in land use associated with grazing, recreation, and other direct impacts because of their proximity to population centers (high confidence). Many of the alpine zones with greatest biodiversity, such as the Caucasus and Himalayas, are areas where human

population pressures may lead to most pronounced land-use change. Overgrazing, trampling, and nutrient/pollution deposition may tend to destabilize vegetation, leading to erosion and loss of soils that are the long-term basis of the productive capacity of alpine ecosystems.

- Opportunities for adapting to expected changes in Arctic and alpine ecosystems are limited because these systems will respond most strongly to globally induced changes in climate (medium confidence). Opportunities for mitigation will include protection of peatlands, yedoma sediments, and other carbon-rich areas from large-scale hydrological change, land use, and pollutant levels. Careful management of wildlife resources could minimize climatic impacts on indigenous peoples. Many Arctic regions depend strongly on one or a few resources, such as timber, oil, reindeer, or wages from fighting fires. Economic diversification would reduce the impacts of large changes in the availability or economic value of particular goods and services.
 - The goods and services provided by many Arctic regions depend on the physical integrity of permafrost and therefore are vulnerable to climate change (high confidence). The large carbon stocks in these regions are vulnerable to loss to the atmosphere as CO₂ or methane.
 - The high levels of endemism in many alpine floras and their inability to migrate upward means that these species are most vulnerable (medium confidence).
-

5.1. Introduction and Scope

Ecosystems provide many products and services that are crucial to human survival (Daily, 1997; UNEP, 1998; WRI, 2000). Ecosystems affect biogeochemical and physical feedbacks to the biosphere and atmosphere, hence are important for the functioning of the Earth's systems. Ecosystems form a landscape and are connected in many ways, often by streams, rivers, and wildlife. Thus, landscape fragmentation, along with other human activities, affects ecosystems' ability to meet human needs and will continue to do so for the future, possibly at a faster rate (UNEP, 1998). Changes in global climate and atmospheric composition are likely to have an impact on most of these goods and services, with significant impacts on socioeconomic systems (Winnett, 1998).

This chapter assesses the impacts of climate change on ecosystem goods and services from sectors such as agriculture, forests, and wetlands. Inland aquatic systems are covered from an ecosystem perspective in this chapter; hydrology and water as a physical resource are covered in Chapter 4. Marine and coastal systems are considered in Chapter 6. When ecosystems are highly managed, as in agriculture and forestry, or their goods and services are traded in markets, the social and economic consequences of climate change that naturally arise are assessed explicitly.

Biomass production, biogeochemical cycling, soil and water relationships, and animal-plant interactions (including biodiversity) are considered to be some of the major functions of ecosystems. Within these functions, various products (goods) and services can be identified, including food, fiber, fuel and energy, fodder, medicines, clean water, clean air, flood/storm control, pollination, seed dispersal, pest and disease control, soil regeneration, biodiversity, and recreation/amenity (UNEP, 1998; WRI, 2000). Society places values on these goods and services, directly or indirectly (Table 5-1). Ecosystems provide many of these goods and services simultaneously. For example, agricultural systems provide much of our food, fiber, and fuel needs and at the same time influence biogeochemical cycling, soil and water quality, and biodiversity. Many services from ecosystems lie outside market systems, making it difficult to price them (Bawa and Gadgil, 1997; Goulder and Kennedy, 1997; National Research Council, 1999). However, these nonmarket values are likely to be larger (as much as 1,000-fold; WRI, 2000) than the value of services provided by markets in total and at many specific sites (Costanza *et al.*, 1997). Although several studies estimating different values for nonmarket services from ecosystems exist (see Table 5-2), they can be applied only with low to medium confidence (Goulder and Kennedy, 1997). Valuation of ecosystem services is complex because many goods and services occur simultaneously. Thus, it is not sufficient to consider, for example, the timber value of

Table 5-1: Ecosystems function with links to good/services and possible societal value (modified from Ewel *et al.*, 1998).

Function	Goods/Service	Value ^a
Production	<ul style="list-style-type: none"> – Food – Fiber (timber and non-wood products) – Fuel – Fodder 	Direct
Biogeochemical cycling	<ul style="list-style-type: none"> – Nutrient cycling (especially N and P absorption/deposition) – Carbon sinks 	Mostly indirect, although future values have to be considered
Soil and water conservation	<ul style="list-style-type: none"> – Flood and storm control – Erosion control – Clean water – Clean air – Water for irrigation – Organic matter or sediment export – Pollution control – Biodiversity 	Mostly indirect, although future values have to be considered
Animal-plant interactions	<ul style="list-style-type: none"> – Pollination – Animal migration – Biodiversity 	Mostly indirect, future, bequest, and existence values have to be considered
Carrier	<ul style="list-style-type: none"> – Landscape connectivity – Animal migration – Biodiversity – Aesthetic/spiritual/cultural service 	Mostly indirect and existence, but bequest may have to be considered

^aValue definitions are from Pearce and Moran (1994); see Table 5-2.

Table 5-2: Examples of goods and services with possible uses and values (adapted from Pearce and Moran, 1994).

Value	Examples of Goods and Services
Direct use	Food, fiber, fuel, fodder, water supply, recreation, non-wood forest products
Indirect use	Biodiversity, biogeochemical cycles, tourism, flood and storm control, clean water supply, pollution control
Option	Future discoveries (i.e., pharmacological and biotechnological), future recreation
Bequest	Intergenerational and sustainable development
Existence	Mostly conservation, aesthetic, spiritual

the forest; we also must consider the soil/water protection that the trees provide, the habitat for pollinators, or the bequest value of the forest (WRI, 2000).

The Earth is being subjected to many human-induced and natural changes, often referred to as global change. These changes include pressures from increased demand for resources driven by economic growth, increased human population, land-use and land-cover change, the accelerated rate of anthropogenic nitrogen production and other air pollutants, and urbanization and industrialization; resulting fossil fuel emissions contribute to a discernible impact on global climate (Naiman *et al.*, 1995a; Vitousek *et al.*, 1997a; IPCC, 1998; UNEP, 1998; Walker *et al.*, 1999). For ecosystems, the impacts of climate change include changes in atmospheric composition and disturbance regimes, such as frequencies of fires, storms, floods, and drought. The impacts of other pressures often lead to increased demand for access to land, water, and wildlife resources. The result is a change in the state of the Earth's land surface, the services humans receive, and the landscapes where humans live at regional and global scales. Governance and equity issues are important (UNEP, 1998) in overcoming some of these; these are covered in detail in TAR WGIII Chapter 1.

Understanding the current status of ecosystems, pressures on them, and their responses is important for assessing the impact of the additional pressure of climate change. The State-Pressure-Response model of the Organisation for Economic Cooperation and Development (OECD) has been used as a framework in structuring many subsequent sections of this chapter (see Figure 5-1). Using this model, the "state" refers to assessments of current status and recent trends of each sector and "pressures" include direct and indirect human pressures. The concept of "response" has been modified to include automatic responses of ecosystems (referred to as automatic adaptation in Chapter 18) to the impacts of climate change (including that of natural climatic variability). Deliberate "adaptation" options to climate change to overcome some of these impacts-responses could alleviate some of the pressures. Systems that are not able to adapt are likely to become vulnerable (see Chapter 18); thus, vulnerability also is assessed.

In many sections, four goods and services have been emphasized because of the availability of literature and space constraints: food, fiber, carbon storage, and biodiversity. Many other topics—for example, related to water cycling and hydrology—could have been considered. Some of these are covered in other

chapters of this report (e.g., Chapter 4 and as key regional concerns in Chapters 10–17).

Some impacts of global change apply across many sectors and are considered in Section 5.2. Many of the impacts of climate change are projected by using models, and Section 5.2 includes a critique of several of these models. Some studies in the literature already have identified regional impacts of post-industrial climate change on some ecosystems. These are discussed in the most appropriate sections under "impacts-response" but are dealt with mainly in Sections 5.2 and 5.4.

5.2. Effects of Global Change on the Terrestrial Biosphere

Terrestrial ecosystems consist of plants, animals, and soil biota and their environment. The distribution of biota within and across ecosystems is constrained by the physical and chemical conditions of the atmosphere, the availability of nutrients and/or pollutants, and disturbances from natural origin (fire, wind-throw, etc.) or human land use. Global change affects all of these factors, but through widely differing pathways and at different scales. Global climate change, for example, affects local weather and climate in ways that are strongly dependent on location. Increased atmospheric CO₂ concentration, on the other hand, is geographically more uniform.

At the global scale, the sum of all ecosystems (including the marine biosphere) exerts a significant role on the balance of carbon and water in the atmosphere. Feedbacks exist between climate-driven changes in biospheric functioning, such as enhanced or reduced primary productivity, and the amount of greenhouse gas (GHG)-related radiative forcing. In addition, changes in land surface characteristics affect the atmosphere by altering the radiation balance at the reflective surface, creating further feedbacks. These biospheric feedbacks are discussed in TAR WGI Chapter 3.

In trying to understand the effects of global change on the biosphere as a whole, scientists often focus on higher level entities such as ecosystems or biomes (the collection of ecosystems within a particular climatic zone with similar structure but differing species—e.g., the temperate forest biome). However, all factors of change act on individual organisms that are part of a complex web of interactions within and between species and their ecosystem and within landscapes that contain

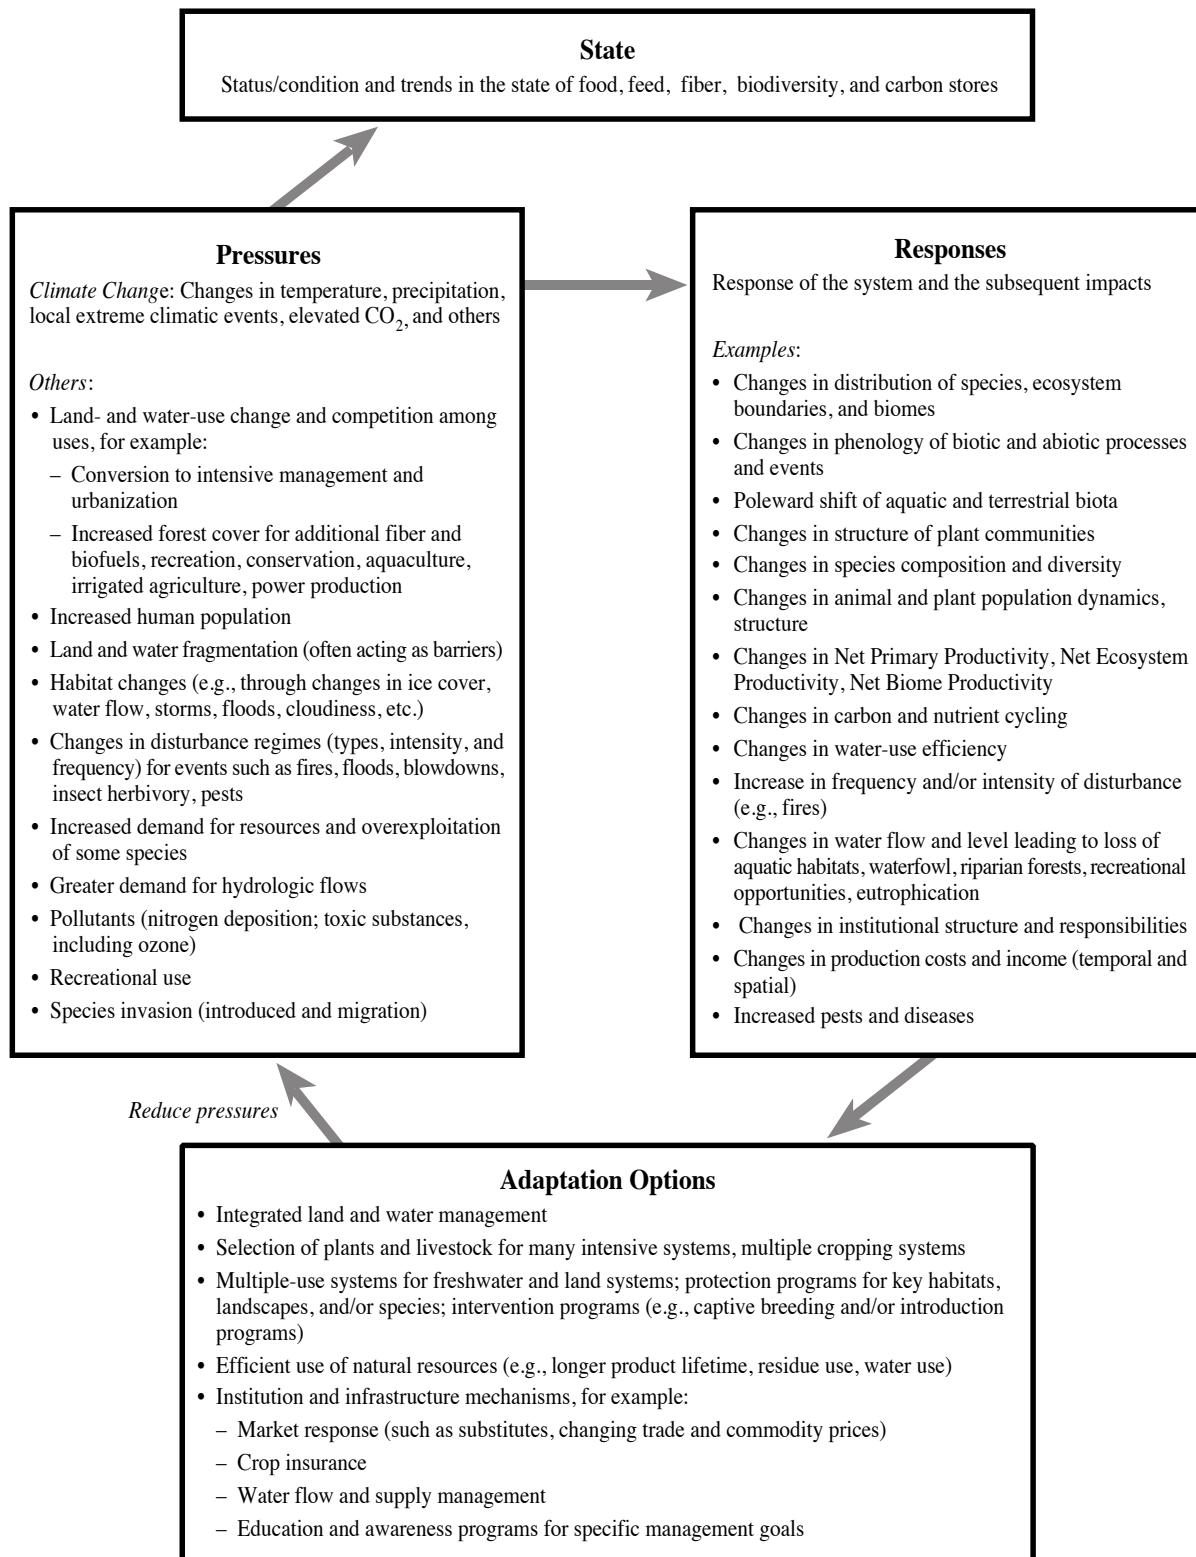

Figure 5-1: Generalized diagram of the state of specific goods and services that ecosystems provide; how these goods and services are affected by the multiple pressures of climate change and human activities; and how the system responds (autonomous adaptation as in Chapter 19), thus affecting the provision of goods and services. Adaptation options reduce the impacts and thus change the vulnerability of the system.

mosaics of different ecosystems. It is not feasible to model the impacts of global change at global, or even regional or landscape, scales at an individual-by-individual level. Thus, most models of global change have dealt with impacts at the ecosystem or biome level. This is in contrast with limitations to observational and experimental studies in which only a selection of individuals and species of a few ecosystems can be included.

5.2.1. Observational Studies

There is now a substantial number of observational and experimental studies that demonstrate the link between climate and biological or physical processes in ecosystems. The authors of this chapter assembled a database of more than 2,500 studies that address climate and either a physical process (e.g., melting of ice on lakes) or a biological factor (e.g., spring arrival time) of an animal or plant. Most of these studies address experiments that are valuable primarily in helping to

understand the biological mechanisms prompting the responses of plants and animals to climate but are not helpful in detecting patterns of change. Many of these studies were conducted over a period of shorter than 10 years. Because at least 10 years of data are needed to show a possible trend, this narrowed the number of studies to approximately 500. Because temperature is the variable that can most reliably be predicted with increasing GHGs, only studies that addressed temperature as the climatic variable were examined, leaving approximately 250 studies. All 250 studies then were examined to determine if they met at least two of the following criteria:

- The authors found a statistically significant correlation between temperature and a species trait (e.g., egg-laying date, location of range boundaries) or physical process.
- The authors found a statistically significant change in the species trait over time.
- The authors found a statistically significant change in temperature over time.

Table 5-3: The number of species and processes in each region that were found in each particular study to be significantly associated with regional temperature change. For inclusion in the table, each study had to meet two of the following three criteria: species or processes changing over time; regional temperature changing over time; and significant association between how the temperature and species or processes were changing. The first number indicates the number of species or processes changing in the manner predicted with global warming. The second number is the number of species or processes changing in a manner opposite to that predicted with a warming planet. When considering those species that have shown a change, 80% are changing in the manner expected with global warming, while 20% are changing in the opposite direction. Note that about 61 of all species examined did not show a statistically significant change. References for each cell are located below the table and collated by row number and column number (e.g., references for European birds are under E,5—row E, column 5). “—” indicates that no studies were found for this region and category.

In some cases, the criteria were met by two companion papers rather than a single paper. These criteria narrowed the qualifying studies to 60; seven were companion papers. Among the 60 studies, 16 look at physical processes, 10 examine vegetation changes, eight look at invertebrates, six investigate amphibians and reptiles, 26 examine birds, and one addresses mammals. Some of these studies investigate multiple taxa (e.g., bird and insect) in the same paper. A total of 39 physical processes, 117 plants, 65 insects, 63 amphibians and reptiles, 209 birds, and 10 mammal species were examined in the 43 studies (summarized in Table 5-3). Approximately 39% of these species showed no change. Changes in the other 61% included earlier ice-off and later freeze dates in inland lakes and streams, earlier breeding times, shifting to higher elevations or latitudes, and changes in densities, development, morphologies, and genetics.

Several lines of evidence indicate lengthening of the vegetative growing season by 1.2–3.6 days per decade in the Northern Hemisphere, particularly at higher latitudes where temperature rise also has been greatest. This lengthening involved earlier onset of spring and later onset of fall. Summer photosynthetic activity [based on Normalized Differential Vegetation Index (NDVI) estimates from satellite data] increased from 1981 to 1991 (Myneni *et al.*, 1997), concurrent with an advance (by 7 days) and an increase in amplitude of the annual CO₂ cycle since the 1960s, most intensely during the 1980s (Keeling *et al.*, 1996). Phenological/climate models for Finland indicate an overall increase in growing season length since 1900 (Carter, 1998). These physical measures are in accord with observations on organisms. In controlled, mixed-species gardens across Europe, a lengthening of the growing season by 10.8 days occurred from 1959 to 1993 (Menzel and Fabian, 1999). Likewise, a study of 36 species in the central United States documented advances in flowering dates by an average of 7.3 days from 1936 to 1998 (Bradley *et al.*, 1999).

Responses to increased atmospheric CO₂ have been detected in increased stomatal densities in the leaves of temperate woodland plants (Beerling and Kelly, 1997). Recent changes (over 9- to 30-year periods) in community composition have occurred at protected sites in the lower United States and Alaska, concurrent with local warming trends (Chapin *et al.*, 1995; Brown *et al.*, 1997a; Alward *et al.*, 1999). Results of warming experiments coupled with previous knowledge of species' habitat requirements implicate climate as one factor in these community reorganizations, but additional effects of multiple pressures have led to complex responses that were not always predicted by bioclimatic theory (Schneider and Root, 1996).

Multiple studies of treelines at high latitudes in the northern hemisphere have shown 20th century poleward shifts, often measured as increased growth at northern boundaries and decreased growth at southern boundaries. Interpretation of these trends is not straightforward because most change occurred during the early 20th century warming and the trends have been less pronounced or absent in recent warm decades (Kullman, 1986, 1990; Hamburg and Cogbill, 1988; Innes, 1991; Lescop-Sinclair and Payette, 1995; Jacoby and D'Arrigo,

1995; Briffa *et al.*, 1998). These authors have hypothesized that the general lack of response to recent warming is a result of increases in water stress, severity of insect attack, and UV radiation and trends toward earlier snowmelt or to sunlight becoming a limiting growth factor. In addition, some localities that showed warming and increased growth in the early 20th century have shown cooling and stable growth since the 1970s (Kullman, 1991, 1993). In contrast, simple predictions of range shifts have been fulfilled in alpine herbs, which have moved to higher altitudes concurrent with warming in Switzerland (Grabherr *et al.*, 1994), and loss of low-elevation pine forests in Florida as sea-level rise has caused toxic levels of salination near coastal areas (Ross *et al.*, 1994).

5.2.2. Current Models of Ecosystem Change

A large literature is developing on modeling the response of ecosystems to climate and global changes. Most of these models simulate changes in a small patch of land. These models are reviewed as appropriate in other sections of this chapter and elsewhere in this report. The focus here is on modeling changes in ecosystem composition, structure, and function at global or regional scales. There are several reasons for developing such models. One is to estimate carbon fluxes and their contribution to the global carbon cycle. This involves making estimates of NPP, net ecosystem productivity (NEP), and net biome productivity (NBP) (see Box 5-1). Another is to develop models of feedbacks

Box 5-1. Plant Productivity: Terms and Definitions

Plants are responsible for the vast majority of carbon uptake by terrestrial ecosystems. Most of this carbon is returned to the atmosphere via a series of processes, including respiration, consumption (followed by animal and microbial respiration), combustion (i.e., fires), and chemical oxidation. Gross primary productivity (GPP) is the total uptake through photosynthesis, whereas net primary productivity (NPP) is the rate of accumulation of carbon after losses from plant respiration and other metabolic processes in maintaining the plant's living systems are taken into account. Consumption of plant material by animals, fungi, and bacteria (heterotrophic respiration) returns carbon to the atmosphere, and the rate of accumulation of carbon over a whole ecosystem and over a whole season (or other period of time) is called net ecosystem production (NEP). In a given ecosystem, NEP is positive in most years and carbon accumulates, even if only slowly. However, major disturbances such as fires or extreme events that cause the death of many components of the biota release greater than usual amounts of carbon. The average accumulation of carbon over large areas and/or long time periods is called net biome productivity (NBP) (see also Box 3-1 in TAR WGI).

between the atmosphere and the land surface (Van Minnen *et al.*, 1995; Foley *et al.*, 1998). Neither of these applications are covered in detail in this chapter (see TAR WGI Chapter 3). Instead, we concentrate on their application in forecasting the impacts of climate change on biodiversity and the provision of other ecosystem goods and services.

5.2.2.1. Two Paradigms Describing Ecosystem Responses to Climate Change

There are two paradigms about the way ecosystems (thus biomes) will respond to global change. The ecosystem movement paradigm assumes that ecosystems will migrate relatively intact to new locations that are closer analogs to their current climate and environment. This paradigm clearly is a gross simplification of what will actually happen, but it has the advantage that the well-demonstrated relationship between ecosystem range and existing climate can be used to project new ecosystem distributions under changed climate scenarios.

Basic ecological knowledge suggests that the ecosystem movement paradigm is most unlikely to occur in reality because of different climatic tolerance of species involved, including intra-species genetic variability (Crawford, 1993); different longevities, including clonal regeneration (e.g., survival over 2,000 years by *Carex curvula*; Steinger *et al.*, 1996); different migration abilities (Pitelka and Plant Migration Workshop Group, 1997); and the effects of invading species (Dukes and Mooney, 1999). It is an idealized working paradigm that is useful for screening scenarios of climate change for potential significant effects.

The alternative paradigm, ecosystem modification, assumes that as climate and other environmental factors change there will be *in situ* changes in species composition and dominance. These changes will occur as some species decline in abundance or become locally extinct (Jackson and Weng, 1999) and others increase in abundance. The longevity of individuals, the age structure of existing populations, and the arrival of invading species will moderate these changes. The outcome will be ecosystem types that may be quite different from those we see today. Paleoecological data indicate that ecosystem types broadly similar to those seen today did exist in the past (Pregitzer *et al.*, 2000), but that there also occurred combinations of dominant species that are not observed today (Davis, 1981; Jablonski and Sepkoski, 1996; Ammann *et al.*, 2000; Prieto, 2000).

Numerous paleoecological studies provide evidence of important species within an ecosystem responding differently to climate change. For example, the postglacial migration pattern for Sierra lodgepole pine (*Pinus contorta* ssp. *murrayana*) was largely elevational, with little migrational lag, whereas the more widely distributed Rocky Mountain subspecies (*P. contorta* var. *latifolia*) migrated both latitudinally and elevationally (Anderson, 1996). Colinvaux *et al.* (1997) have interpreted pollen data to show that during glacial cooling, Andean vegetation did not move upslope and downslope as belts but that plant

associations were reorganized as temperature-sensitive species found different centers of distribution with changing temperature. Similarly, heat-intolerant plants have moved in and out of the Amazonian rainforests during periods of cooling and warming (Colinvaux *et al.*, 2000). Colinvaux *et al.* (2000) also argue that expulsion of heat-intolerant species from the lowland forests in this postglacial warming already is complete and that the forest property of maintaining its own microhabitat will allow high species richness to survive more global warming, provided large enough tracts of forest are conserved. This conclusion is at odds with some modeling studies (e.g., White *et al.*, 1999).

The problem with the ecological modification paradigm is that it is very difficult to use in practical forecasting of possible trends. Thus, most global and regional studies assessing the potential impacts of climate change have had to use the ecosystem paradigm, as illustrated in Box 5-2. They also tend to be limited to projecting changes in vegetation distributions, with the implicit assumption that animal populations will track the vegetation components of an ecosystem. However, observational and experimental studies show many cases in which animals are responding to climate and environmental change well before any significant changes in the vegetation (see Section 5.4).

5.2.2.2. Climate or Environment Envelope Models

Climate envelope models have been used since at least the 1980s (e.g., Box, 1981; Busby, 1988). Usually they are based on describing the climate or environment encompassing the current distribution of a species or ecosystem (the environmental envelope or climatic envelope), then mapping the location of this same envelope under a climate change scenario. Sometimes, other forms of bioclimatic correlations or categorization systems are used, but they are based on the same assumption of a close correlation between climate and ecosystems associated with it. These models are useful as a first screening device to point to potential significant changes in ecosystem composition resulting from climate change (e.g., Huntley, 1995, and Huntley *et al.*, 1995 for European plants and birds; Somaratne and Dhanapala, 1996, for Sri Lankan plants; Brereton *et al.*, 1995, for Australia mammals; Gignac *et al.*, 1998, for Canadian peatlands; Eeley *et al.*, 1999, for South African woody plants; Iverson and Prasad, 1998; Iverson *et al.*, 1999, for eastern U.S. trees).

A basic problem with these models is that every species has a “potential niche”—that is, a location in which it could survive and reproduce under the climatic conditions (Kirschbaum *et al.*, 1996). What is observed and used as the basis for the model, however, is the “realized niche,” which is a more limited area in which the species is found given the effects of competitors, predators, and diseases. If climate change results in species remaining within their potential niche and the competitors and predators change, the species may be able to survive *in situ*. In some models, some locations are predicted to have climates that are not encompassed by any of the climate envelopes of any of the vegetation types (Lenihan and Neilson, 1995). Used cautiously, however, the approach can point to

Box 5-2. Illustration of Use and Limitation of Ecosystem Movement Models

The study by Malcolm and Markham (2000) is a good example of modeling that uses the ecosystem movement paradigm, but it also demonstrates the inherent weaknesses of the approach.

The study uses two models of existing ecosystem distributions (MAPSS and BIOME3; Neilson *et al.*, 1998) and compares predicted distributions at present CO₂ levels with the equilibrium climate associated with doubled CO₂ as projected by several general circulation models (GCMs). It avoids the naive assertion that the latter climate constitutes a forecast of the future distribution of ecosystems; instead, it uses the two predictions to calculate the necessary rate of migration (m yr⁻¹) for species in the ecosystems to migrate to the new locations within 100 years (other time frames also are explored in a sensitivity analysis). It then maps these required rates to show areas where unusually high rates may be required in the future if a “climatically appropriate” ecosystem is to be established (referred to as “migration-stressed” locations).

The study predicted that about 20% of the Earth’s surface will require migration rates ≥ 1 km yr⁻¹, which is equivalent to the highest rates observed in the geological past. The effects of natural barriers (e.g., lakes) or barriers resulting from land-cover modification by humans are globally small but can be regionally significant. Their approach also gives an indication of which regions of the globe may be most likely to be migration-stressed by climate change. It shows that much of the Earth’s surface will be “stressed” in at least one of the 14 combinations of vegetation and climate models used. For some regions in the northern boreal zones of Eurasia and North America, most of the models predict such stress.

The study then goes on to deal with locations where the models predict that under climates applying a doubled CO₂ scenario, current ecosystems will fall outside their climatic range (referred to as “climate-stressed” locations). One must be careful not to attribute specific impacts or changes to climate-stressed locations. Biomes (or, more correctly, species constituting ecosystems of the biome) may be able to tolerate the new climatic conditions (i.e., new conditions fall within the potential niche) and thus may be relatively little changed. This same proviso should be applied to migration-stressed locations (i.e., existing vegetation may continue to occupy the site; thus, the migratory restriction does not come into play for decades to centuries).

The authors move on to equate climate-stressed locations with habitat loss and conclude that 36% of the land area will be affected. For aforementioned reasons, this must be regarded as an upper bound. The authors then attempt to estimate the reduction in habitat patch size by counting pixels affected by climate-stress in contiguous blocks of the same biome type, then applying a simple species area relationship to estimate species loss (see McDonald and Brown, 1992). Little reliance should be placed on these estimates given the foregoing provisos and the caveats listed by the authors themselves.

priority areas for further study. For example, Lassiter *et al.* (2000) analyzed data for 200 woody plant species in the eastern United States and found the usual result: a northward shift in predicted range. Excluding water limitations (i.e., allowing increased WUE under elevated CO₂ to compensate for a drier climate), however, most species survive in their current locations. This implies the need to better understand water-use and water-availability relationships under climate change. If species are able to persist, there may be little spread into new regions and thus little vegetation change for many decades.

In a study of 80 species of trees in the United States, using 100,000 plots to describe current distribution and importance, nearly half of the species assessed showed the potential for ecological optima to shift at least 100 km to the north (Iverson *et al.*, 1999). Whether these species will be able to achieve these potential distributions will depend on their migration rates through fragmented landscapes. When Iverson *et al.* (1999) incorporated a migration model, they found severely limited migration in regions of high forest fragmentation, particularly when the species is low in abundance near the range boundary.

Kirilenko and Solomon (1998) also have developed a bioclimate correlative model that incorporates a migration component. They demonstrate the importance of incorporating migration by showing that in simulations in which tree migration is delayed, the estimated global terrestrial carbon stock decreases by 7–34 Gt C, in contrast to an increase in carbon stock projected under nonlimiting migration (Solomon and Kirilenko, 1997).

Climate envelopes continue to be a useful tool in identifying potential changes in species distributions but are limited by the foregoing problems. Emphasis is shifting to more mechanistically based dynamic models of vegetation change that are linked directly to transient outputs from GCMs.

5.2.2.3. Toward Dynamic Global and Regional Ecosystem Models

Since the SAR, there have been significant changes in vegetation models and GCMs. A major modeling comparison project—Vegetation/Ecosystem Modeling and Analysis Project (VEMAP)—compared six equilibrium models of vegetation distribution and

biogeochemistry (VEMAPMembers, 1995). In the IPCC *Special Report on the Regional Impacts of Climate Change*, Neilson *et al.* (1998) compared two leading vegetation models (MAPSS and BIOME3) run against transient outputs from recent GCMs.

In MAPPS and BIOME3, potential vegetation is simulated by first calculating carbon flux (plant growth) on the basis of climate and hydrology information derived from the GCM. The models calculate a leaf area index that represents the capacity of the site to support plant canopy. Physiologically based rules are then used to classify the site into a vegetation type (e.g., forest, shrub, or grassland; evergreen or deciduous), leading to allocation to one of 45 vegetation types in MAPSS or 18 in BIOME3. These vegetation models are equilibrium models in that they calculate which vegetation type might be most suited to the climate and do not consider how the existing vegetation type might change to that new type. Details of the model outputs and maps are presented in IPCC (1998) and Neilson *et al.* (1998).

Neilson *et al.* (1998) compared the more recent combination of vegetation and climate models with those being used in the SAR. They found that the newer, transient GCMs produce a cooler climate than earlier versions, mostly because lag effects are simulated and the temperature does not increase to its equilibrium value within the model runs. This means that changes in predicted vegetation tend to be less than those reported in the SAR. Nevertheless, there are significant poleward shifts in cold-limited vegetation types. Vegetation types that are limited by water availability showed more complex changes, depending on the balance between precipitation change, hydrological balance, and physiological adjustment under higher CO₂.

The newer modeling combinations continue to predict significant potential changes in the distribution of most ecosystem types and increases in the area of tropical and temperate forests, but it cannot be determined whether this potential will be observed until transient (or dynamic) global vegetation models are developed. These models simulate the change in abundance of important species or “functional groups” of species on a year-by-year (or similar) basis in response to the output of the GCM (Cramer *et al.*, 1999).

Such models are being developed and used for assessments of overall carbon storage potential of the land biosphere (Cramer *et al.*, 2001), but at this stage it is too early to place much reliance on the outputs for specific biomes or ecosystems. The results show the sensitivity of ecosystems to the treatment of water use and especially the balance between changes in water availability resulting from climate change (often decreased availability in a warmer climate) and response to higher CO₂ concentrations in the atmosphere (often increased water-use efficiency). This means that model output can vary significantly, depending on the GCM used, because these models have tended to produce different interannual variability in precipitation and thus water availability. Other challenges are to simulate loss of vegetation from disturbances such as fire, blowdown, or pest attacks and migration of species or groups of species to new locations.

Van Minnen *et al.* (2000) have shown that by modifying the IMAGE2 model to include unlimited migration, limited migration and no migration result in significantly different patterns of vegetation change, especially in high-latitude regions.

5.2.3. Impacts on Biodiversity

Biodiversity is assessed quantitatively at different levels—notably at the genetic level (i.e., the richness of genetically different types within the total population), the species level (i.e., the richness of species in an area), and the landscape level (i.e., the richness of ecosystem types within a given area). Overall, biodiversity is forecast to decrease in the future as a result of a multitude of pressures, particularly increased land-use intensity and associated destruction of natural or semi-natural habitats (Heywood and Watson, 1996). The most significant processes are habitat loss and fragmentation (or reconnection, in the case of freshwater bodies); introduction of exotic species (invasives); and direct effects on reproduction, dominance, and survival through chemical and mechanical treatments. In a few cases, there might be an increase in local biodiversity, but this usually is a result of species introductions, and the longer term consequences of these changes are hard to foresee.

These pressures on biodiversity are occurring independent of climate change, so the critical question is: How much might climate change enhance or inhibit these losses in biodiversity? There is little evidence to suggest that processes associated with climate change will slow species losses. Palaeoecology data suggest that the global biota should produce an average of three new species per year, with large variation about that mean between geological eras (Sepkoski, 1998). Pulses of speciation sometimes appear to be associated with climate change, although moderate oscillations of climate do not necessarily promote speciation despite forcing changes in species’geographical ranges.

Dukes and Mooney (1999) conclude that increases in nitrogen deposition and atmospheric CO₂ concentration favor groups of species that share certain physiological or life history traits that are common among invasive species, allowing them to capitalize on global change. Vitousek *et al.* (1997b) are confident that the doubling of nitrogen input into the terrestrial nitrogen cycle as a result of human activities is leading to accelerated losses of biological diversity among plants adapted to efficient use of nitrogen and animals and microorganisms that depend on them. In a risk assessment of Switzerland alpine flora, Kienast *et al.* (1998) conclude that species diversity could increase or at least remain unchanged, depending on the precise climate change scenario used.

5.2.3.1. Global Models of Biodiversity Change

Several general principles describe global biodiversity patterns in relation to climate, evolutionary history, isolation, and so forth. These principles continue to be the subject of considerable ecological theory and testing; the Global Biodiversity Assessment

(Heywood and Watson, 1996) and the Encyclopaedia of Biodiversity (Levin, 2000) contain detailed reviews.

Kleidon and Mooney (2000) have developed a process-based model that simulates the response of randomly chosen parameter combinations (“species”) to climate processes. They demonstrate that the model mimics the current distribution of biodiversity under current climate and that modeled “species” can be grouped into categories that closely match currently recognized biomes. Sala *et al.* (2000) used expert assessment and a qualitative model to assess biodiversity scenarios for 2100. They conclude that Mediterranean climate and grassland ecosystems are likely to experience the greatest proportional change in biodiversity because of the substantial influence of all drivers of biodiversity change. Northern temperate ecosystems are estimated to experience the least biodiversity change because major land-use change already has occurred.

Modeling to date demonstrates that the global distribution of biodiversity is fundamentally constrained by climate (see Box 5-2). Future development along these lines (e.g., adding competitive relations and migration processes) could provide useful insights into the effect of climate change on biodiversity and the effects of biodiversity on fluxes of carbon and water on a global scale.

5.2.4. Challenges

There has been considerable progress since the SAR on our understanding of effects of global change on the biosphere. Observational and experimental studies of the effects of climate change on biological and physical processes have increased significantly, providing greater insights into the nature of the relationships. Greater biological realism has been incorporated into models of small patches of vegetation (point models), and more realistic biological representations have been incorporated into regional and global change models. The main improvement has been development of dynamic representations of biological processes that respond directly to climate. Nevertheless, several major challenges remain before fully effective models of the interaction between climate and biophysical processes will be available.

5.2.4.1. Landscape Processes

Most vegetation models still treat patches of vegetation as a matrix of discrete units, with little interaction between each unit. However, modeling studies (Noble and Gitay, 1996; Rupp *et al.*, 2000) have shown that significant errors in predicting vegetation changes can occur if spatial interactions of landscape elements are treated inadequately. For example, the spread of fires is partly determined by the paths of previous fires and subsequent vegetation regrowth. Thus, the fire regime and vegetation dynamics generated by a point model and a landscape model with the same ignition frequencies can be very different. There has been considerable progress in modeling of spatial

patterns of disturbances within landscapes (Bradstock *et al.*, 1998; He and Mladenoff, 1999; Keane *et al.*, 1999), but it is not possible to simulate global or regional vegetation change at the landscape scale. Thus, the challenge is to find rules for incorporating landscape phenomena into models with much coarser resolution.

Another challenge is to develop realistic models of plant migration. On the basis of paleoecological, modeling, and observational data, Pitelka and Plant Migration Workshop Group (1997) conclude that dispersal would not be a significant problem for most species in adapting to climate change, provided that the matrix of suitable habitats was not too fragmented. However, in habitats fragmented by human activities that are common over much of the Earth’s land surface, opportunities for migration will be limited and restricted to only a portion of the species pool (Björkman, 1999).

5.2.4.2. Will Organisms have to Migrate?

Section 5.2.2 raises the question of whether organisms will need to migrate under climate change or whether many species will be able to survive *in situ* under new climatic conditions (Woodward and Beerling, 1997). Some species do occupy sites that are on the limits of their physiological tolerance, and if climate change takes local climate beyond that threshold, clearly they will not be able to persist at that site (see Section 5.6 for examples). However, there is mounting paleoecological evidence of vegetation types persisting through significant climate changes.

Lavoie and Payette (1996) conclude that the stability of the black spruce (*Picea mariana* [Mill.] BSP.) forest boundary during warm and cold periods of the late Holocene [warm approximately 2,000 years before present (BP), medieval times, and this century; cold approximately 3,000 years BP, 1,300 years BP, and the Little Ice Age] demonstrates that mechanisms that allow forest boundaries to advance or retreat are not easily triggered by climatic change. The black spruce old growth forest persisted for more than 1,500 years through many variations in climate probably because of the buffering effect of the trees on the local environment (Arseneault and Payette, 1997). Only a fire in 1568 AD broke this forest influence on microclimate and local growth conditions and caused the forest vegetation to shift to krummholz. Such studies emphasize the importance of effectively incorporating sufficient biophysical detail to capture climate-ameliorating effects and realistic disturbance regimes.

5.2.4.3. Human Land-Use Issues

No projection of the future state of the earth’s ecosystems can be made without taking into account past, present, and future human land-use patterns. Human land-use will endanger some ecosystems, enhance the survival of others, and greatly affect the ability of organisms to adapt to climate change via migration.

Leemans (1999) used IMAGE2 to forecast possible global shifts in vegetation types and land-use change. Using a mid-level scenario of human responses to global change, he forecasts that nondomesticated land (his proxy for biodiversity) will decrease from 71 to 62% of the land area between 2000 and 2025, then remain approximately stable until the end of the 21st century. Losses in Africa and parts of Asia from 2000 to 2025 may be as much as 20–30% of remaining nondomesticated land.

5.2.4.4. Testing Models of Ecosystem Response

It is clear that ecosystem change models still contain assumptions that are not fully tested, and most models inevitably work better for the geographical regions and time periods for which they were constructed (Hurt et al., 1998). This derives from a mixture of fitting parameters to available data and deliberate and subconscious bias in selecting processes to include in a model. However, testing of ecosystem response models is gradually improving. Bugmann and Solomon (1995) tested the behavior of a model developed for European ecosystems by running it for a comparable North American site. The results were broadly in agreement, with useful indicators about where the model could be improved.

Another test is to compare different approaches to modeling for a particular purpose, as Yates et al. (2000) did for correlative models such as the Holdridge climatic correlation model and more mechanistic models of vegetation distribution. The strengths, weaknesses, and appropriate areas of application can be determined. Another approach is to conduct sensitivity studies in which the sensitivity of model outputs to changes in the input data and assumptions is evaluated. Hallgren and Pitman (2000) have carried out a sensitivity analysis of BIOME3 (Haxeltine and Prentice, 1996); they conclude that parameters that affect photosynthesis, water use, and NPP change the competitive interactions between specific plant groups (e.g., C₃ versus C₄ plants). Numerous studies have found that the outputs of ecosystem response models are sensitive to the precise treatment of water availability and water use by vegetation (Gao and Yu, 1998; Churkina et al., 1999; Hallgren and Pitman, 2000; Lassiter et al., 2000). This points to areas in which further development is needed.

Beerling et al. (1997) used a climate change experiment (CLIMEX) that exposed an entire catchment of boreal vegetation to elevated CO₂ and temperature for 3 years to test their Sheffield dynamic global vegetation model. There generally was a good match between observations and predictions, but longer runs of such experiments are needed to test such models thoroughly. As paleoecological data sets improve, there is increasing opportunity to test models against these data. However, this is a multiple test because the validity of paleoclimate models themselves also is under test. For example, Kohfeld and Harrison (2000) tested the ability of GCMs to describe changes in data collected for the environments of the last glacial maximum (21,000 years BP) and/or mid-Holocene (6,000 years BP). They conclude that better land-surface (including vegetation)

response models are needed to capture the detail observed in the paleoecological data.

In summary, recent studies show that the potential for significant disruption of ecosystems under climate change remains. Further development of simple correlative models that were available at the time of the SAR points to areas where ecosystem disruption and the potential for ecosystem migration are high. Observational data and newer dynamic vegetation models linked to transient climate models are refining the projections. However, the precise outcomes depend on processes that are too subtle to be fully captured by current models.

5.3. Agriculture

Conclusions regarding the consequences of climate change for the agriculture sector in the SAR (Reilly et al., 1996) provide an important benchmark for this section. The focus in this section is on basic mechanisms and processes that regulate the sensitivity of agriculture to climate change, relying mostly on research results since the SAR. Specifically, we ask how the conclusions of the SAR have stood the test of new research. Research advances since the SAR have brought several new issues to light—for example, understanding the adaptation of agriculture to climate change.

The discussion in this section is guided by the State-Pressure-Impact-Response-Adaptation model (see Figure 5-1). The pace of social, economic, and technological change in the agriculture sector will steadily transform the setting in which climate change is likely to interact with sensitive features of the food system. The current *state* of the sector and important trends that would transform it provide a baseline against which to examine the potential consequences of climate change (Section 5.3.1). Multiple *pressures* are being exerted on the agriculture sector, including the need to meet rising demand for food and fiber, resource degradation, and a variety of environmental changes (Section 5.3.2). Agricultural impacts, response, and adaptation are discussed concurrently because they are inseparable parts of the calculus of the vulnerability of agricultural systems to climate change. Hence, we consider the response and adaptive potential of agriculture in each of the succeeding sections. Agriculture is likely to *respond* initially to climate change through a series of automatic mechanisms. Some of these mechanisms are biological; others are routine adjustments by farmers and markets. Note that we equate response with automatic adaptation, as discussed in Chapter 18.

Climate change will *impact* agriculture by causing damage and gain at scales ranging from individual plants or animals to global trade networks. At the plant or field scale, climate change is likely to interact with rising CO₂ concentrations and other environmental changes to affect crop and animal physiology (Section 5.3.3). Impacts and adaptation (agronomic and economic) are likely to extend to the farm and surrounding regional scales (Section 5.3.4). Important new work also models agricultural impacts and adaptation in a global economy (Section 5.3.5).

Finally, the vulnerabilities of the agriculture sector, which persist after taking account of adaptation, are assessed (Section 5.3.6).

5.3.1. State of the Global Agricultural Sector

As Reilly *et al.* (1996) argue in the SAR, one of the foremost goals for global agriculture in coming decades will be expansion of the global capacity of food and fiber in step with expansion of global demand. Agriculture in the 20th century accomplished the remarkable achievement of increasing food supply at a faster rate than growth in demand, despite rapidly growing populations and per capita incomes. Key summary indicators of the balance between global demand and supply are world prices for food and feed grains. Johnson (1999) and Antle *et al.* (1999a) show that during the second half of the 20th century, real (inflation-adjusted) prices of wheat and feed corn have declined at an average annual rate of 1–3%. Climate change aside, several recent studies (World Bank, 1993; Alexandratos, 1995; Rosegrant *et al.*, 1995; Antle *et al.*, 1999a; Johnson, 1999) anticipate that aggregate food production is likely to keep pace with demand, so that real food prices will be stable or slowly declining during the first 2 decades of the 21st century.

According to the U.S. Department of Agriculture (1999), food security¹ has improved globally, leading to a decline in the total number of people without access to adequate food. The declining real price of food grains has greatly improved the food security of the majority of the world's poor, who spend a large share of their incomes on these staples. The global number, however, masks variation in food security among regions, countries, and social groups that are vulnerable because of low incomes or a lack of access to food (FAO, 1999a). In lower income countries, political instability and inadequate physical and financial resources are the root causes of the food security problem (see Section 5.3.6). In higher income, developing countries, food insecurity stems from unequal distribution of food that results from wide disparities in purchasing power.

Agricultural production and trade policies also affect global food availability and food security. There is a widespread tendency for high-income countries to maintain policies that effectively subsidize agricultural production, whereas low-income countries generally have policies that tax or discourage agricultural production (Schiff and Valdez, 1996). Many low-income countries also pursue policies that promote food self-sufficiency. Although all of these policies tend to reduce the efficiency of agricultural resource utilization in low- and high-income countries, they have not changed long-run trends in global supply and demand (Antle, 1996a).

Relatively few studies have attempted to predict likely paths for food demand and supply beyond 2020. There are reasons

for optimism that growth in food supply is likely to continue apace with demand beyond 2020. For example, population growth rates are projected to decline into the 21st century (Bos *et al.*, 1994; Lutz *et al.*, 1996; United Nations, 1996), and multiple lines of evidence suggest that agricultural productivity potential is likely to continue to increase. Rosegrant and Ringler (1997) project that current and future expected yields will remain below theoretical maximums for the foreseeable future, implying opportunities for further productivity growth.

Other analysts are less optimistic about long-term world food prospects. For example, there is evidence that the Asian rice monoculture may be reaching productivity limits because of adverse impacts on soils and water (Pingali, 1994). Tweeten (1998) argues that extrapolation of the downward trend in real food prices observed in the latter half of the 20th century could be erroneous because the supply of the best arable land is being exhausted and rates of productivity growth are declining. At the same time, demand is likely to continue to grow at reasonably high rates well into the 21st century. Other studies indicate concerns about declining rates of investment in agricultural productivity and their impacts on world food production in some major producing and consuming areas (Hayami and Otsuka, 1994; Rozelle and Huang, 1999). Ruttan (1996) indicates that despite advances in biotechnology, most yield improvements during the first decades of the 21st century are likely to continue to come from conventional plant and animal breeding techniques. These concerns about future productivity growth, if correct, mean that simple extrapolation of yield for impact assessment (e.g., Alexandratos, 1995) may be overoptimistic. The implication is that confidence in predictions of the world food demand and supply balance and price trends beyond the early part of the 21st century is low.

5.3.2. Pressures on Agriculture Sector

5.3.2.1. Degradation of Natural Resources

Degradation of natural resources—taken here as soils, forests, marine fisheries, air, and water—diminishes agricultural production capacity (Pinstrup-Andersen and Pandya-Lorch, 1998). Soil degradation emerges as one of the major challenges for global agriculture. It is induced via erosion, chemical depletion, water saturation, and solute accumulation. In the post-World War II period, approximately 23% of the world's agricultural land, permanent pastures, forests, and woodland were degraded as defined by the United Nations Environment Programme (UNEP) (Oldeman *et al.*, 1991). Various estimates put the annual loss of land at 5–10 Mha yr⁻¹ (Scherr and Yadav, 1997). Although irrigated land accounts for only 16% of the world's cropland, it produces 40% of the world's food. There are signs of a slowing in the rate of expansion of irrigation: 10–15% of irrigated land is degraded to some extent by waterlogging and salinization (Alexandratos, 1995). Degradation of natural resources is likely to hinder increases in agricultural productivity and could dim optimistic assessments of the prospects of satisfying growing world food demand at acceptable environmental cost.

¹Food security often is defined as “access by all peoples at all times to enough food for an active, healthy life” (Chen and Kates, 1996).

5.3.2.2. Other Global Change Factors

Regional scenarios of seasonal temperature and precipitation change for 32 world regions analyzed in Chapter 3 show the current variability of climate and the range of changes predicted by GCMs for 30-year time periods centered on 2025, 2055, and 2085. This background information is essential to interpret the potential impacts of climate change on crops and livestock production. Equally important background information is provided by agroclimatic indices. Agroclimatic indices are useful in conveying climate variability and change in terms that are meaningful to agriculture. They give a first approximation of the potential effects of climate change on agricultural production and should continue to be used (Sirotenko *et al.*, 1995; Sirotenko and Abashina, 1998; Menzhulin, 1998).

Several other climate-related global environmental changes are likely to affect the agriculture sector in coming years. Reilly *et al.* (1996) reviewed the exposure of crops to tropospheric ozone (O_3). Progress in sorting out interactions between O_3 , CO_2 , and climate variability is reviewed below.

Climate change is likely to interact with other global changes, including population growth and migration, economic growth, urbanization, and changes in land use and resource degradation. Döös and Shaw (1999) use an accounting system to estimate the sensitivity of agricultural production to various aspects of global change, including loss of cropland from soil degradation and urbanization. Imhoff *et al.* (1997) use remote-sensing techniques and soils data to show that urbanization in the United

States has occurred primarily on high-quality agricultural lands.

5.3.3. Response of Crops and Livestock and Impacts on Food and Fiber

5.3.3.1. Interaction between Rising CO_2 Concentrations and Climate Change

Advances in knowledge of CO_2 effects on crop and forage plants establish convincingly, although incompletely, that it is no longer useful to examine the impacts of climate change absent their interactions with rising atmospheric CO_2 (see Boxes 5-3 and 5-4). Crop and forage plants are likely to be forced to deal with the combined effects of climate change and rising atmospheric CO_2 concentrations. In this section, emphasis is placed on understanding basic interactions between plant productivity, climate change, and rising CO_2 concentrations. The direct effects of climate change on livestock also are considered.

5.3.3.1.1. Interactive effects of temperature increase and atmospheric CO_2 concentration

Because temperature increase enhances photorespiration in C_3 species (Long, 1991), the positive effects of CO_2 enrichment on photosynthetic productivity usually are greater when temperature rises (Bowes *et al.*, 1996; Casella *et al.*, 1996). A rise in mean global nighttime temperatures (Horton, 1995)

Box 5-3. Impacts of Climate Change and Elevated CO_2 on Grain and Forage Quality from Experimentation

The importance of climate change impacts on grain and forage quality emerges from new research. For rice, the amylose content of the grain—a major determinant of cooking quality—is increased under elevated CO_2 (Conroy *et al.*, 1994). Cooked rice grain from plants grown in high- CO_2 environments would be firmer than that from today's plants. However, concentrations of iron and zinc, which are important for human nutrition, would be lower (Seneweera and Conroy, 1997). Moreover, the protein content of the grain decreases under combined increases of temperature and CO_2 (Ziska *et al.*, 1997).

With wheat, elevated CO_2 reduces the protein content of grain and flour by 9–13% (Hocking and Meyer, 1991; Conroy *et al.*, 1994; Rogers *et al.*, 1996a). Grain grown at high CO_2 produces poorer dough of lower extensibility and decreased loaf volume (Blumentahl *et al.*, 1996), but the physiochemical properties of wheat starch during grain fill are not significantly modified (Tester *et al.*, 1995). Increases in daily average temperatures above 30°C, even applied for periods of up to 3 days, tend to decrease dough strength (Randall and Moss, 1990). Hence, for breadmaking, the quality of flour produced from wheat grain developed at high temperatures and in elevated CO_2 degrades.

With high-quality grass species for ruminants, elevated CO_2 and temperature increase have only minor impacts on digestibility and fiber composition of cut material (Akin *et al.*, 1995; Soussana *et al.*, 1997). The large increase in water-soluble carbohydrates in elevated CO_2 (Casella and Soussana, 1997) could lead to faster digestion in the rumen, whereas declines in nitrogen concentration occurring mainly with C_3 species (Owensby *et al.*, 1994; Soussana *et al.*, 1996; Read *et al.*, 1997) reduce the protein value of the forage. The protein-to-energy ratio has been shown to be more critical in tropical climates than in temperate countries (Leng, 1990). Livestock that graze low protein-containing rangeland forage therefore may be more detrimentally affected by increased C:N ratios than energy-limited livestock that graze protein-rich pastures (Gregory *et al.*, 1999). Basically, lowering of the protein-to-energy ratio in forage could reduce the availability of microbial protein to ruminants for growth and production, leading to more inefficient utilization of the feed base and more waste, including emissions of methane.

Box 5-4. Elevated CO₂ Impacts on Crop Productivity: Recent Estimates with Field-Grown Crops under FACE Experimentation

The short-term responses to elevated CO₂ of plants grown in artificial conditions are notoriously difficult to extrapolate to crops in the field (Körner, 1995a). Moreover, with field-grown plants, enclosures tend to modify the plant's environment (Kimball *et al.*, 1997). However, even the most realistic free-air CO₂ enrichment (FACE) experiments undertaken to date create a modified area (Kimball *et al.*, 1993), analogous to a single irrigated field in a dry environment, and impose an abrupt change in CO₂ concentration. A cotton crop exposed to FACE increased biomass and harvestable yield by 37 and 48%, respectively, in elevated (550 ppm) CO₂. This effect was attributed to increased early leaf area, more profuse flowering, and a longer period of fruit retention (Mauney *et al.*, 1994). At 550 ppm CO₂, spring wheat increased grain yields by 8–10% under well-watered conditions (Pinter *et al.*, 1996). More recent studies with optimal nitrogen and irrigation increased final grain yield by 15 and 16% for two growing seasons at elevated CO₂ concentration (550 ppm), compared with control treatments (Pinter *et al.*, 1996). If these latter results are linearly extrapolated to the possible effect of a doubling (700 ppm) of the current atmospheric CO₂ concentration, yields under ideal conditions would be 28% greater—in agreement with previous statements by Reilly *et al.* (1996). In grass-clover mixtures, the proportion of legume increased significantly under elevated CO₂ (Hebeisen *et al.*, 1997)—a conclusion also reached by several experimental studies with temperate and fertile managed grasslands (Newton *et al.*, 1996; Soussana and Hartwig, 1996; Stewart and Potvin, 1996).

could enhance carbon losses from crops by stimulating shoot dark respiration (Amthor, 1997). Despite possible short-term effects of elevated CO₂ on dark respiration (Amthor, 1997; Drake *et al.*, 1997), the long-term ratio of shoot dark respiration to photosynthesis is approximately constant with respect to air temperature and CO₂ concentration (Gifford, 1995; Casella and Soussana, 1997). With moderate temperatures, long-term doubling of current ambient CO₂ under field-like conditions leads to a 30% enhancement in the seed yield of rice, despite a 5–10% decline in the number of days to heading (Horie *et al.*, 2000). The grain yield of CO₂-enriched rice shows about a 10% decline for each 1°C rise above 26°C. This decline is caused by a shortening of growth duration and increased spikelet sterility. Similar scenarios have been reported for soybean and wheat (Mitchell *et al.*, 1993; Bowes *et al.*, 1996). With rice, the effects of elevated CO₂ on yield may even become negative at extremely high temperatures (above 36.5 °C) during flowering (Horie *et al.*, 2000). However, in some cropping systems with growth in the cooler months, increased rates of phenological development with warm

temperatures and/or earlier planting dates may tend to move the grain fill period earlier into the year during the cooler months, offsetting at least part of the deleterious effects of higher temperatures (Howden *et al.*, 1999a).

5.3.3.1.2. Interactive effects of water availability and atmospheric CO₂ concentration

Although stomatal conductance is decreased under elevated CO₂, the ratio of intercellular to ambient CO₂ concentration usually is not modified, and stomata do not appear to limit photosynthesis more in elevated CO₂ compared to ambient CO₂ (Drake *et al.*, 1997). Elevated-CO₂ effects on crop evapotranspiration per unit land area (E) have been small with cotton (Dugas *et al.*, 1994; Hunsaker *et al.*, 1994; Kimball *et al.*, 1994) and spring wheat (Kimball *et al.*, 1995, 1999) crops supplied with ample nitrogen fertilizer. With rice, under field-like conditions, CO₂ enrichment reduced seasonal total E by 15% at 26°C but increased E by 20% at 29.5°C (Horie *et al.*, 2000). A larger decline (-22%) in the daily E of a C₄-dominated tallgrass prairie was reported by Ham *et al.* (1995), and a strong reduction in water use per plant also was observed for maize (Samarakoon and Gifford, 1996), a C₄ plant. The consequences of these direct effects of elevated CO₂ concentrations on E are still unclear at the catchment scale (see Section 4.3.3).

Relative enhancement of growth owing to CO₂ enrichment might be greater under drought conditions than in wet soil because photosynthesis would be operating in a more CO₂-sensitive region of the CO₂ response curve (André and Du Cloux, 1993; Samarakoon and Gifford, 1995). In the absence of water deficit, C₄ photosynthesis is believed to be CO₂ saturated at present atmospheric CO₂ concentration (Bowes, 1993; see also Kirschbaum *et al.*, 1996). However, as a result of stomatal closure, it can become CO₂-limited under drought. Some of the literature examples in which C₄ crop species, such as maize, have responded to elevated CO₂ may have involved (possibly unrecognized) minor water deficits (Samarakoon and Gifford, 1996). Therefore, CO₂-induced growth enhancement in C₄ species (e.g., Poorter, 1993) may be caused primarily by improved water relations and WUE (Samarakoon and Gifford, 1996) and secondarily by direct photosynthetic enhancement and altered source-sink relationships (Ruget *et al.*, 1996; Meinzer and Zhu, 1998). With rice, at the optimal temperature for growth, a doubling of CO₂ increases crop WUE by about 50%. However, this increase in WUE declines sharply as temperature increases beyond the optimum (Horie *et al.*, 2000). Although increased productivity from increased WUE is the major response to elevated CO₂ in a C₃ or C₄ crop that is exposed frequently to water stress (Idso and Idso, 1994; Ham *et al.*, 1995; Drake *et al.*, 1997), changes in climatic factors (temperature, rainfall) may interact with elevated CO₂ to alter soil water status, which in turn will influence hydrology and nutrient relations. Therefore, to realistically project impacts on crop yields and regional evaporation (see Chapter 4), more research is needed on the interactions of elevated CO₂, high temperature, and precipitation.

5.3.3.1.3. Interactive effects of atmospheric chemistry and CO₂ concentration

An exposure-response model that linearly relates a change in gas exposure over a time period to log-scale change in biomass increment of a plant during the same period suggests that a decline in recent yields of grain crops caused by an increase in surface ozone concentrations may have reached 20% in some parts of Europe (Semenov *et al.*, 1997, 1998, 1999). Recent research has shown that multiple changes in atmospheric chemistry can lead to compensating or synergistic effects on some crops. Heagle *et al.* (1999) used field studies to examine the impact of higher O₃ levels on cotton growth under higher CO₂ conditions. They found that higher CO₂ compensates for growth suppression resulting from elevated O₃ levels. With wheat, elevated CO₂ fully protects against the detrimental effects of O₃ on biomass but not yield (McKee *et al.*, 1997). Similar results have been reported with soybean (Fiscus *et al.*, 1997) and tomato (Reinert *et al.*, 1997). Meyer *et al.* (1997) measured responses of spring wheat to different levels of ozone in chambers at different growth stages and found that photosynthesis and carbohydrate accumulations were strongly affected during anthesis, especially after a period of heat stress.

Mark and Tevini (1997) observed combined effects of UV-B, temperature, and CO₂ in growth chambers in seedlings of sunflower and maize. They found that a 4°C rise in daily maximum temperature (from 28 to 32°C), with or without higher CO₂, compensated for losses from enhanced UV-B. Teramura *et al.* (1990) report that yield increases with elevated CO₂ are suppressed by UV-B more in cereals than in soybean; rice also loses its CO₂-enhanced WUE. However, Unsworth and Hogsett (1996) assert that many research studies from the preceding decade used unrealistic UV-B exposures, and they conclude that UV-B does not pose a threat to crops alone or in combination with other stressors.

5.3.3.2. Interactive Effects of CO₂ Concentrations, Climate Change, Soils, and Biotic Factors

5.3.3.2.1. Interactive effects of CO₂ concentrations with soils

There is not yet any clear consensus regarding the magnitude and sign of interactions between elevated CO₂ and nutrient availability for crop growth. Reviews of available data indicate that, on average, plants grown at high nutrient supply respond more strongly to elevated CO₂ than nutrient-stressed plants (Poorter, 1993, 1998). Nevertheless, the current rise in atmospheric CO₂ concentration may help plants cope with soil nutritional deficiencies (Idso and Idso, 1994) and especially with low nitrogen availability (Lloyd and Farquhar, 1996; Drake *et al.*, 1997). Several authors emphasize that a strong increase in biomass production under elevated CO₂ cannot be sustained in low fertilizer input systems without an appropriate increase in nutrients assimilation (Comins and McMurtrie, 1993; Gifford, 1994; Schimel, 1998). When other nutrients are not strongly limiting, a decline in nitrogen availability could be prevented

by an increase in biological N₂ fixation under elevated CO₂ (Gifford, 1992, 1994). In fertile grasslands, legumes benefit more from elevated CO₂ than nonfixing species, resulting in significant increases in symbiotic N₂ fixation (Soussana and Hartwig, 1996; Zanetti *et al.*, 1996).

Plants grown under elevated CO₂ generally increase the allocation of photosynthates to roots (Rogers *et al.*, 1996b; Murray, 1997), which increases the capacity and/or activity of belowground carbon sinks (Rogers *et al.*, 1994; Canadell *et al.*, 1996; Körner, 1996), enhancing root turnover (Pregitzer *et al.*, 1995; Loiseau and Soussana, 1999b), rhizodeposition (Cardon, 1996), and mycorrhizal development (Dhillon *et al.*, 1996) in some but not all systems. Some measurements also have shown an increase in soil N cycling (Hungate *et al.*, 1997a), in response to short-term enrichment in CO₂, although other studies have shown either no detectable change (Prior *et al.*, 1997) or even a reduction in soil N mineralization (Loiseau and Soussana, 2001). The relationships between C and N turnover in soils after exposure to elevated CO₂ therefore are not fully understood, and it is still a matter of debate whether the availability of soil nitrogen for crop plants is reduced after a step increase in atmospheric CO₂ concentration.

Soil organic carbon (SOC) stocks result from the balance between inputs and decomposition of soil organic matter (SOM). Residues of cotton (Torbert, *et al.*, 1995), soybean, and sorghum (Henning *et al.*, 1996) display increased C:N ratios from growth under elevated CO₂, which may reduce their rate of decomposition in the soil and lead to an increment in ecosystem carbon stocks, similar to that observed in fertile grasslands (Casella and Soussana, 1997; Loiseau and Soussana, 1999a). However, some studies (Newton *et al.*, 1996; Ross *et al.*, 1996, Hungate *et al.*, 1997b) suggest higher carbon turnover rather than a substantial net increase in soil carbon under elevated CO₂. Predicted increased air and soil temperatures can be expected to increase the mineralization rate of SOM fractions that are not physically or chemically protected. The degree of protection of SOM varies with several soil-specific factors, including structure, texture, clay mineralogy, and base cation status. This may lead in the long term to negative effects on structural stability, water-holding capacity, and the availability of certain nutrients in the soil (see Reilly *et al.*, 1996). Organic matter decomposition tends to be more responsive than NPP to temperature, especially at low temperatures (Kirschbaum, 2000). Within this range, any warming would stimulate organic matter decomposition (carbon loss) more than NPP (carbon gain); the net response would be a loss of soil carbon. Mineralization rates also are influenced by soil water content. For example, lower soil moisture in Mediterranean regions (see Chapter 3) would compensate temperature increase effects on carbon and nitrogen mineralization (Leiros *et al.*, 1999).

As a result of these interactions with soil processes, experiments that impose sudden changes in temperature or CO₂ and last only a few years are unlikely to predict the magnitude of long-term responses in crop productivity, soil nutrients (Thornley and Cannell, 1997), and carbon sequestration (Luo and Reynolds,

1999). This may imply—in agreement with Walker *et al.* (1999)—that the actual impact of elevated CO₂ on crop yields in farmers' fields could be less than in earlier estimates that did not take into account limitations of nutrient availability and plant-soil interactions.

5.3.3.2.2. Interactions between effects of climate change and soil degradation

Land management will continue to be the principal determinant of SOM content and susceptibility to erosion during the next few decades, but changes in vegetation cover resulting from short-term changes in weather and near-term changes in climate are likely to affect SOM dynamics and erosion, especially in semi-arid regions (Valentin, 1996; Gregory *et al.*, 1999).

The severity, frequency, and extent of erosion are likely to be altered by changes (see Table 3-10) in rainfall amount and intensity and changes in wind (Gregory *et al.*, 1999). Models demonstrate that rill erosion is directly related to the amount of precipitation but that wind erosion increases sharply above a threshold windspeed. In the U.S. corn belt, a 20% increase in mean windspeed greatly increases the frequency with which the threshold is exceeded and thus the frequency of erosion events (Gregory *et al.*, 1999). Thus, the frequency and intensity of storms would have substantial effects on the amount of erosion expected from water and wind (Gregory *et al.*, 1999). Different conclusions might be reached for different regions. Thus, before predictions can be made, it is important to evaluate models for erosion and SOM dynamics (Smith *et al.*, 1997). By reducing the water-holding capacity and organic matter contents of soils, erosion tends to increase the magnitude of nutrient and water stress. Hence, in drought-prone and low-nutrient environments such as marginal croplands, soil erosion is likely (high confidence) to aggravate the detrimental effects of a rise in air temperature on crop yields.

5.3.3.2.3. Interactions with weeds, pests, and diseases

Modest progress has been made in understanding of pest (weeds, insects, pathogens) response to climate change since the SAR. Oerke *et al.* (1995) estimate preharvest losses to pests in major food and cash crops to be 42% of global potential production. Rosenzweig *et al.* (2000) suggest that ranges of several important crop pests in the United States have expanded since the 1970s, including soybean cyst nematode and corn gray leaf blight; these expansions are consistent with enabling climate trends, although there are competing explanations. Promising work linking generic pest damage mechanisms with crop models is reported by Teng *et al.* (1996). For example, Luo *et al.* (1995) linked the BLASTSIM and CERES-RICE models to simulate the effects of climate change on rice leaf blast epidemics. They found that elevated temperature increases maximum blast severity and epidemics in cool subtropical zones; it inhibits blast development in warm humid subtropics. Such model linkages have been used to examine climate

change impacts on weed-crop competition (e.g., for rice-weed interactions see Graf *et al.*, 1990) and insect pests (Venette and Hutchison, 1999; Sutherst *et al.*, 2000). Any direct yield gain caused by increased CO₂ could be partly offset by losses caused by phytophagous insects, pathogens, and weeds. Fifteen studies of crop plants showed consistent decreases in tissue nitrogen in high CO₂ treatments; the decreases were as much as 30%. This reduction in tissue quality resulted in increased feeding damage by pest species by as much as 80% (Lincoln *et al.*, 1984, 1986; Osbrink *et al.*, 1987; Coviella and Trumble, 1999). Conversely, seeds and their herbivores appear unaffected (Akey *et al.*, 1988). In general, leaf chewers (e.g., lepidoptera) tend to perform poorly (Osbrink *et al.*, 1987; Akey and Kimball, 1989; Tripp *et al.*, 1992; Boutaleb Joutei *et al.*, 2000), whereas suckers (e.g., aphids) tend to show large population increases (Heagle *et al.*, 1994; Awmack *et al.*, 1997a; Bezemer and Jones, 1998)—indicating that pest outbreaks may be less severe for some species but worse for others under high CO₂. It is important to consider these biotic constraints in studies on crop yield under climate change. Nearly all previous climate change studies excluded pests (Coakley *et al.*, 1999).

5.3.3.3. Impacts on Livestock

Recent research supports the major conclusions of Reilly *et al.* (1996) on animal husbandry. Farm animals are affected by climate directly and indirectly. Direct effects involve heat exchanges between the animal and its environment that are linked to air temperature, humidity, windspeed, and thermal radiation. These linkages influence animal performance (e.g., growth, milk and wool production, reproduction), health, and well-being. Indirect effects include climatic influences on quantity and quality of feedstuffs such as pastures, forages, and grain and the severity and distribution of livestock diseases and parasites. When the magnitudes (intensity and duration) of adverse environmental conditions exceed threshold limits with little or no opportunity for relief (recovery), animal functions can become impaired by the resulting stress, at least in the short term (Hahn and Becker, 1984; Hahn and Morrow-Tesch, 1993; Hahn, 1999). Genetic variation, life stage, and nutritional status also influence the level of vulnerability to potential environmental stresses. These relationships form the basis for developing biological response functions that can be used to estimate performance penalties associated with direct climate factors (Hahn, 1976, 1981, 1995). Earlier work (Hahn *et al.*, 1992; Klinedinst *et al.*, 1993) used such response functions with the Goddard Institute for Space Studies (GISS), Geophysical Fluid Dynamics Laboratory (GFDL), and United Kingdom Meteorological Office (UKMO) scenarios and found substantial reductions in dairy cow performance with climate change. For example, milk production of moderate- to high-producing shaded dairy cows in hot/hot-humid southern regions of the United States might decline an additional 5–14% beyond expected summer reductions. Conception rates of dairy cows were reduced by as much as 36% during the summer season in the southeastern United States. Short-term extreme events (e.g., summer heat waves, winter storms) can result in

the death of vulnerable animals (Balling, 1982; Hahn and Mader, 1997; Hahn, 1999), which can have substantial financial impacts on livestock producers.

5.3.3.4. Response of Plant Crops and Possible Adaptation Options

Very little work has investigated prospects for natural adaptation of crop species to climate change, and the results of the few studies that do have been inconclusive. However, there appears to be a wide range of resistance to high-temperature stress within and among crop species. For example, moderately large genetic variation in the tolerance to high-temperature induced spikelet sterility has been reported among and between indica- and japonica-type rice genotypes (Matsui *et al.*, 1997). Some rice cultivars have the ability to flower early in the morning, thereby potentially avoiding the damaging effects of higher temperatures later in the day (Imaki *et al.*, 1987).

Prospects for managed genetic modification appear to be more optimistic than for natural adaptation. Intraspecific variation in seed yield of soybean in response to elevated CO₂ was observed by Ziska *et al.* (1998). Differences in carbon partitioning among soybean cultivars may influence reproductive capacity and fecundity as atmospheric CO₂ increases, with subsequent consequences for future agricultural breeding strategies (Ziska *et al.*, 1998). However, no significant intraspecific variability in responses to elevated CO₂ was detected in studies with wheat and temperate forage species (Lüscher and Nösberger, 1997; Batts *et al.*, 1998). To promote adaptation to an environment of high CO₂ and high temperature, plant breeders have suggested selection of cultivars that exhibit heat tolerance during reproductive development, high harvest index, small leaves, and low leaf area per unit ground (to reduce heat load) (Hall and Allen, 1993). However, prospects to improve adaptation of crop species to elevated CO₂ remain very uncertain, and more research in this direction is required.

5.3.4. Impacts and Adaptation at Farm to Subnational Regional Scales

5.3.4.1. Modeling Crop Yield Impact

The number of studies that model the yield impacts of climate change (with and without CO₂ direct effects and with and without adaptation) across individual sites in regions has continued to grow since the SAR. Of particular note is the expansion of studies that explicitly model the effects of change in climate variability and means simultaneously versus change in climate means only (Southworth *et al.*, 1999), use transient climate change scenarios, and report modeling of agronomic and socioeconomic adaptation. A selection of major global and regional model-based studies reported since the SAR is summarized in Table 5-4.

Table 5-4 yields are reported as ranges of percentage change over the climate change scenarios, modeling sites, and crop as

noted. Thirteen of the yield ranges—without adaptation—are from studies of tropical crops. Of the 13 ranges, 10 encompass changes that are exclusively lower than current yields. In three ranges, a portion of the range is approximately no different from current yields or slightly above. In the tropics, most crops are at or near theoretical temperature optima, and any additional warming is deleterious to yields. Thirty ranges of percentage changes in temperate crop yields also appear in Table 5-4. Of these 30 ranges, six encompass changes that are exclusively higher than current yields. In another seven, half or more of the changes were more than current yields. In yet another seven, less than half of the changes extended above current yields. The remaining 10 ranges encompassed changes that were exclusively less than current yields. Hence, in two-thirds of the cases, temperate crop yields benefited at least some of the time from climate change.

New work on climate change scenarios (Mitchell *et al.*, 2000) generated with stabilized radiative forcing at 550 and 750 ppm equivalent-CO₂ and unstabilized radiative forcing (i.e., unmitigated emissions) in the HadCM2 model simulated major cereal yield response globally in 2080 (Arnell *et al.*, 2001). The pattern of yield changes with unstabilized forcing duplicates the pattern described above: Generally positive changes at mid- and high latitudes overshadowed by reductions in yields at low latitudes. Stabilization at 550 ppm ameliorates yield reductions everywhere, although substantial reductions persist in many low-latitude countries. Stabilization at 750 ppm produces a pattern of yield response that is intermediate relative to the 550 ppm and unstabilized forcing scenarios, with anomalous yield increases in mid-latitudes relative to 550 ppm as a result of interactions between atmospheric CO₂, temperature, and moisture. More studies are needed before confidence levels can be assigned to understanding of the agricultural consequences of stabilization, although this work is an important step.

In all agricultural regions, the effects of natural climate variability are likely to interact with human-induced climate change to determine the magnitude of impacts on agricultural production. Some analyses postulate an increase in weather variability (Mearns *et al.*, 1992, 1995; Rosenzweig *et al.*, 2000); simulations of wheat growth indicate that greater interannual variation of temperature reduces average grain yield (Semenov and Porter, 1995). Hulme *et al.* (1999) simulated natural climate variability in a multi-century control climate for comparison with changed variability in a set of transient climate change simulations. Wheat yields were simulated with control and climate change scenarios. For some regions, the impacts of climate change on wheat yields were undetectable relative to the yield impacts of the natural variability of the control climate (see Table 5-4). Greater efforts to take account of the “noise” of natural climate variability are indicated (Semenov *et al.*, 1996).

The importance of diurnal climate variability has emerged since the SAR (Reilly *et al.*, 1996). Cold temperatures presently limit the yield of rice in all temperate rice-growing regions. Jacobs and Pearson (1999) provide new field results on irreversible

Table 5-4: Recent agricultural studies: a) studies with explicit global economics and/or global yields; b) studies of yield and production in developed regions, nations, and subnational regions; and c) studies of yield and production in economies-in-transition and developing regions, nations, and subnational regions.

Study	Scope	Crops	Climate Scenario ^a	Yield Impact w/o Adaptation ^b	Yield Impact w/ Adaptation ^b	Socioeconomic Impact	Comments
<i>a) Studies with Explicit Global Economics and/or Global Yields</i>							
Parry <i>et al.</i> (1999)	Global	Wheat, rice, maize, soybeans	Transient scenarios: 4 HadCM2 ensemble scenarios, 1 HadCM3 (both assume IS92a forcing)	All cereals by 2080s: NA (-10 to +3%); LA (-10 to +10%); WE (0 to +3%); EE (-10 to +3%); AS (-10 to +5%); AF (-10 to +3%)	By the 2080s: production (-4 to -2%), cereal prices (+13 to +45%), number of people (+13 to +45%), at risk of hunger (+36 to +50%)	Farm-level adaptations (changes in plant date, varieties, irrigation, fertilizer); economic adjustments (increased investment, reallocation of resources, more land in production); no feedback between economic adjustments and yields; CO ₂ direct effects included	
Darwin <i>et al.</i> (1995)	Global	13 commodities	UKMO, GISS	Agriculture prices [wheat (-10 to -3%), other grains (-6 to -4%)]; global GDP (+0.3 to +0.4%)	Adaptation through market-induced land-use change; CO ₂ effect not included		
Darwin (1999)	Global	Same as Darwin <i>et al.</i> (1995)	OSU, GFDL, GISS, UKMO	Qualitative impacts: world (positive for temperature change <2°C, negative for temperature change >2°C), regional (positive for high latitudes, negative for tropics)	Same as Darwin <i>et al.</i> (1995)		
Darwin and Kennedy (2000)	Global	Same as Darwin <i>et al.</i> (1995)	CO ₂ effect on yields only, no climate change	Yield changes with full CO ₂ effect: wheat (7%), rice (19%), soybeans (34%), other crops (25%)	Previous studies' estimates of economic value of CO ₂ fertilization effect overstated by 61–166%	Scenarios run for CO ₂ effect on yields ranging from very low to full effect	
Adams <i>et al.</i> (1998)	USA	Various	+2.5°C, +7% ppt.; +5°C, +0% ppt.	Agricultural price changes (-19 to +15%), GDP (+0 to +0.8%)	Includes direct effects of CO ₂		

effects and retardation (but recoverable) impacts of cold temperatures on various physiological processes in rice. On the other hand, rice spikelet sterility above 35°C at flowering

(usually during daytime) puts rice at risk from increased daily maximum temperatures (Horie *et al.*, 1996). In light of recent observed rises in temperatures that are larger for daily minima

Table 5-4 (continued)

<i>a) Studies with Explicit Global Economics and/or Global Yields (continued)</i>							
Yates and Strzepek (1998)	Egypt	Wheat, rice, maize, soybean, fruit	GFDL and UKMO 2xCO ₂ equilibrium scenarios, GISS-A transient scenario at 2xCO ₂	Yield changes: wheat (-51 to -5%), rice (-27 to -5%), maize (-30 to -17%), soybean (-21 to -1%), fruit (-21 to -3%)	Yield changes: wheat (-25 to -3%), rice (-13 to -3%), maize (-15 to -8%), soybean (-10 to 0%), fruit (-10 to -2%)	Change in selected economic indicators ^d : consumer-producer surplus (-3 to +6%), calories per day (-1 to +5%), trade balance (-15 to +36%)	Includes direct effects of CO ₂ ; adaptations (shift in plant date, increased fertilizer, new varieties)
Rosenzweig and Iglesias (1998)	global (same sites as Parry <i>et al.</i> , 1999)	Wheat, rice, soybean, maize	Sensitivity analysis (+2, +4°C)	+2°C ^e [<+8% (maize) to +16% (soybean)]; +4°C ^e [-8% (rice) to -2% (wheat)]	Adaptation more successful at high and mid-latitudes than at low latitudes		Includes direct effects of CO ₂ ; transient yield response highly nonlinear
			GISS-A transient scenario, GISS 2xCO ₂ scenario	Wheat ^f [2050 (-18 to +25%), 2xCO ₂ (-32 to +27%)]; maize ^f [2050 (-26 to +13%), 2xCO ₂ (-35 to +23%)]; soybean ^f [2050 (+23 to +24%), 2xCO ₂ (+13 to +17%)]			

than daily maxima (Easterling *et al.*, 1997), Dhakhwa *et al.* (1997) and Dhakhwa and Campbell (1998) conclude that, compared to equal day-night warming, differential warming leads to less water loss through evapotranspiration and better WUE. This is likely to lead to enhanced photosynthesis, crop growth, and yield—although at a possible loss of nutritional quality (Murray, 1997). Possible reduction of frost incidence is not normally considered in these studies. On the negative side, higher nighttime temperatures could extend the overwintering range for some insect pests and broaden the range of other temperature-sensitive pathogens.

Substantial progress has been made in development of transient (time-evolving) scenarios of climate change for use in agricultural impact assessment. An important question arises regarding whether 2 years with exactly the same climate, one produced by a transient scenario and the other by an equilibrium scenario, would give different production system responses. Many crop models contain cumulative functions that retain environmental information over several years (e.g., water balance, soil nutrients). This factor alone could account for substantial yield response

differences between transient and equilibrium climate change scenarios. Only a few studies deliberately have compared simulated yields with transient and equilibrium climate change scenarios. Using the UKHIV equilibrium scenario with increased interannual variability at Rothamsted, Semenov *et al.* (1996) simulate a loss of wheat yield relative to current with two crop models and no change with a third. With the UKTR transient scenario, all three models show yield increases relative to current climate. The U.S. Country Studies Program (Smith *et al.*, 1996a) used the Clouds and Earth's Radiant Energy System (CERES) model to simulate larger average increases in winter wheat across Kazakhstan with the GFDL transient climate change scenario (for the 10th decade) (+21% winter wheat yield) than the GFDL equilibrium scenario (+17% winter wheat yield). Spring wheat yields decreased with both scenarios; again, however, yields simulated with the transient climate change were not as adversely affected as those simulated with the equilibrium climate change. Rosenzweig and Iglesias (1998) also found that wheat, maize, and soybean yields are less adversely affected by transient climate change than equilibrium climate change. Lack of consistency

Study	Scope	Crops	Climate Scenario ^a	Yield Impact w/o Adaptation ^b	Yield Impact w/ Adaptation ^b	Socioeconomic Impact	Comments
<i>a) Studies with Explicit Global Economics and/or Global Yields (continued)</i>							
Winters <i>et al.</i> (1999)	Africa, Asia, Latin America	Maize, rice, wheat, coarse grains, soybean, “cash crops”	GISS, GFDL, UKMO	<i>Africa</i> [maize (-29 to -23%), rice (0%), wheat (-20 to -15%), coarse grains (-30 to -25%), soybean (-2 to +10%), cash crops (-10 to -4%)]; <i>Asia</i> [maize (-34 to -20%), rice (-12 to -3%), wheat (-54 to -8%), coarse grains (-34 to -22%), soybean (-9 to +10%), cash crops (-13 to +2%)]; <i>Latin America</i> [maize (-26 to -18%), rice (-26 to -9%), wheat (-34 to -24%), coarse grains (-27 to -19%), soybean (-8 to +12%), cash crops (-20 to -5%)]	<i>Africa</i> [total agricultural production (-13 to -9%), GDP per capita (-10 to -7%), agricultural prices (-9 to +56%)]; <i>Asia</i> [total agricultural production (-6 to 0%), GDP per capita (-3 to 0%), agricultural prices (-17 to +48%)]; <i>Latin America</i> [total agricultural production (-15 to -6%), GDP per capita (-6 to -2%), agricultural prices (-8 to +46%)]	<i>Africa</i> [total agricultural production (-13 to -9%), GDP per capita (-10 to -7%), agricultural prices (-9 to +56%)]; <i>Asia</i> [total agricultural production (-6 to 0%), GDP per capita (-3 to 0%), agricultural prices (-17 to +48%)]; <i>Latin America</i> [total agricultural production (-15 to -6%), GDP per capita (-6 to -2%), agricultural prices (-8 to +46%)]	Yield impacts based on Rosenzweig and Parry (1994) values for “level 1” (farm-level) adaptations and CO ₂ direct effects; yield impacts are weighted (by production) average of country-level yield changes; values for total agricultural production and per capita GDP include both yield and price impacts; range for agricultural prices is across food and cash crops, and GCMs

in application of transient climate change scenarios to impact modeling between studies results in competing explanations about differences in impact estimates between the two types of climate change scenarios.

5.3.4.2. Historical Analogs of Adaptation

The agriculture sector historically has shown enormous capacity to adjust to social and environmental stimuli that are analogous to climate stimuli. Historical analogs of the adaptability of agriculture to climate change include experience with historical climate fluctuations, deliberate translocation of crops across different agroclimatic zones, rapid substitution of new crops for old ones, and resource substitutions induced by scarcity (Easterling, 1996). In the Argentine Pampas, the proportion of land allocated to crops has increased markedly at the expense of grazing land during historic humid periods, and vice versa

during dry periods (Viglizzo *et al.*, 1997). Historical expansion of hard red winter wheat across thermal and moisture gradients of the U.S. Great Plains provides an example of crop translocation (Rosenberg, 1982). At present, the northern boundary of winter wheat in China is just south of the Great Wall and the north edge of China, where large temperature increases are expected under climate change (Lin, 1997). Winter wheat planting has shifted from Dalian (38°54'N) to Shenyang (41°46'N) in Liaoning province. The shift was aided by introduction of freeze-resistant winter wheat varieties from high-latitude countries such as Russia, the United States, and Canada into Liaoning province (Hou, 1994, 1995; Chen and Libai, 1997). Rapid introduction of canola in Canadian agriculture in the 1950s and 1960s shows how rapidly farmers can modify their production systems to accommodate a new crop (National Research Council, 1991). Adaptation to declining groundwater tables by substituting dryland for irrigated crops in regions of the U.S. Great Plains is an example of substitutions to deal with water

^a GCMs are 2xCO₂, unless otherwise noted.

^b Unless otherwise noted, range is across GCM scenarios and site values are averaged; for sensitivity analyses, yield range is across sites.

^c Range across countries and GCM scenarios; NA = North America, LA = Latin America, WE = Western Europe, EE = Eastern Europe, AS = Asia, AF = Africa.

^d Range across three GCM scenarios, two levels of adaptation, and two baseline scenarios for 2060 (optimistic and pessimistic).

^e World yields (weighted by production); range across crops.

^f Range across countries in study.

^g Range across countries and GCM scenarios.

^h Range across sites.

ⁱ Temporal distribution accomplished using SCENGEN scenario generator.

^j Change in global mean temperature (used as surrogate for time); regional temperature change may be higher or lower.

^k One site only; range across three 2xCO₂ equilibrium GCM scenarios (two sites and seven GCMs considered in *without adaptation* values).

^l One site (two sites considered in *without adaptation* values).

^m Range across two climate scenarios and degree of adjustment (e.g., different planting date options).

ⁿ Range across two crop models and CO₂ levels (1, 1.5, and 2xCO₂).

^o Range across crop model and GCM scenarios.

^p Transient scenario.

^q Adaptation not applied when climate change increases yields in the no-adaptation case.

^r Average of “normal” and El Niño years; range across two sites.

^s Range across sites.

^t Range across sites and GCM scenarios.

becoming a scarce production resource (Glantz and Ausubel, 1988). None of these examples, however, deals specifically with an evolving climate change and all are historic—which limits confidence in extending their conclusions to future climate change.

5.3.4.3. Agronomic Adaptation of Yields

Increasing numbers of studies have investigated the effectiveness of agronomic adaptation strategies (e.g., adjustments in planting dates, fertilization rates, irrigation applications, cultivar traits) in coping with climate-induced yield losses and gains since the SAR (see Table 5-4). Considerable costs could be involved in this process, however—for example, in learning about and gaining experience with different crops or if irrigation becomes necessary. In some cases, a lack of water resulting from climate change might mean that increased irrigation demands cannot be met (see Section 4.7.2).

Methodologically, there has been little progress since the SAR in modeling agronomic adaptations. On one hand, the adaptation strategies being modeled are limited to a small subset of a much

larger universe of possibilities, which may underestimate adaptive capacity. On the other hand, the adaptations tend to be implemented unrealistically, as though farmers are perfectly clairvoyant about evolving climate changes, which may inflate their effectiveness (Schneider *et al.*, 2000). Some studies find agronomic adaptation to be most effective in mid-latitude developed regions and least effective in low-latitude developing regions (Rosenzweig and Iglesias, 1998; Parry *et al.*, 1999). This finding clearly is supported across the studies summarized in Table 5-4, although the number of studies that include adaptation is not large. A small number of studies in Table 5-4 compare yield changes with and without agronomic adaptation. Percentage changes in yields across a range of climate change scenarios for those studies are shown in Figure 5-2. Each pair of vertical bars represents the range of percentage changes by crop, with and without adaptation, for each study. Clearly, adaptation ameliorates yield loss (and enhances yield gains) in most instances. The median adapted yields (mid-point of the vertical bars) shift upward relative to the median unadapted yields in six of the eight studies. Two studies do not show such an upward shift (Mongolia, Romania) because of peculiarities in the modeling (see figure caption). Adaptation ameliorates the worst yield losses in seven of the eight studies.

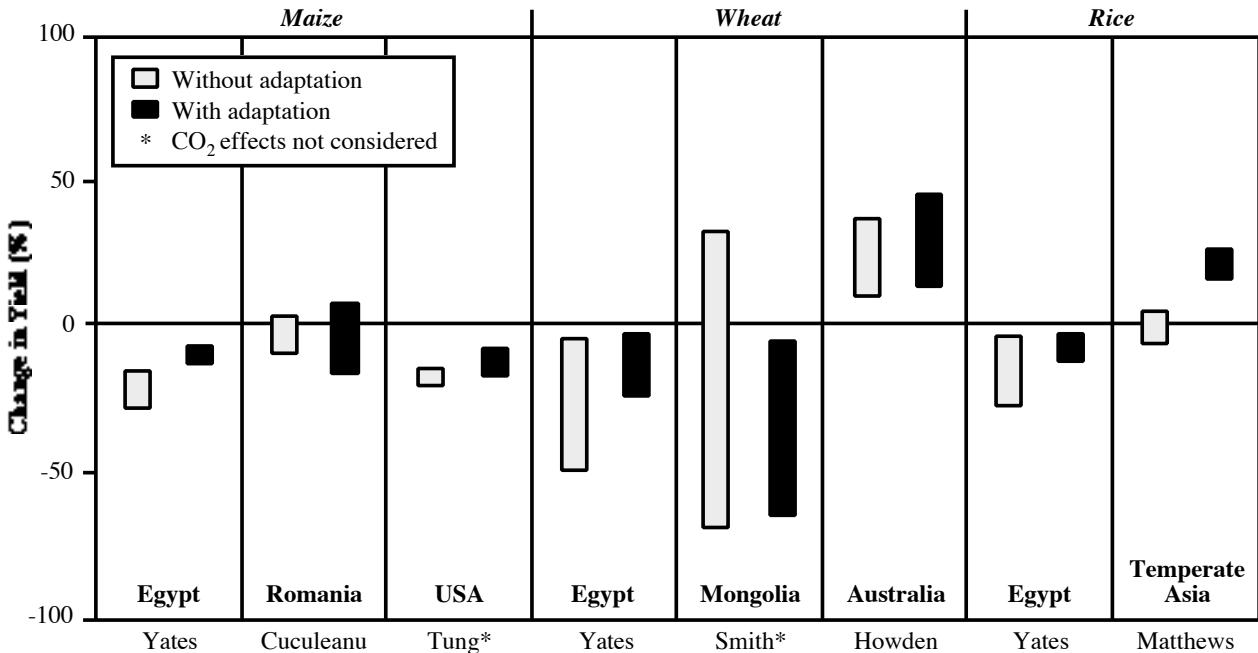

Figure 5-2: Ranges of percentage changes in crop yields (expressed in vertical extent of the vertical bars only) spanning selected climate change scenarios—with and without agronomic adaptation—from paired studies in Table 5-4. Each pair of ranges is differentiated by geographic location and crop. Pairs of vertical bars represent the range of percentage changes with and without adaptation. Endpoints of each range represent collective high and low percentage change values derived from all climate scenarios used in the study. Horizontal extent of the bars is not meaningful. Note that on the x-axis the last name of the lead author is listed as it appears on Table 5-4. See Table 5-4 for details on climate scenarios used and types of adaptation strategies modeled in each study. In the case of Mongolia, adaptation was not modeled when climate change resulted in positive yield change. In Romania, earlier planting of irrigated maize results in slightly lower yields than with current planting dates.

It is important to note, however, that differences in modeling methodology and aggregation of results often lead to conflicting conclusions in specific regions. For example, in two studies that used the same GCM scenarios, Matthews *et al.* (1997) simulate large increases, whereas Winters *et al.* (1999) simulate large decreases in rice yield with adaptation across several countries in Asia (see Table 5-4c). Hence, confidence in these simulations is low.

Important work has investigated the geographic distribution of crop potential under climate change. Carter and Saarikko (1996) used crop models to demonstrate a poleward shift in Finnish potential cereal cultivation by 100–150 km for each 1°C increase in mean annual temperature. Reyenga *et al.* (1999) indicate that climate change accompanied by a doubling of CO₂ is likely to enable expansion of existing Finnish wheat-growing areas into dry margins, considerably extending potential cropping areas. This expansion is moderated by dry conditions but not effectively enhanced by wetter conditions.

5.3.4.4. Adaptation of Livestock

Significant costs can be incurred to counter the effects of climate change on animal production; moreover, the impact of

a warmer climate in terms of costs is not linear: Larger changes in climate can increase costs exponentially (Hahn and Morgan, 1999). Possible benefits of climate change during cooler seasons are not well documented, but the benefits are likely to be less than the consequential negative hot weather impacts (Hahn *et al.*, 1992). The ability of livestock managers to cope with climate is demonstrated daily in their coping with normally varying conditions. A variety of management adaptations are available for livestock production systems. For example, Hahn and Mader (1997) outline a series of proactive management countermeasures that can be taken during heat waves (e.g., shades and/or sprinklers) to reduce excessive heat loads. Historical success in coping with climate variability suggests that livestock producers are likely to adjust to climate change successfully. Johnson (1965) provides examples from advances in genetics and breeding as related to the environment. These capabilities should allow adaptation to changing, less favorable circumstances associated with projected rates of climate change. However, coping can entail significant dislocation costs for certain producers. For individual producers, uncertainties associated with potential climate change imply additional risks related to how and when to adapt current production practices (Lewandrowski and Schimmelpfennig, 1999). Confidence in the foregoing projections of the ability of livestock producers to adapt their herds to the physiological stresses of climate change is difficult to judge.

The general lack of simulations of livestock adaptation to climate change is problematic. This absence of a well-developed livestock counterpart to crop modeling of adaptation assessments suggests a major methodological weakness. Hence, we give only low to moderate confidence in projections of successful livestock adaptability.

5.3.4.5. Adaptation Effects on Farm and Regional Land Use and Income

Reilly *et al.* (1996) review several studies that analyzed the effects of climate scenarios at the farm scale. One important implication of these studies is that changes in production activities and management adaptations could play an important role in mitigating the impacts of climate change.

Survey-based studies on farm-level decisionmaking in response to climate change have propagated since the SAR. Case studies in Canada suggest several farm-level adaptive strategies to which farmers may resort (Brklacich *et al.*, 1997; Smithers and Smit, 1997; Chiotti, 1998). In southern Ontario, Smit *et al.* (1997) found that farmers' choice of cultivar to plant in the current year is highly conditioned by the climate experienced the year before. There have been few quantitative, farm-level economic studies of response and adaptation to climate change since the SAR. In the U.S. midwest, Doering *et al.* (1997) used a crop-livestock linear programming model linked to the Century biogeochemistry model to investigate the impacts of climate change on 11 representative farms in the region under

a doubled-CO₂ scenario. The analysis considered these farms under static technology and adapted technology; thus, the analysis could be regarded as representing farm-level economic responses to climate change as well as farm-level combined technological and economic adaptation. It showed that climate change may cause substantial shifts in the mix of crops grown in the upper midwest, with much less land planted to a corn-soybean rotation and more land devoted to wheat than now. Earlier planting of corn increased returns; hence, a more frost-resistant corn variety was found to be important to farm-level adaptation. Using a similar methodology, Parry *et al.* (1996) predict optimal agricultural land use in response to climate change in England and Wales.

Antle *et al.* (1999b) used an econometric-process simulation model of the dryland grain production system in Montana linked to the Century model (as reported in Paustian *et al.*, 1999) to assess the economic impacts of climate change in that region. Unlike other farm-level studies, this analysis is based on a statistically representative sample of commercial grain farms in the region, not on a small number of representative farms, so the results can be interpreted as representing the entire population of farms in the study area. Moreover, instead of using linear programming models, this analysis combines site-specific data and econometric production models in a stochastic simulation model, allowing representation of physical and economic heterogeneity in the region. Simulations were conducted for baseline and doubled CO₂ (Canadian Climate model) with observed production technology, with and without land-use adaptation and with and without CO₂ fertilization.

Box 5-5. Extending Uncertainty in Crop Models to Uncertainty in Economic Analysis

Several factors contribute uncertainty to modeling of impacts of climate change on agricultural systems (Parry *et al.*, 1999). Crop modeling studies invariably highlight the need to develop confidence that the outputs are not "model-dependent." There is uncertainty because of the fact that yield estimates obtained in climate impact assessments vary from one impact model to another. In some cases, simulations across models may exhibit good agreement. Comparison of rice models showed that their predictions for potential production were quite close to observed values (Peng *et al.*, 1995). The Erosion Productivity Impact Calculator (EPIC), a generalized crop model, predicts observed yields most closely during years with extreme warmth, lending confidence to its ability to predict yields under climate change conditions (Easterling *et al.*, 1996). In other situations, agreement is not as good. In comparisons between wheat simulation models (Goudriaan *et al.*, 1994; Wolf *et al.*, 1996), grain yield predictions were markedly different between models. Such findings have stimulated work to compare the performance of different models and to analyze the underlying reasons for differences (Gregory *et al.*, 1999; Mearns *et al.*, 1999).

Spatial resolution of crop models is another important source of uncertainty in crop models. Crop models simulate processes that regulate growth and development at fine scales (a few kilometers), whereas climate change scenarios that drive crop models typically are produced by climate models operating at coarse scales (1,000 km or more) (Barrow and Semenov, 1995; Easterling *et al.*, 1998). Studies that use statistical downscaling techniques and nested limited area numerical models to increase the resolution of GCM scenarios of climate change have shown large simulated yield discrepancies between coarse-resolution (GCM) and fine-resolution (downscaled) climate change scenarios. Mearns *et al.* (1999) demonstrate for a site in Iowa that yields can change algebraic sign depending on the resolution of the climate change scenario: Maize yield decreases (-11%) with low-resolution climate change (CSIRO model) and increases (2%) with high-resolution climate change (RegCM limited area model nested within CSIRO model). Causes of variance in model output must be identified.

Box 5-5. Extending Uncertainty in Crop Models to Uncertainty in Economic Analysis (continued)

Some analysts use statistical approaches to relate historical climate to yields as a basis for projecting yield response to future climate change. Spatial analog models use reduced-form econometric models that are based on historical data and estimate the relationship between economic variables such as asset values or value of production and climate variables. These models then can be used to simulate the effects of climate change on economic outcomes (Mendelsohn *et al.*, 1994). A strength of the spatial analog approach is that it embeds the complex responses of agricultural decisionmakers to spatial variations in climate. A disadvantage of some spatial analog models is that they do not represent market equilibrium. They can be used, however, to simulate price scenarios or be linked to an equilibrium model (e.g., see Adams *et al.*, 1999). Another key limitation is that these models do not represent productivity explicitly, so they cannot be linked to process models to incorporate the important effects of CO₂ fertilization on productivity and economic behavior. Kaufmann and Snell (1997) relate underlying determinants of yields to historical climate, to exploit the advantages of statistical analysis in capturing adaptation while utilizing the robustness of process-based crop modeling.

Integrated assessments of agricultural impacts of climate change (Table 5-4) often link outputs from climate models with crop process models and economic models that together predict changes in land use, crop choice, production, prices, and impacts on economic welfare of producers and consumers. The studies listed in Table 5-4 provide some indication of sensitivity to alternative climate models by comparing results from several different models or model variants. These comparisons show that model results are highly sensitive to alternative climate model inputs, reflecting the wide range of yield impacts that have been estimated with crop models. For example, Adams *et al.* (1999) report that net U.S. welfare changes from climate change range from -\$16 billion to +\$117 billion, depending on the climate scenario used. This surely illustrates Schneider and Moss' (Chapter 2) cascading uncertainty. By changing the assumptions about demand for U.S. exports, Adams *et al.* (1999) also find that the impacts of climate change on U.S. agriculture are highly sensitive to assumptions about the demand for U.S. exports, with impacts ranging from -\$1.3 billion to +\$123 billion. Many other assumptions are described in these studies (and, given the large size and complexity of these models, many other assumptions are not discussed explicitly) that are embedded in these models and that have not been subjected to sensitivity analysis. The limited sensitivity analyses that have been performed suggest that uncertainties in economic models alone are large and further imply that the economic impacts of climate change on agriculture, such as those presented in the SAR (Reilly *et al.*, 1996) and in Table 5-4, are given low confidence.

In view of the significant potential impacts of CO₂ on crop yields and the many interactions with climate and soil factors (Section 5.3.3), another significant question is how this effect is incorporated into integrated assessments of agricultural impacts. Some of the studies cited in Table 5-4 do not incorporate CO₂ fertilization effects; others use estimates of yield changes that are based on experiments or models that do incorporate these effects. Another question is whether experimental or simulated estimates of the CO₂ fertilization effect on yields is a realistic estimate of on-farm yield changes. Darwin and Kennedy (2000) found that estimates of the economic benefits of CO₂ fertilization are sensitive to the magnitude of yield change.

Taken together, it is clear that the results of existing agricultural impact studies must be assigned a low degree of confidence. How uncertain these results are has not been quantified. The implication is that econometric and integrated assessment modelers need to undertake sensitivity analysis to determine key assumptions and parameters and focus quantitative uncertainty analysis on those dimensions of the models.

With climate change, CO₂ fertilization, and adaptation, mean returns change by -11 to + 6% relative to the base climate and variability in returns increases by +7 to +25%, whereas without adaptation mean returns change by -8 to -31% and variability increases by +25 to 83%. These findings provide support for the hypothesis that ability to adapt plays a critical role not only in mean impacts but also in the spatial variability of impacts. They provide empirical support to the hypothesis advanced in the SAR that climate change is likely to have its greatest adverse impacts on areas where resource endowments are poorest and the ability of farmers to respond and adapt is most limited.

5.3.4.6. Environmental and Natural Resource Consequences of Responses and Adaptation to Climate Change

None of the economic studies in Reilly *et al.* (1996) analyze the environmental consequences of adaptation to climate change, such as increased demands on land and water resources. Adams *et al.* (1998) observe that this shortcoming remains true of most recent studies. However, Darwin *et al.* (1995) do include an analysis of impacts of climate change on land and water resources in a global model with the world subdivided into eight regions. They argue that competition

from crop production could aggravate direct climate-induced losses of forests in moist tropical regions. IMAGE 2.0 simulations with future scenarios of limited CO₂ emissions show that increased deforestation increases agricultural capacity because of a smaller CO₂ fertilization effect on crops than if emissions continue on the current trajectory (Leemans, 1997).

Lewandrowski and Schimmelpfennig (1999) draw implications for impacts on land and water resources, wild species, and natural ecosystems from the literature. They suggest that increased demand for irrigation predicted by these studies is likely to increase the opportunity cost of water and possibly reduce water availability for wildlife and natural ecosystems. However, it is difficult to go beyond such generalities with these aggregate models because most environmental impacts of agriculture are site-specific. Strzepek *et al.* (1999) show that some scenarios of climate change may reduce irrigation system reliability in the lower Missouri River in the U.S. corn belt, which may induce instream environmental stress. In many developing countries, current irrigation efficiencies are very low by developed-country standards. Irrigation efficiency in the Philippines in 1990 was 18%, compared to the global average of 43% (Asian Development Bank, 1998). Currently, 3,480–5,000 liters of water are used to produce 1.0 kg rough rice (equivalent to 640 g milled rice) in the Philippines (Baradas, 1999) and some neighboring countries. At those irrigation efficiencies, increased irrigation demand caused by climate change would strain irrigation supplies. Hence, one adaptation strategy is to increase irrigation efficiency.

Agriculture is a source and a sink of GHGs; hence, climate-induced agricultural land-use change is likely to impact soil carbon stocks in agricultural soils (Paustian *et al.*, 1996; Lal *et al.*, 1998; IPCC, 2000). Antle *et al.* (1999b) and Paustian *et al.* (1999) link a field-scale econometric-process simulation model to the Century ecosystem model to assess the impacts of climate change (from the Canadian Climate Centre model) on soil carbon in the dryland grain production system of the U.S. northern Great Plains. In a related set of studies, Antle *et al.* (2000) and Paustian *et al.* (2000) link a regional economic agricultural land-use model to the Century ecosystem model to assess the impacts of climate change on soil carbon in central U.S. cropland. These studies demonstrate that adaptive changes in land use and management are likely to have greater impacts on soil carbon than the direct effects of climate. Thus, adverse effects of climate change on soil carbon tend to be offset by the adaptive changes in land use that would be made by farmers in response to climate change. The degree of this offset depends on the magnitude of CO₂ fertilization effects on crop yields.

5.3.4.7. Note on Costs of Adaptation

Adaptation is unlikely to come without cost. In a literature survey, Tol *et al.* (1998) conclude that adaptation costs (as opposed to net costs of damages) are not reported in most impact studies, especially in agriculture. Yet transition costs (e.g., to retrain farmers in new practices) and equilibrium costs

(e.g., to develop additional irrigation or apply more fertilizer) may be considerable. The absence of a benefit-cost calculus for agricultural adaptation is a key deficiency. Existing studies also fail to account for the process of long-term, endogenous adaptation of technology in ways that are consistent with the extensive economic literature on that subject (Antle, 1996b). This process also will involve significant costs. An extensive body of economic research has studied the benefits and costs of agricultural research and has shown that institutions that are responsible for agricultural research adapt agricultural technology across space and time in response to relative resource scarcity (Hayami and Ruttan, 1985). Quiggin and Horowitz (1999) argue that changes in fixed capital for on-farm and off-farm infrastructure may be the most significant cost associated with adaptation to climate change.

5.3.5. Modeling Impacts and Adaptation in a Global Economy

Relatively few studies cited in the SAR linked estimates of yield responses to climate change with regional or global economic models to estimate production and welfare impacts. New studies that make such links provide important information on climate change-induced impacts on agriculture and on global and regional well-being (summaries are in Darwin *et al.*, 1995; Adams *et al.*, 1998; Lewandrowski and Schimmelpfennig, 1999). Recent contributions incorporate more crops and livestock, utilize Geographic Information System (GIS)-based land-use data, and link structural and spatial analogs (Table 5-4a). As noted in Section 5.3.2, the price of agricultural commodities is a useful statistic to summarize the net impacts of climate change on the regional or global supply/demand balance and on food security. Table 5-4a shows that the global model used by Darwin *et al.* (1995) and the U.S. model developed by Adams *et al.* (1998) predict that, with the rate of average warming expected by IPCC scenarios over the next century, agricultural production and prices are likely to continue to follow the downward path observed in the 20th century (see Section 5.3.2). As a result, impacts on aggregate welfare are a small percentage of GDP and tend to be positive, especially when the effects of CO₂ fertilization are incorporated. The only study that predicts real price increases with only modest amounts of climate change is Parry *et al.* (1999).

An important limitation of studies summarized in Reilly *et al.* (1996) is their focus on high-income regions of the world. Antle (1996b), Reilly *et al.* (1996), and Smith *et al.* (1996a) have suggested that impacts of climate change may be larger and more adverse in poorer parts of the world, where farmers and consumers are less able to adapt. The first study to address this question quantitatively in an aggregate regional analysis is Winters *et al.* (1999); they studied the impacts of climate change on Africa, Asia, and Latin America by using a computable general equilibrium model. Their analysis used larger price increases than those predicted by more recent studies in Table 5-4a, so this analysis should show more adverse impacts than an analysis based on prices from the more recent global studies.

The results summarized in Table 5-4a focus on the most vulnerable groups in poor countries—poor farmers and urban poor consumers. The results show that impacts on the incomes of these vulnerable groups would tend to be negative and in the range of 0 to –10%; in contrast, the impacts on consumer and producer groups predicted for the United States by Adams *et al.* (1998) ranged from –0.1 to +1%. Darwin (1999) reports results disaggregated by region and concludes that developing regions are likely to have welfare effects that are less positive or more negative than more-developed regions.

5.3.6. Vulnerability of the Agricultural Sector

A population, region, or sector is vulnerable to climate change when serious deficits or unused opportunities remain after taking account of adaptation. Assessment of agricultural vulnerability to climate change calls attention to populations, regions, and sectors that may lose the means to satisfy basic needs (food security, progress toward development, a healthy environment) or fail to seize opportunities to improve social welfare. Particularly when such cases result in part from market failure, issues of consequential equity arise that signal policy interventions. Although no single measure of agricultural vulnerability exists, several indices together provide a sketch of vulnerability, including crop yields, crop prices, production, income, number of people at risk of hunger, rates of erosion, and irrigation demand.

5.3.6.1. How Much Warming can Global Agriculture Absorb Before Prices Rise?

Is there an amount of climate change to which the global food production system can adapt with little harm but beyond which it is likely to impose serious hardship? An answer can be sketched only with very low confidence at this time because of the combination of uncertainties noted above. As noted in Section 5.3.2, prices are the best indicator of the balance between global food supply and demand. They determine the access of a majority of the world's population to an adequate diet. Two of three global studies reviewed here project that real agricultural output prices will decline with a mean global temperature increase of as much as 2.5°C, especially if accompanied by modest increase in precipitation (Darwin *et al.*, 1995; Adams *et al.*, 1998). Another study (Parry *et al.*, 1999) projects that output prices will rise with or without climate change, and even a global mean temperature increase of ~1°C (projected by 2020) causes prices to rise relative to the case with no climate change. When studies from the SAR are included with these more recent ones, there is general agreement that a mean global temperature rise of more than 2.5°C could increase prices (Reilly *et al.*, 1996; Adams *et al.*, 1998; Parry *et al.*, 1999), with one exception (Darwin *et al.*, 1995). Thus, with very low confidence, it is concluded from these studies that a global temperature rise of greater than 2.5°C is likely to exceed the capacity of the global food production system to adapt without price increases. However, results are too mixed

to support a defensible conclusion regarding the vulnerability of the global balance of agricultural supply and demand to smaller amounts of warming than 2.5°C.

5.3.6.2. Vulnerable Regions and Populations

Although one may be reasonably optimistic about the prospects of adapting the global agricultural production system to the early stages of warming, the distribution of vulnerability among regions and people is likely to be uneven. As pointed out in Section 5.3.3, in the tropics—where some crops are near their maximum temperature tolerance and where dryland, nonirrigated agriculture predominates—yields are likely to decrease with even small amounts of climate change. The livelihoods of subsistence farmers and pastoral people—who make up a large proportion of rural populations in some regions, particularly in the tropics, and who are weakly coupled to markets—also could be negatively affected. In regions where there is a likelihood of decreased rainfall, agriculture could be substantially affected regardless of latitude. However, regional economic analysis (see Table 5-4) indicates that aggregate impacts on incomes even in the most vulnerable populations may not be large.

Clearly, in addition to the foregoing generality on productivity, other features of agricultural vulnerability are likely to vary widely among people, regions, nations, and continents (see Chapters 10–17). As noted in several places in this section and elsewhere (Downing *et al.*, 1996a), the poor—especially those living in marginal environments—will be most vulnerable to climate-induced food insecurity. Parry *et al.* (1999) assessed the consequences of climate change for the number of people at risk of hunger as defined by the Food and Agriculture Organization (FAO, 1988) (see Table 5-4 for details of the study). By the 2080s, the additional number of people at risk of hunger as a result of climate change is estimated to be about 80 million. However, some regions (particularly in the arid and subhumid tropics) may be affected more. Africa is projected to experience marked reductions in yield, decreases in production, and increases in the risk of hunger as a result of climate change. The continent can expect to have 55–65 million extra people at risk of hunger by the 2080s under the HadCM2 climate scenarios. Under the HadCM3 climate scenario, the effect is even more severe, producing an estimated additional 70+ million people at risk of hunger in Africa. It should be noted, however, that these hunger estimates are based on the assumption that food prices will rise with climate change, which (as noted above) is highly uncertain as far as 80 years into the future.

Who are these extra people at risk of hunger likely to be? Downing *et al.* (1996b) suggest the following classes: rural smallholder producers, pastoralists, rural wage laborers, urban poor, and refugees and displaced people. In addition, they point to particular kinds of individuals: rural women, malnourished children, handicapped and infirm people, and the elderly.

5.4. Wildlife in Ecosystems

The overall mobility of wildlife and the fact that they are physiologically constrained by temperature and moisture make them effective indicators of climatic changes (Root, 1988a; Parmesan *et al.*, 2000). Evidence is presented below that shows that many different taxa from around the world already are exhibiting recognizable changes, such as poleward and elevational range shifts and changes in the timing of events such as breeding (see Table 5-3). Many factors (e.g., habitat conversion, pollution) pressure animals (see Figure 5-1). The information that follows indicates that the changes from such pressures could result in patterns that differ from those created by rapid climate change, which are created by the physiological constraints of organisms in response to climatic variables. For example, the pattern many species are showing of general poleward movement is not likely to be created by habitat conversion because such conversion generally does not occur less frequently along the poleward sides of many species ranges (e.g., along the northern boundaries in the northern hemisphere) than along those nearer the equator. Consequently, the balance of evidence suggests that, for animals that are exhibiting significant large-scale patterns of changes, the most consistent explanation is recent climatic change. Thus, like the proverbial “canaries in the coal mine,” wildlife seem to be providing an important early indicator of how ecosystems might respond to the discernible human impact on climate that is contributing to its change (Santer *et al.*, 1996).

Much of the early work on the effects of climate change on ecosystems focused on vegetation. Animals (nondomestic animals or wildlife—these terms are used interchangeably) are important members of ecosystems and are affected by weather and climate (Andrewartha and Birch, 1954). Consequently, concerns about the impacts that rapid climatic change may have on wildlife and the risks these changes may impose on ecosystem services are assessed and summarized in this section.

5.4.1. State of Wildlife

5.4.1.1. Current Status of Endangered/Extinct Animals

Recent estimates indicate that 25% (~1,125 species) of the world’s mammals and 12% (~1,150 species) of birds are at a significant risk of global extinction (Stattersfield *et al.*, 1998; UNEP, 2000). One indicator of the magnitude of this problem is the speed at which species at risk are being identified. For example, the number of birds considered at risk has increased by almost 400 since 1994, and current population sizes and trends suggest an additional 600–900 soon could be added to these lists (IUCN, 1994; UNEP, 2000). The number of animals threatened with extinction varies by region (see Table 5-5). Global patterns of total diversity are reflected in the number of species at risk in each region, in that areas with more total species are likely to have more at risk. The number of threatened invertebrates in Table 5-5 is unrealistically low. The extinction rate of invertebrates in tropical forests alone has been estimated at 27,000 yr⁻¹, largely because of habitat conversion (Wilson, 1992).

5.4.1.2. Species Status from Secure to Extinction: Ranking Risks

Extinction often is caused by a combination of pressures acting over time (Wilson, 1992). Three traits of species populations that contribute to endangerment status are range size, distribution of suitable habitat within the range, and population size. Species that are most at risk often have small ranges, inhabit a unique type of habitat or one found in isolated areas (patchy in distributions), and/or typically occur at low population densities (Rabinowitz, 1981; Rabinowitz *et al.*, 1986). Using these criteria, signs that a species may be at risk include shrinking range, decreased availability of habitat within the range, and local or widespread population declines.

Species with restricted habitat requirements typically are most vulnerable to extinction (Pimm *et al.*, 1995), including many

Table 5-5: State of some of the world’s vertebrate wildlife. For each region, the table lists the number of critically endangered, endangered, and vulnerable species, separated by slashes (UNEP, 2000).

Region	Totals	Amphibians	Reptiles	Birds	Mammals
Africa	102 / 109 / 350	0 / 4 / 13	2 / 12 / 34	37 / 30 / 140	63 / 63 / 163
Asia and the Pacific	148 / 300 / 739	6 / 18 / 23	13 / 24 / 67	60 / 95 / 366	69 / 163 / 283
Europe and Central Asia	23 / 43 / 117	2 / 2 / 8	8 / 11 / 10	6 / 7 / 40	7 / 23 / 59
Western Asia	7 / 11 / 35	0 / 0 / 0	2 / 4 / 2	2 / 0 / 20	3 / 7 / 13
Latin America ^a and the Caribbean	120 / 205 / 394	7 / 3 / 17	21 / 20 / 35	59 / 102 / 192	33 / 80 / 150
North America ^a	38 / 85 / 117	2 / 8 / 17	3 / 12 / 20	19 / 26 / 39	14 / 39 / 41

^aUNEP data place Mexico in North America because of similarity of biomes.

endemic species that could be lost with loss of their habitat (Wyman, 1991; Bibby *et al.*, 1992; Stattersfield *et al.*, 1998). For example, the Sundarban, the only remaining habitat of Bengal tigers (*Panthera tigris tigris*) in Bangladesh, is projected to decrease considerably in size as a result of rising sea levels; Milliman *et al.* (1989) estimate a loss of 18% of the land by 2050 and as much as 34% by 2100. For tigers and the many other species that inhabit these forested wetland habitats, migration to higher ground probably would be blocked by human habitation of adjacent lands (Seidensticker, 1987; ADB, 1994). Many mountainous areas also have endemic species with narrow habitat requirements (Dexter *et al.*, 1995; Stattersfield *et al.*, 1998). With warming, habitats may be able to move up in elevation if the mountain is high enough. If not, the habitat could be lost (Still *et al.*, 1999). Some montane species that are susceptible to this change include forest birds in Tanzania (Seddon *et al.*, 1999), Resplendent Quetzal (*Pharomachrus mocinno*) in Central America (Hamilton, 1995), mountain gorilla (*Gorilla gorilla beringei*) in Africa, and spectacled bear (*Tremarctos ornatus*) in the Andes (Hamilton, 1995, and references therein). Protecting species that currently are vulnerable, endangered, or critically endangered (see Table 5-5) requires measures that, in general, reverse the trend toward rarity. Without management, there is high confidence that rapid climate change, in conjunction with other pressures, probably will cause many species that currently are classified as critically endangered to become extinct and several of those that are labeled endangered or vulnerable to become much rarer, and thereby closer to extinction, in the 21st century (Rabinowitz, 1981).

5.4.1.3. Wildlife Ties to Goods and Services

Concern that species will become rare or extinct is warranted because of the goods and services provided by intact ecosystems and the species themselves. Most of the goods and services provided by wildlife (e.g., pollination, natural pest control; see Table 5-1) derive from their roles within systems. Other valuable services are provided by species that contribute to ecosystem stability or to ecosystem health and productivity. The recreational value (e.g., sport hunting, wildlife viewing) of species is large in market and nonmarket terms. Losses of species can lead to changes in the structure and function of the affected ecosystems, as well as loss of revenue and aesthetics (National Research Council, 1999).

5.4.2. Pressures on Wildlife

Rapid climate change is only one of a long list of pressures on wildlife. Alone or in combination, these pressures may greatly increase species' vulnerabilities to rarity and extinction. Pressures such as land use and land-use change, introduction of exotic species, pollution/poisoning, and extreme climatic events and recent rapid climate change are of major concern and are discussed below. Other pressures include wildlife diseases, human persecution (e.g., overharvest, harassment),

collisions with towers and other structures, collisions with cars and other forms of transportation, electrocutions, anthropogenic barriers to dispersal, war and other civil conflict, and wildlife trade (see Price *et al.*, 2000, for more information and references).

Conversion of natural and semi-natural habitats currently is quite extensive. Although climate change is starting to have observable effects on wildlife and the predicted future impact of climate change is expected to be large, the immediate principal current threat to the world's wildlife is habitat conversion (Vitousek *et al.*, 1997a). Roughly 80% of forests that originally covered the Earth have been cleared or degraded, and logging, mining, or other large-scale developments threaten 39% of what remains (UNEP, 2000). Roughly 65% of Asia's wildlife habitat has been converted to other uses, as well as nearly 75% of Australian rainforests (UNEP, 2000). Habitat conversion and degradation affect nearly 89% of all threatened birds and 83% of all threatened mammals (IUCN, 2000). Nearly 75% of all threatened bird species are found in forests (Stattersfield *et al.*, 1998), and tropical forests are the most species-rich terrestrial habitats; an estimated 90% of the world's species occur in moist tropical forests, which cover only 8% of the land area (UNEP, 2000).

Introduction of exotic species, intentionally and accidentally, has had deleterious effects on wildlife populations. Overall, 18% of threatened mammals in Australia and the Americas and 20% of the world's birds are challenged by introduced species (UNEP, 2000). Most extinctions on islands can be tied to introduction of species that prey on native species or destroy critical habitats (Stattersfield, *et al.*, 1998).

Pollution and other biochemical poisonings have direct and indirect effects on wildlife. Chemical contaminants have been detected in the tissues of species from around the globe, in regions such as Brazilian Pantanal wetlands (Alho Cleber and Vieira Luiz, 1997) and remote arctic habitats (UNEP, 2000). The most obvious effects of chemicals are direct poisoning events. These frequently are side effects of pesticide applications and can lead to losses of thousands of individuals (Biber and Salaté, 1991). In addition to affecting wildlife directly, contaminants can indirectly affect them by modifying their habitats.

Stochastic and extreme climatic events can cause deaths of large numbers of individuals and contribute significantly to determining species composition in ecosystems (Parmesan *et al.*, 2000). Hurricanes can lead to direct mortality, and their aftermath may cause declines because of loss of resources required for foraging and breeding (Wiley and Wunderle, 1994). Many of these extreme climatic events are cyclical in nature, such as sea surface temperature (SST) changes that are associated with the El Niño-Southern Oscillation (ENSO). Sea temperature increases associated with ENSO events have been implicated in reproductive failure in seabirds (Wingfield *et al.*, 1999), reduced survival and reduced size in iguanas (Wikelski and Thom, 2000), and major shifts in island food webs (Stapp *et al.*, 1999). Extreme drought in Africa was thought to have contributed to declines in the populations of many Palearctic

migratory birds that wintered in the savanna and steppe zones of the Sahel (Biber and Salathe, 1991).

Climate and climate change are strong drivers of biotic systems. The distribution and survival of most species are moderated by climate (Root, 1988a,b,c; Martin, 1998; Duellman, 1999). Although species have responded to climatic changes throughout evolutionary time (Harris, 1993), the primary concern today is the projected rapid rate of change. High species richness appears to be related to stable conditions; abrupt impoverishment of species has occurred during times of rapid change (Tambussi *et al.*, 1993).

Synergistic effects are likely to be quite damaging to animals. As habitat becomes more fragmented, barriers to dispersal or expansions of species' ranges could occur. This could force individuals to remain in inhospitable areas, decreasing the range and population size of species and ultimately leading to extinction (Rabinowitz, 1981). Fragmentation also may facilitate movement of invasive species into an area, leading to potential population declines through predation, competition, or transmission of disease (e.g., May and Norton, 1996). Increasing urbanization also could lead to increasing exposure to contaminants, which may make species less fit to survive changes in environmental conditions or weaken their immune systems (Pounds and Crump, 1987; Berger *et al.*, 1998). Human responses to climate change also may contribute to synergistic effects; for example, if new pest outbreaks are countered with increased pesticide use, nontarget species might have to endure climate- and contaminant-linked stressors.

5.4.3. Responses of Wildlife and Impacts on Goods and Services

Findings indicate that many animals already may be responding to local climatic changes. Types of changes already observed include poleward and elevational movement of ranges, changes in animal abundance, changes in body size, and shifts in the timing of events such as breeding to earlier in the spring. These responses have been identified by a group of studies from around the world in a variety of different species (see Table 5-3). Far more information is available than can be summarized here. More detail on these changes is available in Hughes (2000) and Price *et al.* (2000).

5.4.3.1. Changes Exhibited by Animals

Results from most studies that use large-scale data sets provide circumstantial (e.g., correlational) evidence about the association between changes in climate-related environmental factors and animal numbers or activities. Circumstantial evidence, though insufficient by itself, is highly suggestive when multiple studies examining a myriad of different species on all continents find similar results. Combined with smaller scale studies, experimental studies, and modeling studies that examine mechanistic connections between animals and climate change,

the weight of evidence becomes even stronger. Such is the case for wildlife already exhibiting change related to climate forcings (see Table 5-3). The information given in the following subsections is a sampling of the types of studies that have examined the potential impacts of climate change on animals. The studies were selected for taxonomic and geographic inclusiveness and are not inclusive of the breadth of range of published studies. Information on more studies can be found in Table 5-3 and in Price *et al.* (2000).

5.4.3.1.1. Shifts in animal ranges and abundances

Ranges and abundances of prehistoric animals are known to have changed significantly over time (Goodfriend and Mitterer, 1988; Baroni and Orombelli, 1994; Coope, 1995). Currently, many species are undergoing range changes because of habitat conversion, land degradation (e.g., grazing, changes in fire regime), climate change, or a combination of factors. Possible climatically associated shifts in animal ranges and densities have been noted on three continents (Antarctica, Europe, and North America) and within each major taxonomic group of animals (see Table 5-3).

Invertebrates: Insect dispersal to favorable areas to make effective use of microclimatic differences is a common response to changing climate (e.g., Fielding *et al.*, 1999). The ranges of butterflies in Europe and North America have been found to shift poleward and upward in elevation as temperatures have increased (Pollard, 1979; Parmesan, 1996; Ellis *et al.*, 1997; Parmesan *et al.*, 1999). Warming and changed rainfall patterns also may alter host plant-insect relations, through community or physiological responses (e.g., host plant food quality) (Masters *et al.*, 1998).

Amphibians and Reptiles: Amphibians may be especially susceptible to climatic change because they have moist, permeable skin and eggs and often use more than one habitat type and food type in their lifetimes (Lips, 1998). Many amphibious species appear to be declining, although the exact causes (e.g., climate change, fungus, UV radiation, or other stresses) are difficult to determine (Laurance, 1996; Berger *et al.*, 1998; Houlahan *et al.*, 2000). Disappearance of the golden toad (*Bufo periglenes*) and the harlequin frog (*Atelopus varius*) from Costa Rica's Monteverde Cloud Forest Reserve appear to be linked to extremely dry weather associated with the 1986–1987 ENSO event (Pounds and Crump, 1994). Correlation between warming, reduced frequency of dry-season mist, and the timing of population crashes of four other frog species and two lizard species from the same cloud forest also has been found (Pounds *et al.*, 1999).

Birds: Bird ranges reportedly have moved poleward in Antarctica (Emslie *et al.*, 1998), North America (Price, 2000), Europe (Prop *et al.*, 1998), and Australia (Severnty, 1977). For example, the spring range of Barnacle Geese (*Branta leucopsis*) has moved north along the Norwegian coast, correlated with a significant increase in the number of April and May days with

temperatures above 6°C (Prop *et al.*, 1998). The elevational range of some Costa Rican tropical cloud forest birds also apparently are shifting (Pounds *et al.*, 1999).

Mammals: Changes in mammal abundance can occur through changes in food resources caused by climate-linked changes or changes in exposure to disease vectors. For example, the Australian quokka (*Setonix brachyurus*) differs in susceptibility to *Salmonella* infections depending on climatic environmental conditions (Hart *et al.*, 1985).

5.4.3.1.2. Changes in timing (phenology)

Invertebrates: Warmer conditions during autumn and spring adversely affect the phenology of some cold-hardy species. Experimental work on spittlebugs (*Philaenus spumarius*) found that they hatched earlier in winter-warmed (3°C above ambient) grassland plots (Masters *et al.*, 1998).

Amphibians: Two frog species, at their northern range limit in the UK, spawned 2–3 weeks earlier in 1994 than in 1978 (Beebee, 1995). These changes were correlated with temperature, which also showed increasing trends over the same period.

Birds: Changes in phenology, or links between phenology and climate, have been noted for earlier breeding of some birds in Europe, North America, and Latin America (see Table 5-3). Changes in migration also have been noted, with earlier arrival dates of spring migrants in the United States (Ball, 1983; Bradley *et al.*, 1999), later autumn departure dates (Bezzel and Jetz, 1995), and changes in migratory patterns in Europe (Gatter, 1992).

5.4.3.1.3. Changes in morphology, physiology, and behavior

Amphibians and Reptiles: Correlations between temperature and calling rates have been found in Egyptian frogs (Akef Mamdouh and Schneider, 1995). Indian tree frogs show differences in behaviors that depend on their level of hydration (Lillywhite *et al.*, 1998). Painted turtles grew larger in warmer years, and during warm sets of years turtles reached sexual maturity faster (Frazer *et al.*, 1993). Physiological effects of temperature, primarily sex determination, also can occur while reptiles are still within their eggs (Gutzke and Crews, 1988).

Birds: Spring and summer temperatures have been linked to variations in the size of eggs of the Pied Flycatcher (*Ficedula hypoleuca*). Early summer mean temperatures explain ~34% of the annual variation in egg size between the years 1975 and 1994 (see Figures 5-3 to 5-5; Jarvinen, 1996).

Mammals: Body size is correlated with many life-history traits, including reproduction, diet, and size of home ranges. North American wood rat (*Neotoma spp.*) body weight has shown a significant decline that is inversely correlated with a significant increase in temperature over the past 8 years (Smith *et al.*,

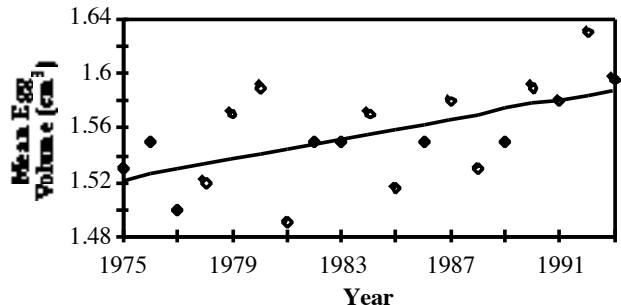

Figure 5-3: Change in egg volume of Pied Flycatcher birds over time. Regression line is $y = 1.24 + 0.004 x$ ($P < 0.01$).

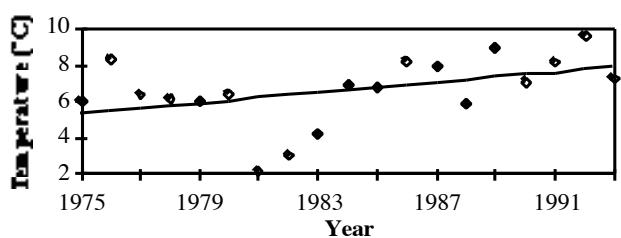

Figure 5-4: Change in the mean air temperature during the egg laying time period of the Pied Flycatcher. Regression line is $y = -5.5 + 0.14 x$ ($P < 0.7$).

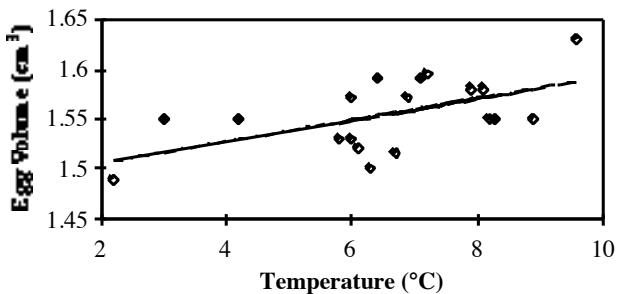

Figure 5-5: Correlation between egg volume of the Pied Flycatcher over the years and mean air temperature (regression is significant at $P < 0.01$).

1998). Juvenile red deer (*Cervus elaphus*) in Scotland grew faster in warm springs, leading to increases in adult body size (Albon and Clutton-Brock, 1988).

5.4.3.1.4. Changes in community composition, biotic interactions, and behavior

Differential responses by species could cause existing animal communities to undergo restructuring. This occurred in prehistoric plant communities because no analogous communities exist today (Davis, 1990). Similarly, Graham and Grimm (1990) found no present-day mammal communities that are analogous to some prehistoric animal communities.

Invertebrates: Potato aphids grown on plants kept in elevated CO₂ (700 ppm) showed a reduced response to alarm pheromones in comparison to those grown on plants in ambient CO₂ (350 ppm). Aphids were more likely to remain on leaves, possibly making them more susceptible to predators (Awmack *et al.*, 1997b).

Amphibians: Temperature and dissolved oxygen concentrations can alter the behavior of amphibian larvae, and changes in thermal environments can alter the outcome of predator-prey interactions (Manjarrez, 1996; Moore and Townsend, 1998).

Birds: In the UK, climate change may be causing a mismatch in the timing of breeding of Great Tits (*Parus major*) with other species in their communities (Visser *et al.*, 1998). The phenology of plants and some animals in the study area has advanced over the past 23 years, whereas breeding timing of Great Tits has not changed. This decoupling could lead to birds hatching when food supplies may be in low abundance (Visser *et al.*, 1998).

Mammals: Post *et al.* (1999) document a positive correlation between gray wolf (*Canis lupus*) winter pack size and snow depth on Isle Royale (USA). Greater pack size leads to three times more moose kills than in years with less snow. Fewer moose mean less browsing and thus better growth of understory balsam fir (*Abies balsamea*).

5.4.3.2. Model Projections of Wildlife Responses

Invertebrates: Because changes in the distribution of disease vectors, such as mosquitoes, and crop and forest pests can have major human health and economic impacts, most modeling of changes in insect range and abundance have focused on pest species (Sutherst *et al.*, 1995). In southern Africa, models project changes in the ranges of tsetse flies, ticks, and mosquitoes (Rogers, 1996). Potential range changes of other disease vectors are discussed in Chapter 9.

High proportions of boreal forest insect pests overwinter as eggs. The strong link between patterns of minimum temperature and the location of outbreaks are best explained by the fact that eggs are killed when temperatures dip below a species' tolerance threshold (Sullivan, 1965; Austara, 1971; Virtanen *et al.*, 1996). Modeling work that is based on these observations and projected climate data suggests that increasing nighttime winter temperatures may increase the frequency of these pest species in northern areas (Tenow, 1996; Virtanen *et al.*, 1996, 1998), although warmer summer temperatures may reduce the intensity of outbreaks (Niemelä, 1980; Neuvonen *et al.*, 1999; Virtanen and Neuvonen, 1999; but see Ayres, 1993).

Amphibians and Reptiles: In studies on altitudinal (Pettus and Angleton, 1967; Licht, 1975; Bizer, 1978; Berven, 1982a,b) and latitudinal (Collins, 1979) gradients, a general pattern of faster metamorphosis at smaller sizes occurs at high elevations and northern latitudes. Changes in these life history attributes

Box 5-6. Penguins as Indicators of Climate Warming in Western Antarctic

Midwinter surface air temperatures in the Western Antarctic Peninsula (WAP) region have increased by 4–5°C over the past 50 years (Smith *et al.*, 1996b). Studies confirm that the spatial and temporal patterns of winter sea-ice development in the WAP have changed during this time in response to rapid warming (Fraser *et al.*, 1992; de la Mare, 1997; Jacobs and Comiso, 1997; Loeb *et al.*, 1997). Chinstrap (*Pygoscelis antarctica*) and Adélie (*P. adeliae*) penguin populations also have changed during the past 25 years.

Although these two species are ecologically very similar, with diets and breeding ranges that overlap in the WAP (Volkman *et al.*, 1980), their winter habitat preferences are radically different. Adélies are obligate inhabitants of the pack ice, whereas Chinstraps are ice-intolerant, preferring to remain in close association with open water (Fraser *et al.*, 1992; Ainley *et al.*, 1994). The quality and availability of winter habitat is an essential determinant of survival and therefore a key factor regulating seabird populations (Birkhead and Furness, 1984). Adélie penguins have decreased by 22% whereas Chinstrap penguins have increased by more than 400% over the past 25 years (Fraser and Patterson, 1997; Smith *et al.*, 1999). This pattern supports the hypothesis that the increasing availability of open water as a result of warmer winters is favoring the survival of Chinstraps over the ice-dependent Adélies (see Fraser *et al.*, 1992).

may affect species' abundances as a result of susceptibility to predators or environmental extremes or changes in reproductive output (Calef, 1973; Travis, 1981). Species that inhabit high-altitude areas may be at particular risk from climate change because as temperatures increase, their habitats may disappear (Hamilton, 1995; Pounds *et al.*, 1999). In Australia, frog distributions are strongly correlated with patterns of annual rainfall, implying that frogs in these areas may be able to expand their ranges if precipitation increases (Tyler, 1994). Reptile ranges often correlate with temperature (Nix, 1986; Owen and Dixon, 1989; Yom-Tov and Werner, 1996), suggesting that ranges may shift with temperature change. Desert tortoises (*Testudo graeca graeca*) in southern Morocco already have shifted their ranges in response to drier conditions possibly resulting from land-use changes (Bayley and Highfield, 1996).

Birds: In the prairie pothole region of the United States and Canada, a significant correlation between wetlands, duck numbers, and the Palmer Drought Severity Index has been found (Sorenson *et al.*, 1998). Projections of warming and drying for this region suggest that the number of wetlands and, correspondingly, the number of breeding ducks could be reduced.

Similar losses of wetlands have been projected for Africa (Magadza, 1996) and Australia (Hassal and Associates, 1998).

Mammals: Population reductions in mammals in African arid lands are possible if the incidence of drought increases (IPCC, 1998). In Australia, declines in several mammal species may occur if droughts increase in frequency or intensity (Caughley *et al.*, 1985; Roberston, 1986; Gordon *et al.*, 1988). Mountains (see Section 5.4.3.1), patchy habitats, and oceans can be barriers to range shifts. The Arctic Ocean is an obstacle to 25 species of Canadian mammals, with the collared lemming (*Dicrostonyx groenlandicus*) possibly losing at least 60% of its available habitat to climate change (Kerr and Packer, 1998).

The nutritional quality of some plant species has been found to decrease with increased CO₂ availability (Bazzaz, 1996). This could mean that herbivores might have to eat more. Most studies have dealt with insect or domestic mammals, but similar results are likely to hold for wild herbivorous mammals (Baker *et al.*, 1993; Bolortsetseg and Tuvaansuren, 1996). Relative changes in major plant lifeforms also can affect species distributions and populations densities; for example, in high-latitude rangelands, shrub abundance may increase and forb abundance may decrease (Chapin *et al.*, 1995), possibly leading to limitations on food supplies available to migrating caribou (White and Trudell, 1980).

5.4.3.3. Impacts on Goods and Services with Market Values

5.4.3.3.1. Control of pest species and disease vectors

Wildlife plays a role in natural and agricultural ecosystems through reduction of injurious insect pests and disease vectors. In some forested ecosystems, birds, together with parasitoids and other insect predators, are effective predators of insect pests (Crawford and Jennings, 1989; see Price *et al.*, 2000). Insects, ants, and spiders also play key roles in reducing populations of pest insects. For example, when ants were removed from maize plots in Nicaragua, two pest species increased in abundance, and damage to the maize increased (Perfecto, 1991). The annual economic value of wildlife control of insect pests has been estimated to be hundreds of billions of U.S. dollars (de Groot, 1992; Pimentel *et al.*, 1992, 1993; Pimentel, 1997). This includes destruction of pests that are injurious to crops (estimated at US\$90 billion year in the United States alone), as well as those affecting forests.

Climate change could impact many of these systems by decoupling predators from their prey (Root and Schneider, 1995). Studies in North America project reductions in the extent of distribution size of some of the species that feed on pests in forest, grassland, and agricultural ecosystems (see Price, 1995; Price *et al.*, 2000). This could lead to an increasing need to use pesticides, with accompanying health risks (human and wildlife) and economic costs (Kirk *et al.*, 1996; Colburn *et al.*, 1997; Herremans, 1998).

5.4.3.3.2. Pollinators

Pollination is crucial to the reproduction of many plants, thus to maintenance of functioning ecosystems and biodiversity. Many factors influence the occurrence and density of insects (e.g., habitat conversion, excessive pesticide use). The principal mode of pollination of many plant species is by insects. Worldwide, an estimated 400 crop species are pollinated by bees and more than 30 other animal genera; possible crop loss in some species would be more than 90% in the absence of bees (Southwick, 1992; Buchmann and Nabhan, 1996). More than 100,000 different animals around the world pollinate 250,000 types of plants (Buchmann and Nabhan, 1996). The estimated annual value of wildlife pollination to commercial crops and pasture grasses is tens of billions of U.S. dollars (de Groot, 1992; Pimentel *et al.*, 1992, 1995). If pollination of noncommercial plants were added, the figure would be significantly higher.

5.4.3.3.3. Seed dispersal

Seeds of some plants are dispersed by one or a few animal species. In Costa Rican tropical deciduous forests, as many as 60% of plants have their seeds dispersed by birds; the numbers are 75% in subtropical evergreen forests and 80% in montane evergreen forests (Bawa, 1995). On Samoa, the vast majority of seed dispersal in the dry season is mediated by flying foxes (Cox *et al.*, 1991). Plants commonly disperse via seeds passing through the digestive tracts of animals or with animals that cache seeds (Robinson and Handel, 1993; Lanner, 1996). Consequently, if the ranges of the appropriate animals become disjunct from even part of the ranges of specific plants, dispersal of the plants may suffer (see Price *et al.*, 2000, for other examples).

5.4.3.3.4. Decomposers and soil maintainers

Invertebrates and microorganisms living on or below the soil surface provide needed goods and services to human societies (e.g., mixing and aeration of soils, decomposition of materials and human waste) (Daily *et al.*, 1997). These processes contribute to creation of fertile topsoil from organic matter and mineral components of the soil. Some of these organisms (e.g., ants) are susceptible to climatic changes, especially droughts (Folgarait, 1998). On a global scale, the estimated cost of replacing waste elimination services performed by these organisms is hundreds of billions of U.S. dollars annually; the estimated cost of replacing topsoil production services is tens of billions of U.S. dollars annually (de Groot, 1992; Crosson *et al.*, 1995; Pimentel *et al.*, 1995; Daily *et al.*, 1997).

5.4.3.3.5. Protection of endangered species

Another way of assessing the value of wildlife is by examining how much is spent on its conservation. In fiscal year 1995, approximately US\$330 million was spent on the conservation

of threatened and endangered species in the United States and its territories (U.S. Fish and Wildlife Service, 1995). As pressures facing wildlife increase, the number of species that require conservation attention also will most likely increase.

5.4.3.3.6. Subsistence hunting

People in many parts of the world depend on wildlife for their daily nutritional needs. This is most pronounced in less-developed areas. For example, the Cree along James Bay in Canada harvest approximately 800,000 kg of animal food annually. The per capita replacement value of this harvest was estimated to be CDN\$6,000 in 1986 dollars (Scott, 1987). The abundance of caribou (*Rangifer tarandus groenlandicus*) available for harvest by indigenous peoples could decrease as a result of increased temperatures, snowfall, and potential shifts in the timing of precipitation (Brotton and Wall, 1997; Ferguson, 1999). Adverse impacts also have been projected for other subsistence species, including marine birds, seals, polar bears (Stirling, 1997), tundra birds (Jeffries *et al.*, 1992), and other tundra-grazing ungulates (Jeffries, *et al.*, 1992; Gunn, 1995).

Wildlife species also are a significant source of food and medicine for people in many temperate and tropical countries, such as Botswana and Nigeria (McNeely *et al.*, 1990) and Australia (Bomford and Caughey, 1996). Among the Boran (Kenya), birds are used for medicines (ostrich oils) and their feathers for cleaning wounds (Isack, 1987). In many countries, climate change impacts such as reductions in wildlife populations may have the greatest impact on the lowest-income groups—those with the least ability to adapt if hunting opportunities decline (Arntzen and Ringrose, 1996).

5.4.3.3.7. Recreational use of animals and ecotourism

In many African countries, ecotourism to view wildlife is a major contributor to gross national product (GNP). Worldwide, ecotourism is estimated to provide US\$500 billion to 1 trillion annually to the global economy (Munasinghe and McNeely, 1994). Changes in climate could reduce the populations of some of the species people are willing to pay to see (Mills *et al.*, 1995; Allen-Diaz, 1996).

5.4.3.4. Impacts on Goods and Services with Nonmarket Valuations

Though difficult to measure, nonmarket values must be taken into account in discussing the state of wildlife. These values can be described in terms of the cultural, religious, scientific, and aesthetic importance of wildlife species (Bawa and Gadgil, 1997; Goulder and Kennedy, 1997; National Research Council, 1999). At times, monetary value can be assigned to nonmarket aspects, such as a tourist's willingness to pay to see wildlife in natural habitats (e.g., Edwards, 1991). Although this is difficult, monetary values might be able to be assigned to some of the

wildlife services described in this section. The fact that a monetary value is difficult to assign should not diminish the importance of the service; for many, no substitute exists for the services provided by wildlife.

Tools used to assess nonmarket monetary values vary, but a few approaches have become common. One attempts to determine “existence value”: people's willingness to pay to know that an animal simply continues to exist, even if they never see it (National Research Council, 1999). Similarly, an “option value” is based on a person's desire to be able to potentially interact with the animal some time in the future, and a “bequest value” is being assured that future generations will be able to use or view an animal (National Research Council, 1999). Listed below are some areas where it is particularly difficult to estimate a monetary value for animal-related services.

5.4.3.4.1. Cultural and religious importance of animals

Many indigenous peoples use wildlife as integral parts of their cultural and religious ceremonies. For example, birds are strongly integrated into Pueblo Indian (United States) communities. Birds are regarded as messengers to the gods and a connection to the spirit realm. Among Zuni Indians (United States), prayer sticks with feathers from 72 different species of birds are used as offerings to the spirit realm (Tyler, 1991). In Boran (Kenya) ceremonies, selection of tribal leaders involves rituals that require Ostrich (*Struthio camelus*) feathers. Birds also are used for tribal cosmology, meteorology, religion, and cultural ceremonies (Isack, 1987). Wildlife plays similar roles in cultures elsewhere in the world. Thus, shifts in the timing or the ranges of wildlife species could impact the cultural and religious lives of some indigenous peoples.

5.4.3.4.2. Wildlife and scientific information

Researchers have been studying spider silk to learn how this strong and elastic material could be manufactured (Xu and Lewis, 1990). Similarly, scientists have examined the structure of the small scales on butterfly wings to understand how they reflect light and dissipate heat. These studies may help engineers design better processes for manufacturing and designing computer chips (Miaoulis and Heilman, 1998). Researchers also have studied the regenerative properties of cells within rhinoceros horns and have identified potent antimicrobial chemicals from frogs and toads (Cruciani *et al.*, 1992; Moore *et al.*, 1992; Boskey, 1998).

5.4.3.4.3. Ecosystem function and biodiversity maintenance

Other valuable services are provided by species that contribute to ecosystem health and productivity. Reductions in or losses of species can lead to reduced local biodiversity and changes in the structure and function of affected ecosystems (National Research Council, 1999). The most well-known example of

this kind of effect comes from marine systems, where the presence or absence of a starfish species has been found to greatly influence the species composition of intertidal habitats (Paine, 1974). Species in terrestrial systems also can have a strong influence on the biodiversity of their ecosystems; in many cases these effects are related to their functions as pollinators or seed dispersers (see Price *et al.*, 2000).

5.4.4. Adaptation by Humans for Changes in Goods and Services

The ability of wildlife to adapt naturally to climate change is largely a function of available genetic diversity and the rate of change. This section deals not with natural adaptation but with human adaptation to changes in wildlife populations, in terms of conserving wildlife and replacing some of the goods and services that wildlife provides.

5.4.4.1. Parks and Reserves

One typical method to adapt to declines in wildlife populations has been establishment of refuges, parks, and reserves. Placement of reserves, however, rarely has taken into account potential rapid climate change, even though the problems of such change and reserve placement were discussed in the mid-1980s (Peters and Darling, 1985). Managers of current reserves and parks need to be encouraged to consider rapid climate change in developing future management plans (Solomon, 1994; Halpin, 1997). Developing a series of bioindicators to monitor the potential impacts of rapid climate change on parks and reserves may be possible (de Groot and Ketner, 1994).

In the United Kingdom, the Institute of Terrestrial Ecology has estimated that 10% of all designated areas (i.e., nature reserves) could be lost (e.g., to habitat degradation) within 30–40 years and that species distribution in 50% of designated areas could change significantly over the same period (UK DETR, 1999). In light of these changes, there is a need for a robust nature conservation system that can accommodate climate change.

In part, the disparity between siting reserves where wildlife species currently are versus where they may be in the future may stem from uncertainties in the rate and amount of projected climate change. If a species' range shifts out of a reserve created for its survival, the current reserve placement could even be considered maladaptive. However, if reserves are not created and species are lost to other pressures, the potential effects of climate change on species distributions are moot (see Box 5-7).

5.4.4.2. Captive Breeding and Translocations

Another way in which humans have dealt with endangered wildlife populations has been through captive breeding and translocations. These techniques have been put forward in the past as methods to deal with future population pressures caused

Box 5-7. Biodiversity Hotspots and Climate Change

Biodiversity hotspots are areas with exceptional concentrations of endemic species facing extraordinary threats of habitat destruction. Twenty-five hotspots contain the sole remaining habitats for 133,149 (44%) vascular land plants and 9,732 (36%) terrestrial vertebrates (Myers *et al.*, 2000). The number of invertebrates is not known, but in light of the many interactions (e.g., pollination) between plants and invertebrates, especially insects, the concentrations of these animals probably parallel those of plants. Nine of these hot spots occur on islands, making them particularly vulnerable to sea-level rise and limiting or preventing the opportunity for many terrestrial animals to modify their range (Myers *et al.*, 2000). Because these 25 hotspots constitute only 1.4% of the Earth's land surface (Myers *et al.*, 2000), they provide an opportunity for planners to respond to the biodiversity crisis by giving priority status to conserving them.

Unfortunately, synergistic effects of climate change and requirements to conserve areas for species survival may complicate the situation. With warming temperatures, many species are expected to move poleward (Parmesan *et al.*, 1999) or upward in altitude (Pounds *et al.*, 1999). This implies that the locations of hotspot reserves may need to allow for such movement, which may require a somewhat larger region to be conserved. Even with these efforts, some species may not be conserved because they presently are as far poleward (e.g., fynbos region at the southern tip of South Africa) or as high in altitude (e.g., cloud forests in Costa Rica) as they can be.

by climate change (Peters, 1992). However, although captive breeding and translocation are effective tools for conservation of some species, they may be appropriate for only a handful of species (see Box 5-8).

5.4.4.3. Replacing Lost Ecosystem Services

Humans may need to adapt not only in terms of wildlife conservation but also to replace lost ecological services normally provided by wildlife. It may be necessary to develop adaptations to losses of natural pest control, pollination, and seed dispersal. Although replacing providers of these three services sometimes may be possible, the alternatives may be costly (Buchmann and Nabhan, 1996). Finding a replacement for other services, such as contributions to nutrient cycling and ecosystem stability/biodiversity, are much harder to imagine. In many cases, such as the values of wildlife associated with subsistence hunting and cultural and religious ceremonies, any attempt at replacement may represent a net loss.

In many agricultural/silvicultural systems, pesticides are used to prevent losses to pests (insects, pathogens, some vertebrates). In the past 50 years, pesticide use worldwide has increased more than 25-fold (Worldwatch Institute, 1999). The estimated cost of pesticide use in the United States in the mid-1990s was US\$11.9 billion (equivalent to 4.5% of total U.S. farm production expenditures), and worldwide use was US\$30.6 billion (Aspin and Grube, 1999). Given that these values are for systems that still had some natural pest control, changes in wildlife distributions might necessitate changes in economic expenditures for pesticides.

However, pesticides often kill more than the target species, possibly eliminating natural predators that keep pest populations low. For example, increased pesticide use in Indonesia between 1980 and 1985 led to the destruction of the natural enemies of the brown planthopper. Subsequent increases in planthopper numbers caused reductions in rice yields estimated to cost US\$1.5 billion (FAO figures cited in Pimentel *et al.*, 1992).

Adaptation to loss of natural pollinators may be possible in some cases. Farmers sometimes lease bee colonies to pollinate their crops. Although this may be an option for the ~15% of

Box 5-8. Limitations of Captive Breeding and Translocation to Conserve Biological Diversity Threatened by Climate Change

In some cases, threatened populations of sensitive species could be augmented or reestablished through captive breeding for reintroduction, especially if the degree of climate change proves to be small or moderate. In combination with habitat restoration, such efforts may be successful in preventing the extinction of small numbers of key selected taxa. Similarly, translocation of wildlife between areas within their natural range also might mitigate the effects of small to moderate climate change. This strategy has been applied successfully to augment or restore depleted populations of various species (Boyer and Brown, 1988).

Captive breeding for reintroduction and translocation are likely to be less successful if climate change is more dramatic. Such change could result in large-scale modifications of environmental conditions, including loss or significant alteration of existing habitat over some or all of a species' range (Myers *et al.*, 2000). Captive breeding and translocation therefore should not be perceived as panaceas for the loss of biological diversity that might accompany dramatic climate change, especially given the current state of the environment. Populations of many species already are perilously small; further loss of habitat and stress associated with severe climate change may push many taxa to extinction.

One limitation to captive breeding is the lack of space available to hold wildlife for breeding purposes. Zoos and offsite breeding facilities can be expected to accommodate no more than a small fraction of the number of species that might be threatened. Recent studies have indicated that no more than 16 snake species and 141 bird species could be accommodated and sustained in accredited North American zoos and aquariums in long-term management programs (Quinn and Quinn, 1993; Sheppard, 1995).

Captive breeding programs are expensive, and locating funding to support large numbers of programs could be difficult (Hutchins *et al.*, 1996). For example, it costs US\$22,000 to raise a single golden lion tamarin in the United States and reintroduce it to its native Brazil (Kleiman *et al.*, 1991). Part of the cost associated with such programs includes the extensive scientific studies that must be conducted for the program to be successful. Reintroduction is technologically difficult and unlikely to be successful in the absence of knowledge about the species' basic biology and behavior (Hutchins *et al.*, 1996). Rearing and release strategies must be tested experimentally, and released animals must be monitored to assess the efficacy of various methods (Beck *et al.*, 1994). In the case of black-footed ferrets (*Mustela nigripes*) and golden lion tamarins, it took more than a decade to develop the knowledge base required for success.

If wildlife translocation involves moving species outside their natural ranges, other problems may ensue. Exotic species can have devastating effects on host ecosystems, including extinction of native fauna (McKnight, 1993). The unpredictable consequences of species introductions means that translocation is severely limited in its ability to conserve species that are threatened by climate change.

Finally, reintroduction and translocation programs cannot be successful if there is no appropriate habitat left for captive-bred or translocated animals to be released into (Hutchins *et al.*, 1996). Not all of the habitat components that are necessary for a species to survive can be translocated. Entire suites of plant and invertebrate species may be critical elements for a species to succeed in a new environment, but no techniques exist for translocating intact biological communities.

Although captive breeding and translocation have potential value for well-studied animals, these strategies appear to be impractical for the vast number of species threatened by rapid climate change.

crops fertilized by domestic honeybees, it may not be an option for crops typically fertilized by wild pollinators or for the 250,000 types of wild plants that are pollinated by 100,000 different invertebrate species (Buchmann and Nabhan, 1996).

5.4.5. Equity Issues

People in many parts of the world are dependent on wildlife for all or part of their daily nutritional needs. A typical adaptive response to this situation would be to replace all or part of this food with store-bought products. This might be feasible in areas near developed societies but could become increasingly difficult in more remote communities. However, there is more to subsistence hunting than the capture of food. Subsistence hunting plays a major role in the culture of Cree communities in northern Canada. “The killing, preparation, sharing, and consumption of game is central to the seasonal renewal of social relations in Cree villages, and of a relationship to the land which is both secular and sacred in importance” (Scott, 1987). Even if compensations or substitutions for subsistence uses could be made, there still would be equity issues stemming from the loss of culture associated with this way of life.

Many of the aforementioned potential adaptations are more applicable to developed countries than in developing countries. For example, the use of leased honeybees is not applicable to crops fertilized by flying foxes or other wild animals. The same can be said of many forms of seed dispersal. Increased use of pesticides may require more capital than is available to small farmers in some developing countries (Pimentel *et al.*, 1992). Adaptations that may be practical for developed countries simply may not be equitable for developing countries.

5.4.6. Vulnerabilities, Sensitivities, Uncertainties

In trying to understand and predict potential impacts of climate change on wildlife species, some species and geographic areas are found to be at greater risk than others. Species with small populations, restricted ranges, and specific habitat requirements often are most vulnerable (see Section 5.4.1.2).

Migratory species may be especially vulnerable because they require separate breeding, wintering, and migration habitats. In many cases, one or more of these habitats could be at risk because of climate change and other habitat loss. For example, a large portion of the eastern population of the monarch butterfly (*Danaus plexippus*) winters in a small region of warm-temperate dry forest in Mexico. With climate change, this area is projected to contain trees that are more typical of a subtropical dry forest—probably unsuitable for wintering monarchs (Villers-Rufz and Trejo-Vázquez, 1998). The relative vulnerability of shorebird migration sites in the United States varies, depending on local geomorphologic and anthropogenic factors, and these factors could exacerbate the effects of sea-level rise. For example, southern San Francisco Bay could lose most of its intertidal

feeding habitat with a 2°C average temperature rise (medium confidence) (Galbraith *et al.*, 2001).

One key region of concern is the Arctic and Antarctic, where the temperature increase is projected to be large and changes to habitat availability and accessibility (e.g., freezing and thawing of sea ice and tundra) are expected. Such changes may hamper migration, reproduction, and survival of many species, including birds, polar bears (*Ursus maritimus*), caribou, and musk-oxen (Jefferies *et al.*, 1992; Stirling and Derocher, 1993; Gunn and Skoglund, 1997; Stirling, 1997).

Many biological uncertainties exist in the understanding of ecosystem processes. Nevertheless, the balance of evidence suggests that projecting impacts of climatic change on a variety of wildlife species is possible (medium confidence). Laboratory and field studies have demonstrated that climate plays a strong role in limiting species’ ranges (high confidence). Only a small fraction of all species have been monitored long enough to detect significant trends. Most monitored species that show significant trends have exhibited changes over the past few decades that are consistent with local warming and expected physiological responses (high confidence). However, potential *specific* changes in wildlife resulting from climate change can be projected only with low confidence for most species because of many possible contributing factors, such as habitat destruction and exotic invasive species. Some species clearly are responding to global change (see Section 5.4.3), and many more changes probably have gone undetected. Researchers are in the process of coupling these discernible changes with various biological theories regarding climate and species spatial and temporal patterns; through this process, we expect that reliable *general* projections can be and in fact are being made (high confidence).

Scientists also need to develop a better understanding of how all of the components of ecosystems work together. The role each species plays in ecosystem services, in wild and managed systems, is necessary to understand risks and possible surprises associated with species loss. Without this information, the probability of surprises associated with species loss is high (medium confidence).

5.5. Rangelands (Grasslands, Savannas, and Deserts)

Rangelands here are taken to include deserts (cold, hot, and tundra), grasslands (unimproved), scrub, chaparral, and savannas (after, e.g., Allen-Diaz, 1996). This section does not consider improved grasslands or croplands in detail because they are covered in Section 5.3. It does partly cover tundra because it is an important grazing system; that ecosystem is discussed in more detail in Section 5.9.

Ecosystems within rangelands are characterized by low-stature vegetation because of temperature and moisture restrictions; they are found on every continent (Allen-Diaz, 1996). They are adapted to great variations in temperature and rainfall on an annual and interannual basis, but they generally are confined to

areas that have about one unit of precipitation to every 16 units of evapotranspiration (the ratio that is characteristic of drylands; Noble and Gitay, 1996). They often are referred to as “pulse systems” (Noble and Gitay, 1996).

In many countries, human activities in rangelands have evolved in response to variable and often unpredictable climate. Human practices include pastoralism; subsistence farming (Allen-Diaz, 1996); and, more recently, commercial ranching (Canziani and Diaz, 1998). Rangelands also are important for many national economies in terms of foreign cash (e.g., through tourism). They are important stores of biodiversity, including ancestors of many of the cereals (World Bank, 1995), and have high levels of endemism (Barnard *et al.*, 1998). Rangelands are used primarily for grazing and hence livestock production (Squires and Sidahmed, 1997). Thus, they are important for food (mostly livestock, but also wild fruits), fuelwood, wood poles for construction, and feed (Campbell *et al.*, 1997). Other key services are biodiversity, water cycle, and carbon stores. Some of these products and services can be given economic valuation; however, only a small component of the total economic value is represented by products that can be given a market value (Campbell *et al.*, 1997), which suggests that nonmarket values are quite important for some rangelands.

Rangelands are adapted to grazing and other disturbances, such as fire, flood, and insect herbivory (Allen-Diaz, 1996). Vegetation tends to be sparse and thus is not considered worth mechanical harvesting; however, the sparse grass/herbaceous cover is efficiently harvested by grazers (Williams, 1986). In many cases, episodic fires (Bock *et al.*, 1995) are important for providing new and lush growth for grazers, and fire sometimes is used to manage grass-woody shrub balance (Noble *et al.*, 1996), which is important for livestock and meat and wool production (see, e.g., Chapter 12). Human management can be critical to the status of these systems with or without climate change. Previous IPCC reports concluded that fluctuating rainfall and temperatures along with increased human activity (especially in more tropical systems) has led to land degradation and eventually desertification in many areas (Bullock and Le Houérou, 1996; Gitay and Noble, 1996; Canziani and Diaz, 1998).

In this section, food/fiber, biodiversity, and carbon stores are examined in detail (see Table 5-1). Water as a resource is considered elsewhere in the report, at the global level (Chapter 4) and in many of the regional chapters (Chapters 10-12).

5.5.1. Current Status of Key Goods and Services

Estimates for rangeland cover vary between 31 and 51% of the land surface of the Earth (Allen-Diaz, 1996; WRI, 2000); the upper estimate includes tundra grasslands. Rangelands support human populations at low densities (Batchelor *et al.*, 1994) on almost every populated continent. The latest figures suggest a population of at least 938 million people—or about 17% of the world’s population (WRI, 2000).

The World Resources Institute report (WRI, 2000) assesses the food/fiber production and biodiversity of rangelands as “fair” (on a scale of excellent, good, fair, poor, and bad) over the past 20–30 years, but the underlying biological ability of the rangelands to continue to support that productivity and biodiversity is declining, suggesting that productivity and the biodiversity assessment may not hold in the future. Livestock production in rangelands is estimated to be 65 Mt in 1998 (WRI, 2000), with global meat production estimated at 225 Mt. Nineteen percent of the world’s centers for plant diversity are found in rangelands. For carbon stores, the WRI assessment of rangelands is “good”; again, however, the underlying ability is judged to be declining (WRI, 2000). IPCC (2000) estimates carbon stores in rangelands as 84 Gt C in vegetation (of a global total of 466 Gt), 750 Gt C in soils (of a global total of 2,011 Gt). WRI (2000) gives a range of 405–806 Gt for total carbon stores. Both estimates suggest that rangelands are important carbon stores.

Many of the people in rangelands rely on fuelwood for their daily cooking and heating needs. Estimated fuelwood use as a percentage of total energy use in 1993 for countries dominated by rangelands is about 60–90% (e.g., in Afghanistan, Mozambique, Swaziland); the world average is 6%, and Africa’s average is 35% (WRI, 1998).

5.5.2. Major Pressures on Key Goods and Services

Climate change is a pressure on key goods and services in a system that is responsive to climatic fluctuations. It is possible that climate change would lead to increased frequency of extremes of climatic events (such as drought and floods) driven through change in the frequency of ENSO events. Apart from climate change, other direct and indirect pressures from human activities can be important in the delivery of services from rangelands. These pressures include land-use change, which often leads to fragmentation (Allen-Diaz, 1996; Gitay and Noble, 1998; WRI, 2000); changes in the densities of livestock (WRI, 2000); competition for land and water; and altered fire regimes (Russell-Smith *et al.*, 1997). These pressures would have subsequent impacts that cannot be disaggregated from impacts of climate change.

5.5.3. Responses of Rangelands and Impacts on Goods and Services

It has been suggested that for rangelands the possible effect of climate change may be trivial compared with the past and present impacts of human activities, including livestock grazing (Le Houérou, 1996). This may not be entirely true for all rangelands, but it does suggest that it would be difficult to separate the impacts of climate change from the impacts of many of the other pressures that are acting and will continue to act on the system. Subsequent sections assess the direct impacts of climate change; impacts from other aspects of global change, especially the pressures listed above, also are assessed (see

Box 5-9). Major impacts of climate change on key goods and services are mediated through changes in NPP; changes in plant community composition, structure, and forage quality (e.g., through changes in C₃ and C₄ plants); and changes in plant herbivory and phenology.

5.5.3.1. Impacts of Changes in ENSO and Related Events

Many of the world's rangelands are affected by ENSO events. There have been several ENSO events in the 1980s and 1990s that followed each other closely (Polis *et al.*, 1997). Thus, rangelands have been subjected to prolonged drought conditions with little recovery time. Simulation results have shown that ENSO events are likely to intensify (Chapter 2) under a doubled

CO₂ scenario, with the result that dry areas within rangelands are likely to become drier and mesic areas will become wetter during ENSO events (Noble and Gitay, 1996). Thus, some rangelands are likely to experience more extremes of events, with subsequent changes in vegetation and water availability. These changes often are tracked by insect herbivory (Polis *et al.*, 1997), leading to additional impacts.

5.5.3.2. Impacts of Increases in CO₂ and Climate Change on Plant Productivity, Species Composition, Decomposition, and Carbon Stores

The effect of elevated CO₂ concentrations on decomposition, plant productivity, and carbon storage could be as large as the

Box 5-9. Impacts of Some Pressures on Rangelands

Land-Use Change

Major factors in land-use change are conversion of rangelands to croplands (Allen-Diaz, 1996; WRI, 2000) and increased human settlements, especially urbanization (Gitay and Noble, 1998), which lead to fragmentation (WRI, 2000). There have been large-scale changes in land use: For example, in the South Platte Basin in the United States, 40% of the land cover has been converted from rangelands to croplands. This can alter carbon stores, sometimes leading to soil carbon loss of as much as 50% (Allen-Diaz, 1996), but it also can lead to increased plant productivity through irrigated grain production (Baron *et al.*, 1998). Baron *et al.* (1998) conclude that subsequent impacts on the biogeochemical cycles of the basin and on land-atmosphere interactions can affect many rangelands. In many rangelands, native species that occur at low density are used for fuelwood. In some cases, fuelwood collection can lead to decreases in woody vegetation cover and possible land degradation.

Livestock Production

Some rangelands have high densities (>100 km⁻²) of livestock, with livestock being moved to take advantage of the periodic growth, especially after rain and/or fires (WRI, 2000). Modeling studies show that increased grazing pressure (i.e., overgrazing) would cause grass and herbaceous productivity to fall below a certain threshold, resulting in increased and rapid rates of land degradation especially under drier and/or hotter climate conditions (Abel, 1997).

Competition for Land and Water

There is increased demand for water for direct human consumption and for irrigation (WRI, 2000). Food production obviously is positively affected by increased water use (see Section 5.3 and Chapter 4), but this water use is an added pressure on many rangeland ecosystems. Nomadic pastoralism, which was common in many rangelands until recently, allowed pastoralists to cope with the variable climate of the rangelands they inhabited. Land-use changes (to permanent agriculture, urban areas, conservation, and game reserves that have included loss of sources of permanent water) have led to overall loss of land available. Together with increased human population, this has led to competition for land and changes from pastoral communities to more market-orientated and cash-based economies (Allen-Diaz, 1996).

Altered Fire Regimes

The SAR did an extensive review of fires and rangelands. The projected increase in variability in climate led to the conclusion that the frequency and severity of fires will increase in rangelands (Allen-Diaz, 1996), provided that drought and grazing do not lead to a reduction in vegetation biomass. There is historical evidence that fire frequency has changed (increased and decreased, depending on vegetation biomass) in recent decades (see, e.g., Russell-Smith *et al.*, 1997), leading to changes in vegetation composition. Fires also are started by humans; for example, in Africa 25–80% of rangelands are burned every year, often to induce new plant growth (WRI, 2000). This has implications for short-term productivity but possibly long-term land degradation.

impact of climate change alone (Ojima *et al.*, 1993; Parton *et al.*, 1994; Hall *et al.*, 1995).

5.5.3.2.1. Plant productivity

At the global level, plant production is projected to increase in grasslands when climate change and elevated CO₂ are combined (Parton *et al.*, 1994) but could be affected by potential changes in disturbance regimes and by land-use practices in some rangelands (Parton *et al.*, 1994, 1995). As CO₂ concentrations increase, transpiration per unit leaf area is expected to decrease and WUE will increase (Morgan *et al.*, 1994a; Read *et al.*, 1997; Wand *et al.*, 1999). Thus, increased CO₂ could lead to enhanced productivity (e.g., Hunt *et al.*, 1996; Owensby *et al.*, 1996), especially under low soil moisture conditions that are characteristic of rangelands (Wand *et al.*, 1999). However, Bolortsetseg and Tuvaansuren (1996)—using 30-year climatic data as a baseline with projected climate change scenarios that incorporate elevated CO₂—report a decrease in productivity in deserts but an increase in colder areas; Gao and Yu (1998)—using a regional model with elevated CO₂, a 20% increase in precipitation, and a 4°C increase in temperature—project that NPP of most steppes in China will decrease by 15–20% and NPP of woodland and shrublands and desert grasslands will increase by 20–115%. Productivity also is likely to increase because elevated CO₂ could result in enhanced nitrogen uptake (Jones and Jongen, 1996; Coughenour and Chen, 1997). However, the response varies between species: Dominant species show a less enhanced response than rarer species, suggesting a possible change in the composition and structure of the vegetation in rangelands (Jones and Jongen 1996; Berntson *et al.*, 1998). Slower depletion of soil water under increased CO₂ concentrations should favor plants that otherwise might do poorly under water stress (Polley *et al.*, 1997), thus altering the species mix.

5.5.3.2.2. Carbon stores

Many rangelands tend to have large belowground stores (Tate and Ross, 1997). Studies suggest a strong interaction between CO₂ and temperature on soil carbon fluxes, possibly mediated through NPP. Soil carbon losses of about 2 Gt over 50 years under combined climate change and elevated CO₂ have been projected. These losses compare with carbon losses of about 4 Gt from climate change alone (Hall *et al.*, 1995; Parton *et al.*, 1995). Hall *et al.* (1995) project that tropical savannas will be soil carbon sinks under elevated CO₂ and climate change. For temperate grasslands, Thornley and Cannell (1997) suggest an annual carbon sink of 0.5–1.5 t ha⁻¹ yr⁻¹ under a scenario of elevated CO₂ and a temperature increase of 5°C; however, grasslands are likely to be a net source under that temperature increase alone. Based on some experimental studies and supported by observations around CO₂-venting spring areas in temperate grasslands of New Zealand, future carbon storage could be favored in soils of moderate nutrient status, moderate to high clay content, and low to moderately high soil moisture status (Tate and Ross, 1997). In contrast, Cook *et al.* (1999)

show that long-term CO₂ enrichment by a natural CO₂-venting spring in a subarctic grassland is likely to result in slower soil carbon accumulation compared to the ambient CO₂ atmosphere. Soil carbon is greatly affected by management practices, and appropriate management in many rangeland systems could result in carbon sequestration (see below).

Productivity of rangelands also can be affected by changes (which could be a result of climate change) in soil fauna and flora, as well as microbial activity (Yeates *et al.*, 1997; Zaller and Arnone, 1997; Kandeler *et al.*, 1998). These studies, which have not looked at arid systems within rangelands, suggest that elevated CO₂ is likely to cause an increase in soil microbial activity and increased soil CO₂ production. NPP has been reported to be enhanced by elevated CO₂ in nodulated and mycorrhizae-infected species (Allen-Diaz, 1996), although specific infection rates often are unchanged.

5.5.3.2.3. Changes in species composition, C₃ and C₄ plants

C₃ and C₄ plants react differently to elevated CO₂ and climatic factors. In paleostudies in the northern Chihuahuan Desert, Buck and Monger (1999) observe a major shift from C₄ grasses to C₃ desert shrub-dominated vegetation about 7,000–9,000 years BP, associated with a possible increase in aridity and a subsequent increase in C₄ grasses, with an increase in moisture about 4,000 years BP. Photosynthesis in C₃ plants is expected to respond more strongly to CO₂ enrichment than in C₄ plants (Mayeux *et al.*, 1991). If this is the case, it is likely to lead to an increase in the geographic distribution of C₃ plants (many of which are woody plants) at the expense of C₄ grasses (Noble and Gitay, 1996; Ehleringer *et al.*, 1997; Polley *et al.*, 1997). However, the impacts are not that simple. In pot experiments, elevated CO₂ is reported to improve water relations and enhance productivity in the C₄ shortgrass steppe grass *Bouteloua gracilis* (Morgan *et al.*, 1994b). In modeling and experimental studies, NPP of C₃ and C₄ grasses increase under elevated CO₂ for a range of temperatures and precipitation (Chen *et al.*, 1996; Hunt *et al.*, 1996; Owensby *et al.*, 1999) but could result in relatively small changes in their geographical distributions (Howden *et al.*, 1999b). There are additional interactions with soil characteristics and climatic factors. Epstein *et al.* (1998)—using existing distribution of grasslands in the U.S. Great Plains combined with modeling studies but not including the effect of elevated CO₂—found that C₃ plants are more productive in cooler, drier conditions and do particularly well in soils with high clay. There was a differentiation of the response of C₄ plants into two height classes: shortgrasses and tallgrasses. Productivity of C₄ shortgrasses increased with increasing mean annual temperature but decreased with mean annual precipitation and sand content, whereas C₄ tallgrass productivity tended to increase with mean annual precipitation and sand content and was highest at intermediate values of mean annual precipitation. Coffin and Lauenroth (1996) used gap models linked to a soil water model and found that C₄ grasses increase in dominance as a result of increases in temperature in all months. The coolest sites that currently are dominated by C₃ grasses are predicted to shift to

dominance by C₄ grasses, whereas sites that currently are dominated by C₄ grasses have an increase in importance of this group. When the number of frost days is decreased, subtropical C₄ grasses may invade the more palatable C₃ grasses, leading to a decrease in forage quality. The rate and duration of this change is likely to be affected by human activity; high grazing pressure may mean more establishment sites for C₄ grasses (Panario and Bidegain, 1997).

5.5.3.2.4. Woody species, grass, and weeds mix

There have been some suggestions that woody weed encroachment into herbaceous parts of rangeland (up to three-fold in some cases) may be a result of changes in regional climate (Brown *et al.*, 1997b) and may be facilitated by the increase in atmospheric CO₂ concentration since industrialization (Polley *et al.*, 1996). However, the more plausible explanation for the present observed increase in woody weeds in many rangelands is that it is a result of land-use change (especially increased grazing and changes in fire regime) as well as land degradation (Bond *et al.*, 1994; Archer *et al.*, 1995; Brown *et al.*, 1997b; Gill and Burke 1999). A modeling study of semi-arid woodlands in Australia under elevated CO₂ and climate change suggests that future potential burning opportunities may increase as a result of the CO₂ response of the grass layer, which allows adequate fuel to build up more frequently, provided stocking rates are not increased commensurately (Howden *et al.*, 1999c). Thus, regional climate change and elevated CO₂, as concluded in the SAR, may change the balance from more herbaceous species (grasses and herbs) to more woody species (mainly shrubs), subsequently affecting productivity, decomposition, and fire frequency of the system, as well as forage quality (Allen-Diaz, 1996; Noble and Gitay, 1996) and regional carbon cycling (Gill and Burke, 1999).

5.3.3.2.5. Changes in phenology

Increased variability of rainfall and temperature is likely to affect the phenology of plant and animal species (Gitay and Noble, 1998). It also would affect animal abundance and feeding behavior (see Section 5.4) and would be critical for some pests and diseases and availability of forage for livestock and other mammals (Watt *et al.*, 1995). Species composition changes also could occur. Brown and Carter (1998) manipulated the climate of small areas of temperate grasslands and found that weeds become established in gaps created through increased occurrence of spring or summer drought. Warmer winters induce a late spring drought—which, when combined with an imposed summer drought—leads to significant reduction in cover of nonweeds especially and an increase in weedy species. However, if summer moisture is increased, grasses become dominant. Thus, if climate change results in changes in summer and winter soil moisture and land use creates gaps, this is likely to affect species composition in some grasslands. Fuller and Prince (1996)—using satellite data and NDVI to detect vegetation change—found that there is an early greening of the Miombo woodlands. These woodlands are sensitive to the arrival of

spring rains, thus might undergo changes if there is a shift in rainfall patterns.

5.5.3.3. Biogeographical Shifts and Land Degradation

Section 5.2 summarizes the main outputs of recent model outputs. Previous IPCC reports have documented boundary shifts in rangeland vegetation with adjoining vegetation as a response to past climate changes (see, e.g., Gitay and Noble, 1998). The SAR concluded that model outputs suggest significant changes in the boundaries of grasslands and deserts, with expansion of warm grass/shrub types and a decrease in tundra systems (Allen-Diaz, 1996). More recent studies by Allen and Breshears (1998) do not support this rapid change, except perhaps in cases of high drought-induced mortality. Human activities are likely to affect the final changes, especially in tropical and subtropical areas (Allen-Diaz, 1996; Villers-Rúiz and Trejo-Vázquez, 1998), and will negate any gains resulting from amelioration of climate (Gitay and Noble, 1998).

Palaeoecological evidence shows shifts in rangeland vegetation—for example, between the last glacial maximum (LGM) and the Holocene in the Sahara-Gobi desert belt (Lioubimtseva *et al.*, 1998). These shifts have resulted in changes in the carbon stores. Dry and cool conditions during the LGM (about 20,000 years BP) resulted in the spread of arid and semi-arid ecosystems at northern and southern margins of the desert belt. The southern limit of the Sahara migrated southward at least 400 km relative to its present position and almost 1,000 km southward compared to the mid-Holocene (about 9,000 years BP). The northern margin of the temperate deserts and dry steppes of central Asia shifted northward by about 300 km over Kazakhstan, southern Siberia, and Mongolia. During the last world deglaciation, the Sahara-Gobi desert belt was a sink for approximately 200 Gt of atmospheric carbon, but since the mid-Holocene it has been a source.

Modeling studies by Ni (2000), using the BIOME3 model (see Section 5.2) with present climate for the Tibetan Plateau and elevated CO₂ (550 ppm), suggest that there is likely to be a large reduction in temperate deserts, alpine steppe, desert, and ice/polar desert; a large increase in temperate shrubland/meadow and temperate steppe; and a general poleward shift of vegetation zones. Villers-Rúiz and Trejo-Vázquez (1998) found that projected impacts of climate change (using two climate change scenarios generated by the Canadian Climate Center) would result in expansion of some rangeland systems into moist forest areas in Mexico. However, under a GFDL scenario there would be an increase in the distribution of tropical humid and wet forests into rangelands. Zimov *et al.* (1995) suggest that shifts in vegetation boundaries in the rangelands could be influenced by mammalian grazing (in this case, the study area did not have livestock); thus, model projections should include the impact of mammal populations for realistic projections of future vegetation changes (see also Section 5.4).

Desertification tends to be associated with land degradation in rangelands (Pickup, 1998). However, desertification aggregates

many land degradation processes and can be exacerbated by climate change. The main processes involved in land degradation include physical, chemical, and biological degradation (Lal *et al.*, 1989, 1999; see also Section 5.3.3) and result in soil compaction, destruction of soil surfaces (which often are kept intact by the presence of cyanobacteria, lichens, and mosses), and salinization (Dregne, 1995; Pickup, 1998). These processes are sensitive to livestock trampling. The end result can be decreased water penetration, increased surface runoff, and exposure of soils to wind and water erosion, thereby changing the water and nutrient cycles (Belnap, 1995). In some cold deserts, changes to the soil surface and thus water penetration are quite critical because low vegetation cover, low surface rooting plants, few nitrogen fixers, and low soil temperatures result in slow recovery in nutrient cycles (Belnap, 1995). Under many circumstances, recovery of the soil surface in many arid and semi-arid parts of the world is estimated to take several hundred years, with nitrogen-fixing capability (mostly from the soil crust) taking at least 50 years—making them generally vulnerable to further desertification and soil degradation.

Land degradation is a nonlinear process with thresholds that can be triggered by climatic factors and human activities (Puigdefabregas, 1998). This has implications for the sensitivities and vulnerability of these systems. Villers-Ruiz and Trejo-Vázquez (1998) suggest that the impacts of climate change are likely to be minor compared to land degradation in parts of rangelands in Mexico where conversion of forests into grasslands is mainly for cattle ranching. Lavee *et al.* (1998) suggest on the basis of field and experimental work that if climate becomes more arid in Mediterranean to arid areas of Israel (through decreases in annual precipitation and the frequency and intensity of precipitation, together with increasing temperature), productivity would decrease—leading to decreased organic matter, soil permeability, and rates of infiltration and thus land degradation. The rate of change of these variables along the climatic transect is nonlinear. A step-like threshold exists at the semi-arid area, which sharply separates the Mediterranean climate and arid systems. This means that only a relatively small climatic change would be needed to shift the borders between these two systems. Because many regions of Mediterranean climate lie adjacent to semi-arid areas, the former are threatened by desertification in the event of climate change.

Irrigation in semi-arid areas is a major cause of secondary (or dryland) salinity. Elevated CO₂ increases WUE, so it may reduce irrigation needs, whereas warming may enhance water demand and exacerbate problems of secondary salinity (Yeo, 1999). Increased subsoil drainage under elevated CO₂ may increase the risk of secondary salinization and areas potentially affected (Howden *et al.*, 1999d).

5.5.3.4. Changes in Biodiversity

This subject is reviewed extensively in the SAR and the *Special Report on Regional Impacts of Climate Change*. More recent studies mostly suggest that recently observed changes in

rangelands, especially animals (see Section 5.4), are occurring as a result of land degradation. For example, in Australia, land degradation from pastoral activity as well as the impacts of introduced feral mammals (goats, foxes, rabbits) has resulted in extinctions of small- and medium-sized mammals (Pickup, 1998). There have been past changes in plant biodiversity as a result of changes in rangeland vegetation. For example, Prieto (2000), using paleorecords from eastern plains of Argentina, found that there was a replacement of dry steppe by humid grasslands during the late glacial-Holocene transition. The plant composition indicates a frequently disturbed habitat with a lot of weedy species that did not exist in the records in previous ages.

5.5.4. Adaptation Options

Human societies in rangelands would have to adapt to changes in climate, especially temperature and water availability. The SAR concludes that the lack of infrastructure and investment in resource management in many countries dominated by rangelands makes some adaptation options problematic (Allen-Diaz, 1996) but also makes these areas more sensitive to impacts of climate change (Gitay and Noble, 1998). Nevertheless, some adaptation options are available for many of the rangelands.

Specific examples of the interaction between climate change and management decisions may be highlighted better at the regional level. For example, in Australia, Pickup (1998) found that substantial shifts in rainfall have occurred over the past 100 years. If climate change results in further shifts in rainfall patterns, the major impacts are likely to be related to increased climate variability. Pastoral management decisions in these rangelands tend to be taken over the short term; wetter periods generate unrealistic expectations about land use and high stocking rates, which drier periods are unable to support. This has and would lead to land degradation.

5.5.4.1. Landscape Management

Rangelands consist of a mosaic of various ecosystem types (WRI, 2000) with soil and water processes as well as associated nutrient cycles that operate at the landscape or regional scale (Coughenour and Ellis, 1993). Human use of rangelands often affects landscape processes (e.g., water flow, soil erosion) and changes in processes such as productivity, decomposition, and fire. Thus, possible future adaptation options might have to be sought at the landscape level (Aronson *et al.*, 1998) and over long time frames (Allen-Diaz, 1996). Because many rangelands are in semi-arid and arid parts of the world, actions to reduce destruction of the soil crust (which are important for soil stabilization and nitrogen fixation) and thus land degradation are extremely important. These actions could include adjustment in the time and intensity of grazing (Belnap and Gillette, 1998). Restoration of degraded soils has vast potential to sequester carbon in soil and aboveground biomass (Lal *et al.*, 1999), although restoration could be costly (Puigdefabregas, 1998).

5.5.4.2. Selection of Plants and Livestock

Selection of plants (e.g., legume-based systems) and animal species and better stock management are likely to be the most positive management options (Chapman *et al.*, 1996; Gitay and Noble, 1998). Rotational cropping and decreased use of marginal lands might be necessary in rangeland management. This might mean more intensive land management in some areas, leading to more reliable food supplies and perhaps reduction in methane production from livestock (decrease in methane production would be caused by improved forage quality; Allen-Diaz, 1996). Potential stocking rates could be determined via satellite imagery (Oesterheld *et al.*, 1998). However, the decision on stocking rates might still be made on a social basis, especially given the values associated with livestock in many pastoral rangeland communities (Turner, 1993).

5.5.4.3. Multiple Cropping System and Agroforestry

As human population in rangelands increases and land use changes, some traditional practices are becoming less appropriate. Some of the options for sustainable agriculture could include efficient small-scale or garden irrigation, more effective rain-fed farming, changing cropping patterns, intercropping, or using crops with lower water demand (Lal, 1989; Batchelor *et al.*, 1994; Dixon *et al.*, 1994a; Dabbagh and Abdelrahman, 1998). Conservation-effective tillage is an option that could help to achieve improved productivity (Benites and Ofori, 1993). Agroforestry, using potential fuelwood species, also is an obvious option to alleviate land degradation as well as to meet some social needs. Management (e.g., appropriate coppicing in Uganda) or other practices (e.g., collecting only dead or fallen wood; Benjaminsen, 1993) are considered essential for maintenance of fuelwood species. Where woody weeds are increasing, they could be used for domestic fuel supply; otherwise, management options (e.g., use of fire along with regulation of grazing—Archer, 1995; Brown and Archer, 1999) might have to be implemented to control woody weeds.

5.5.4.4. Role of Community Participation and Public Policy

Community participation in decisionmaking and management, along with public policy, can be a favorable and critical issue in implementing some adaptation options. This could result in better management of rangelands (Pringle, 1995; Allen-Diaz, 1996; Thwaites *et al.*, 1998), thereby probably meeting conservation objectives (Pringle, 1995). Decisions to be made might include:

- Determinations about appropriate stocking rates, which might require discussion and negotiations among stakeholders, especially because stocking rates might be more social than technically oriented (Abel, 1997)
- Choosing some agroforestry practices that fulfil local needs, especially because many communities rely on fuelwood (Benjaminsen 1993)

- Diversification, since some communities could get or have already gotten involved in tourism as a way of highlighting some of the unique flora, fauna, and landscape features, thereby conserving the systems, reducing some of the impacts, and obtaining cash (Hofstede, 1995).

In dealing with options for reducing the consequences of land degradation in the future, public policy may have a crucial role (Hess and Holechek, 1995), especially because decisions at the landscape level (which are likely to include many different land tenures) are going to be increasingly important. Policies could be developed to address multiple pressures and, over the long term, to encompass sustainable land management and could include investments by governments to improve rangeland status (Morton *et al.*, 1995; Pickup, 1998).

5.5.5. Vulnerabilities and Sensitivity to Climate Change

For the future of rangelands, it is important to reduce the vulnerability of these systems to climate change. This is likely to be achieved by considering social and economic factors that determine land use by human populations (Allen-Diaz, 1996). Soil stability and thus maintenance of water and nutrient cycles are essential in reducing the risk of desertification. Any changes in these processes could make rangelands particularly vulnerable to climate change. Land degradation is a nonlinear process with thresholds that make these systems sensitive and vulnerable (Puigdefabregas, 1998). Prevention of land degradation might be a cheaper option than restoration, which can be costly (Puigdefabregas, 1998). Some studies suggest that changes in rainfall pattern may make some vegetation types within rangelands more vulnerable (e.g., Miombo woodlands—Fuller and Prince, 1996) if growing periods could not shift or if these growing periods coincide with insect outbreaks.

5.6. Forests and Woodlands

Forests and woodlands² provide many goods and services that society values, including food, marketable timber and non-wood products (fuel, fiber, construction material), medicines, biodiversity, regulation of biogeochemical cycles, soil and water conservation (e.g., erosion prevention), carbon reservoirs, recreation, research opportunities, and spiritual and cultural values. Forests play a key role in the functioning of the biosphere—for example, through carbon and water cycles (the latter is discussed in Chapter 4)—and hence indirectly affect the provision of many other goods and services (Woodwell and MacKenzie, 1995). Changes in global climate and atmospheric composition are likely to have an impact on most of these goods and services, with significant impacts on socioeconomic systems (Winnett, 1998).

²In this section, “forest” includes both forest land and woodlands, unless otherwise specified.

Since the SAR, many studies have dealt with changes in the structure, composition, and spatial patterns of forests (e.g., VEMAPMembers, 1995; Smith *et al.*, 1996a; Bugmann, 1997; Shriner *et al.*, 1998). The biogeochemical literature has focused on the carbon cycle (e.g., Apps and Price, 1996; Fan *et al.*, 1998; Steffen *et al.*, 1998; Tian *et al.*, 1998; IPCC, 2000; Schimel *et al.*, 2000). There is an expectation that directed land-management practices can either increase or retain carbon stocks in forests, thereby helping to mitigate increases in atmospheric CO₂ levels; this is discussed elsewhere (IPCC, 2000; see also TAR WGIII Chapter 4 and TAR WGI Chapter 3).

The influence of climate change on forests and associated goods and services is difficult to separate from the influence of other global change pressures such as atmospheric changes, land use, and land-use change resulting from human activities. The State-Pressure-Impacts approach outlined in Section 5.1 is used here as a framework to examine interrelated responses to global change and expected changes in supply of services from forests and woodlands (see Table 5-1). In this section, the focus is on some of the important pressures, impacts, and responses for three goods and services provided by forests and woodland ecosystems: carbon, timber, and non-wood goods and services. The impact on biodiversity in forests is covered in Sections 5.2 and 5.4. The state of the sector and the pressures acting on it, as well as possible responses, impacts, and adaptation opportunities, will differ among the regions of the world; here the focus is on global commonality.

5.6.1. Current Status and Trends

This section presents an overview of the current status and trends for forests in general; specific regional trends are presented in some of the regional chapters (Chapters 10–17).

The world's forests cover approximately 3,500 Mha (FAO, 1997a), or about 30% of the total land area (excluding Greenland and Antarctica). About 57% of the world's forests, mostly tropical, are located in developing countries. About 60% are located in seven countries (in order): the Russian Federation, Brazil, Canada, the United States, China, Indonesia, and the Democratic Republic of Congo.

In 1995, plantation forests were estimated to cover 81 Mha (2.3% of total estimated cover) in developing countries and about 80–100 Mha in developed countries (FAO, 1997a). They play an important role, particularly in the production of industrial roundwood and fuelwood, restoration of degraded lands, and provision of non-wood products (FAO, 1997a). Some countries obtain 50–95% of their industrial roundwood production from plantations that cover 1–17% of their total forest area (Sedjo, 1999). In many developing countries, plantations often occur as community woodlots, farm forests, and agroforestry operations.

Between 1980 and 1995, the area of the world's forests decreased by about 180 Mha (5% loss of total forest area in 15 years) as a result of human activities (FAO, 1997a). About 200 Mha

were converted to agriculture (subsistence agriculture, cash crops, and ranching), but this loss was partially offset by about 40 Mha increase in plantations. In developed countries, forests increased over the same period by about 20 Mha through afforestation and natural regeneration on land no longer in use by agriculture, despite losses of forests to urbanization and infrastructure development. Loss of native forest in developing countries (tropical and nontropical) appears to have slowed during 1990–1995, with an overall loss of about 65 Mha (FAO, 1997a). However, other changes such as fragmentation, unsustainable logging of mature forests, degradation, and development of infrastructure—all leading to losses of biomass—have occurred over large areas. Of about 92 Mha of tropical closed forest that underwent a change in cover class during 1980–1990, 10% became fragmented forest and 20% was converted to open forest or extended forest fallow (FAO, 1996). There are no global estimates of forest degradation, but data from specific areas give an indication of the extent of degradation. Logging practices damage and degrade more than 1 Mha yr⁻¹ of forest in the Brazilian Amazon; surface fires (e.g., those in 1998) may burn large areas of standing forest in these regions (Cochrane *et al.*, 1999; Nepstad *et al.*, 1999; see also Chapter 14). These authors conclude that present estimates of annual deforestation for Brazilian Amazonia capture less than half of the forest area that is impoverished each year—and even less during years of severe drought. In the boreal zone, there has been continuing encroachment by agriculture and development of infrastructure (roads, survey lines, wellheads, etc.) that open access to primary forests. Preliminary estimates of these effects for Canada, for example, indicate a net loss of 54,000–81,000 ha yr⁻¹ of forest over the period 1990–1998 as a result of various activities (Robinson *et al.*, 1999).

5.6.1.1. Carbon Pools and Flux

Carbon pools in the world's forests are estimated to be 348 Gt C in vegetation and 478 Gt C in soil (to 1 m) (updated since Dixon *et al.*, 1994b, by Brown, 1998). Bolin and Sukumar (2000) based their numbers on Dixon *et al.* (1994b). The largest vegetation and soil carbon pools are in tropical forests (60 and 45% of the total, respectively) because of their large extent and relatively high carbon densities. Carbon stocks in forests vary, depending on the type of forest in relation to climate, soil, management, frequency of disturbances, and level of human-caused degradation.

Based on traditional carbon inventories, terrestrial ecosystems were shown to be carbon sources during the 1980s in the SAR (Brown *et al.*, 1996); a high- and mid-latitude forest sink was exceeded by the source from low-latitude forests. However, recent work—using atmospheric measurements and modeling—suggests that terrestrial ecosystems appear to be net sinks for atmospheric carbon, even when losses from land-use change are taken into account (Bolin and Sukumar, 2000). For the 1980s, a net storage increase of 0.2 ± 1.0 Gt C yr⁻¹ by terrestrial ecosystems (largely in forests) was estimated as the difference between a net emission of 1.7 ± 0.8 Gt C yr⁻¹ from land-use

changes (primarily in the tropics) and global terrestrial uptake of 1.9 ± 1.3 Gt C yr $^{-1}$ (Bolin and Sukumar, 2000). In the 1990s, estimated net emissions from land-use change decreased slightly to 1.6 ± 0.8 Gt C yr $^{-1}$, and global terrestrial uptake increased to 2.3 ± 1.3 Gt C yr $^{-1}$, resulting in a net terrestrial uptake of 0.7 ± 1.0 Gt C yr $^{-1}$ (Bolin and Sukumar, 2000). This terrestrial net sink of carbon arises as the net effect of land-use practices (agricultural abandonment and regrowth, deforestation, and degradation); the indirect effects of human activities (e.g., atmospheric CO₂ fertilization and nutrient deposition); and the effects of changing climate, climatic variation, and disturbances. The relative importance of these different processes is known to vary strongly from region to region.

Regional source and sink relationships also have been inferred by techniques of inverse modeling of observed atmospheric CO₂ gradients and circulation patterns (Ciais *et al.*, 1995; Fan *et al.*, 1998). These estimates are relatively imprecise and are difficult to relate to those that are based on forest inventory data. For example, the study by Fan *et al.* (1998) suggests that 1.4 Gt C yr $^{-1}$ was taken up by terrestrial biota in North America in the 1980s. However, mechanistic models and measurements based on forest inventories do not agree with the magnitude or spatial distribution of this carbon sink (Holland and Brown, 1999; Potter and Klooster, 1999).

Temperate forests are considered to be net carbon sinks at present, with estimates of $1.4\text{--}2.0$ t C ha $^{-1}$ yr $^{-1}$ (Nabuurs *et al.*, 1997; Brown and Schroeder, 1999; Schulze *et al.*, 1999). These findings are consistent with recent estimates of carbon in woody biomass, based on statistics for 55 temperate and boreal countries; these statistics indicate a general increase in forest biomass from the 1980s to the 1990s (UN-ECE/FAO, 2000c). Changes in forest management (reduction of harvest levels, increased regeneration effort, and administrative set-asides), as well as changes in the environment (N and CO₂ fertilization), appear to have contributed to this trend, but the relative contribution of different factors varies among forest regions and countries (Kauppi *et al.*, 1992; Houghton *et al.*, 1998, 1999; Brown and Schroeder, 1999; Liski *et al.*, 1999; Nadelhoffer *et al.*, 1999).

In boreal forests, carbon budgets vary strongly among different forest types (Apps *et al.*, 1993; Bonan, 1993; Shvidenko and Nilsson, 1994). Although some boreal forest regions currently appear to be net carbon sources (Shepashenko *et al.*, 1998; Kurz and Apps, 1999), others appear to be net sinks, varying between 0.5 and 2.5 t C ha $^{-1}$ yr $^{-1}$ (Shvidenko and Nilsson, 1994; Jarvis *et al.*, 1997). The difference between annual increment and net fellings reported to the FAO (reported in UN-ECE/FAO, 2000c) does not account for changes in the frequency and severity of disturbances that have a large influence on source and sink relationships in boreal forests (Kasischke *et al.*, 1995; Kurz and Apps, 1999; Bhatti, 2001). For example, detailed analyses of forest inventory data together with observed changes in disturbance over time indicate that Canadian forest ecosystems changed from a modest sink (0.075 Gt C yr $^{-1}$) from 1920–1970 to a small net source of 0.050 Gt C yr $^{-1}$ in 1994 (Kurz and Apps, 1999). Similarly, in

Russia between 1983 and 1992, managed forest ecosystems in the European portion, where disturbances were relatively controlled, were a sink of 0.051 Gt C yr $^{-1}$ but a net source of $0.081\text{--}0.123$ Gt C yr $^{-1}$ in the less intensively managed Siberian forests of the east (Shepashenko *et al.*, 1998). Factors that were not included in these analyses that may offset losses of biotic carbon from disturbed forests include nitrogen deposition and CO₂ fertilization (Chen *et al.*, 2000; Schimel *et al.*, 2000), but experimental verification of these influences is not yet possible from inventory data.

In the tropics, forests are still reported to be a net carbon source as a result of land-use change. Although some studies suggest net carbon uptake in some tropical forests (Grace *et al.*, 1995; Phillips *et al.*, 1998), losses associated with high rates of forest clearing and degradation exceed such gains. The magnitude of the net carbon source from the tropics has been reported to be about 0.1 Gt C yr $^{-1}$ lower in the first half of the 1990s than in the 1980s (Houghton and Hackler, 1999; Houghton *et al.*, 2000; Houghton, 2001), mostly because of reduced rates of deforestation in the 1990s (FAO, 1996, 1997a).

In summary, carbon stored in forest ecosystems appears to be increasing, and at an increasing rate with about 0.2 Gt C yr $^{-1}$ being stored in the 1980s and 0.7 Gt C yr $^{-1}$ in the 1990s. Most storage occurs in temperate forests, with a small net source from tropical forests and boreal forests varying depending on the disturbance regime they experience.

5.6.1.2. Timber and Non-Wood Products

Forests contribute to GDP in three main ways: industrial wood products, fuelwood, and the economic impacts of recreation and non-wood products (e.g., mushrooms). Regional estimates generally are available only for the first (industrial) component, which captures the direct value of harvesting timber and the value added by manufacturing. At a global level, forestry contributes approximately 2% to GDP (FAO, 1997a)—6% in Africa, 3% in South America, 2% in North and Central America, and 1% in Europe. In developing countries, forestry contributes 4% to GDP; in developed countries the contribution is 1%. Total industrial timber production in 1997 was 1.5 billion m 3 , with more than 60% coming from developed countries (FAO, 1997a).

Although income and population growth influence demand for industrial timber, recycling and technological change (e.g., use of wood chips for manufactured products) can affect the quantity harvested from forests. Total industrial wood harvests have remained relatively constant over the past 20 years, even as global population and incomes have increased (FAO, 1998). Global per capita consumption of wood (including fuelwood and roundwood) is about 0.6 m 3 yr $^{-1}$; this level of consumption has been relatively stable over the past 40 years (Solberg *et al.*, 1996). Global fuelwood production in 1996 is estimated to be 1.9 billion m 3 , with 90% of this production occurring in developing countries (FAO, 1997a). In 1994, annual per capita fuelwood consumption in developing countries was 0.39 m 3 ,

versus 0.16 m³ in developed countries (FAO, 1997a). It is estimated that 2 billion people rely on wood and charcoal for fuel (mostly derived from forests), and ensuring an adequate and sustainable supply will continue to be an important pressure on forests.

Non-wood forest products (NWFP)—such as edible mushrooms, nuts, fruits, palm hearts, herbs, spices, gums, aromatic plants, game, fodder, rattan, medicinal and cosmetic products, resins, and the like—make important contributions to household income, food security, national economies, and environmental objectives of conservation of biodiversity (FAO, 1997a). It is estimated that about 80% of the population of the developing world depends on NWFP to meet some of their health and nutritional needs. Several million households worldwide depend heavily on these products for subsistence consumption and income.

5.6.2. Pressures on Forests and Woodlands

Forests have many pressures acting on them that result in changes to their structure and composition, as well as their function (see Figure 5-1). These structural changes, in turn, alter the function of forests in the physical climate system (Sellers *et al.*, 1990; Apps, 1993).

5.6.2.1. Climate Variability and Climate Change

Changes in climatic conditions affect all productivity indicators of forests (NPP, NEP, and NBP; see Box 5-1) and their ability to supply goods and services to human economies. The effects on forested area and forest productivity, however, vary from location to location, with gains in some regions and losses in others. Furthermore, the impacts vary among different measures of ecosystem productivity. For example, in boreal and alpine forests—where short growing seasons and heat sums are limiting factors to growth—NPP of many forest stands may increase with increasing temperature (Bugmann, 1997; but see Barber *et al.*, 2000), whereas NEP decreases as a result of increased decomposition (Schimel *et al.*, 1994; Valentini *et al.*, 2000; but see Giardina and Ryan, 2000). If higher temperatures lead to summer drought, even NPP may decrease as a result of lowered photosynthetic rates associated with reduced stomatal conductance (Sellers *et al.*, 1997), exacerbating the decrease in NEP from decomposition. If drier conditions also result in increased fires, biomass and soil carbon losses may result in negative NBP (Wirth *et al.*, 1999; Apps *et al.*, 2000).

Projected changes in forest area, structure, NPP, and NEP as a result of climate change vary by forest type and biome (Neilson *et al.*, 1998). Climate change also is likely to include changes in seasonality (Myneni *et al.*, 1997), timing of freeze-thaw patterns (Goulden *et al.*, 1998), the length of the growing season, nutrient feedbacks (Tian *et al.*, 1998), disturbance regimes (Kurz *et al.*, 1995), and diurnal temperature patterns (Clark and Clark, 1999). Changes in intra-annual variation that

fall outside the historical norm for a particular region also may have catastrophic effects—for example, through local climatic extremes or through late and early frost (Repo *et al.*, 1996; Ogren *et al.*, 1997; Colombo, 1998). These factors are likely to influence the distributional range of some tree species (Macdonald *et al.*, 1998; Rehfeldt *et al.*, 1999a). Changes in precipitation may not have immediate effects on mature and old-growth forests, which have well-established root systems, but are likely to have pronounced effects on regeneration success for some species following disturbance, such as harvest or fire (Hogg and Schwarz, 1997; Price *et al.*, 1999a,b).

5.6.2.2. Changes in Disturbance Regimes

At the landscape scale, changes in the disturbance regime introduce instabilities in forest age-class distributions (Bhatti *et al.*, 2000) and eventually in the distribution of plant species. If changes in disturbances are caused or accompanied by changes in environmental conditions, the responses of the forest ecosystem can be very complex. Changes in disturbance regimes, spatially and over time, can be exacerbated or mitigated by human activities (e.g., by fire ignitions and fire suppression).

5.6.2.2.1. Pressures from fires

Large areas of mixed savanna-woodlands in dry tropical zones of Africa, South America, Australia, and large areas of tropical humid forests burn every year (WRI, 2000). These fires are part of the natural seasonal cycle of growth, decay, and combustion and are ignited by lightning strikes. However, humans have long played a significant role in modifying fire regimes by changing the season and frequency of burning and consequently vegetation composition and structure (Goldammer and Price, 1998). During the 1990s in tropical humid areas, major fires have occurred in the Brazilian Amazon, Mexico, and Indonesia (Kalimantan and Sumatra) and were particularly severe in 1997–1998 during an El Niño episode (FAO, 1997a; Nepstad *et al.*, 1999). Fire also is a serious threat to native forests in many parts of tropical and nontropical developing countries. China, for example, suffered large losses in a single fire event in 1987, with 1 Mha (Anon., 1987) to 1.3 Mha (Cahoon *et al.*, 1994) burned. Fire prevention and suppression capability depends on available infrastructure such as imagery, roads, machinery, and human capital. In general, developed countries are better able to manage fire in regions with roads; developing countries may lack one or all of the factors.

The Indonesian fires of 1997–1998 were associated with a significant, but not unique, drought over much of the region. Estimates of the area burned vary from 96,000 ha to more than 8 Mha (Harwell, 2000). Most of this area was not forest but scrub, grassland, and agricultural lands. Almost no fires occurred deep within undisturbed primary forest; most were associated with land-clearing for new settlements or plantations or with logging operations. The most persistent fires were seven clusters of fires along the edges of degraded peat-swamp

forests in southern Sumatra and Kalimantan (Legg and Laumonier, 1999). The extent and persistence of these fires, and similar fires in Brazil, show the importance of interaction between climate and human actions in determining the structure and composition of tropical forests, land-use patterns, and carbon emissions.

In the boreal zone of Canada, there has been a marked increase in fire since about 1970, after a 5-decade decrease (Kurz *et al.*, 1995). The area of boreal forest burned annually in western North America has doubled in the past 20 years (0.28% in the 1970s to 0.57% in the 1990s), in parallel with the observed warming trend in the region (Kasischke *et al.*, 1999), despite much improved detection and suppression technology. Similar trends have been noted for Eurasian forests (Shvidenko and Nilsson, 1994, 1997; Kasischke *et al.*, 1999). Whether these changes are the result of human-induced climate change or are a result of natural climatic variability is not certain (Clark *et al.*, 1996; Flannigan *et al.*, 1998). Changes in the disturbance regime over periods of decades result in changes in forest age-class distribution to younger versus old forests (Kurz and Apps, 1999). These changes will reduce the landscape-averaged biomass stock and dead organic matter pools, including soils (Bhatti *et al.*, 2000). Hence, changes in NBP occur on scales of years to decades.

Fire frequency is expected to increase with human-induced climate change, especially where precipitation remains the same or is reduced (Stocks *et al.*, 1998). A general but moderate increase in precipitation, together with increased productivity, also could favor generation of more flammable fine fuels. Miranda (1994) suggests an increase in risk, severity, and frequency of forest fires in Europe. Stocks *et al.* (1998) used four GCMs and found similar predictions of an earlier start to the fire season and significant increases in the area experiencing high to extreme fire danger in Canada and Russia. Some regions may experience little change or even decreases in fire frequency, where precipitation increases or temperature does not rise (as in eastern Canada, where regional cooling has led to decreased fire frequency—Flannigan *et al.*, 1998). In most regions, there is likely to be an increased risk of forest fires, resulting in a change in vegetation structure that in turn exacerbates this risk (Cramer and Steffen, 1997).

During the past decade, forest fires in developed countries generally have become smaller, with the exception of the former Soviet Union (FAO, 1997a), Canada (Kurz *et al.*, 1995; Kurz and Apps, 1999), and the United States (Sampson and DeCoster, 1998). Where observed, the slight decline in forest areas burned per year is believed to be in part a result of improved prevention, detection, and control of fires. However, many such protected forests have increasing fuel loads and an abundance of dead and dying trees that eventually will make them more susceptible to catastrophic fires (e.g., Sampson and DeCoster, 1998). Several authors suggest that climate change is likely to increase the number of days with severe burning conditions, prolong the fire season, and increase lightning activity, all of which lead to probable increases in fire frequency

and areas burned (Price and Rind, 1994; Goldammer and Price, 1998; Stocks *et al.*, 1998).

5.6.2.2.2. Pressures from diseases and insect herbivory

Insect outbreaks can be extremely important disturbance factors (Hall and Moody, 1994); during outbreaks, trees often are killed over vast areas (Hardy *et al.*, 1986; Candau *et al.*, 1998). Under climate change, damage patterns caused by insects may change considerably, particularly those of insects whose temporal and spatial distributions strongly depend on climatic factors. The ecological interactions are complex, however (see Box 5-10).

In temperate and tropical regions, insect and disease outbreaks are reported mostly for plantation forests; relatively less is known about native forests (FAO, 1997a). In the boreal zone, insect-induced mortality was a significant part of the changing disturbance regime for Canada in the period 1920–1995 (Kurz *et al.*, 1995). Insect mortality accounted for the loss of approximately 76 Mha in that period, with a near tripling of the average annual rate after 1970 (Kurz and Apps, 1999). Similar trends have been observed for Russian forests, where recent annual insect damage and disease mortality affecting as much as 4 Mha was reported by Shvidenko *et al.* (1995). In Siberian and Canadian forests, insect damage is estimated to be of the same magnitude as fire loss (Krankina *et al.*, 1994; Fleming and Volney, 1995; Kurz *et al.*, 1995; Shvidenko *et al.*, 1995; Shvidenko, 2000). Changes in drought conditions appear to play an important role in insect outbreaks (Volney, 1988; Sheingauz, 1989; Isaev, 1997).

There is likely to be an increase in declines and dieback syndromes (Manion, 1991) caused by changes in disease patterns, involving a variety of diseases. For example, in temperate and boreal regions, there may be increased incidence of canker diseases in poplars and other tree species. Some canker diseases increase in severity with decreased bark moisture content brought on by drought (Bloomberg, 1962). As another example, *Armillaria* root disease is found throughout the world and causes significant damage on all forested continents (Kile *et al.*, 1991), through mortality and growth loss. This disease—one of the largest threats to regeneration in the productive forest of the Pacific Northwest of North America—has surfaced as a result of past management practices (Filip, 1977) but may be exacerbated by changing climate. Under present conditions, *Armillaria* root disease causes losses of 2–3 million m³ yr⁻¹ in the forests of Canada's Pacific Northwest (Morrison and Mallett, 1996). More recently, Mallet and Volney (1999) report a 43% decrease in annual volume increment and a 23% loss in annual height increment in lodgepole pine caused by *Armillaria* root disease. The incidence of *Armillaria* root disease can be expected to change under warmer or drier conditions. Significant damage has been observed in forests that have undergone drought stress (Wargo and Harrington, 1991). Moreover, in regions such as the Pacific Northwest where the mean annual temperature presently is below the optimum

Box 5-10. Complex Interactions: North America's Southern Boreal Forests, Pests, Birds, and Climate Change

The eastern spruce budworm (*Choristoneura fumiferana*) is estimated to defoliate approximately 2.3 Mha in the United States (Haack and Byler, 1993) and affects 51 million m³ of timber in Canada annually (Fleming and Volney, 1995). Although the budworm usually is present at low densities, budworm densities can reach 22 million larvae ha⁻¹ during periodic outbreaks (Crawford and Jennings, 1989). Outbreaks can extend over 72 Mha and last for 5–15 years, killing most trees in mature stands of balsam fir (Crawford and Jennings, 1989; Fleming and Volney, 1995).

Weather is thought to play a role in determining the budworm's range. Outbreaks frequently follow droughts (Mattson and Haack, 1987) or start after hot, dry summers (Fleming and Volney, 1995). Drought stresses host trees and changes plant microhabitats (Mattson and Haack, 1987). Moreover, the number of spruce budworm eggs laid at 25°C is 50% greater than the number laid at 15°C (Jardine, 1994). In some areas, drought and higher temperatures also shift the timing of reproduction in budworms so that they may no longer be affected by some of their natural parasitoid predators (Mattson and Haack, 1987). Weather, at least in central Canada, also may play a role in stopping some outbreaks if late spring frosts kill the tree's new growth on which the larvae feed.

Control of some populations of eastern spruce budworm may be strongly aided by bird predators, especially some of the wood warblers (Crawford and Jennings, 1989; but see Royama, 1984). Birds can consume as much as 84% of budworm larvae and pupae when budworm populations are low (approximately 100,000 ha⁻¹), but once larvae populations exceed 1,000,000 ha⁻¹, bird predation is unable to substantially effect budworm populations. This predatory action of birds works in concert with those of other predators, mostly insects.

The spruce budworm's northern range may shift northward with increasing temperatures—which, if accompanied by increased drought frequency, could lead to outbreaks of increasing frequency and severity that lead to dramatic ecological changes (Fleming and Volney, 1995). Increasing temperatures also might reduce the frequency of late spring frosts in southern boreal forests, perhaps increasing outbreak duration in some of those areas.

A changing climate also might decouple some budworm populations from those of their parasitoid and avian predators (Mattson and Haack, 1987; Price, 2000). Distributions of many of the warblers that feed on spruce budworms could shift poleward, perhaps becoming extirpated from latitudes below 50°N (Price, 2000). Replacing biological control mechanisms with chemical control mechanisms (e.g., pesticides) ultimately may yield a different set of problems; there are economic and social issues relating to large-scale pesticide application (see Section 5.4.4.3).

(25°C) for *Armillaria* growth, a warmer climate is likely to result in increased root disease and rate of spread.

5.6.2.2.3. Pressures from other disturbances

Additional disturbances are associated with extreme weather events such as hurricanes, tornadoes, unexpected drought or heavy rainfall, flooding, and icestorms that lead to extensive mortality and ecosystem change (e.g., Lugo *et al.*, 1990; Walker and Waide, 1991). Such events generally are highly localized and take place in a relatively short period of time but have long-term economic impacts (Haight *et al.*, 1995) and effects on ecosystems (Pontailler *et al.*, 1997). There is some evidence of recent increases in damage from such extreme events (Berz, 1999; see also Chapters 8 and 9).

5.6.2.3. Changing Demand for Forest Goods and Services

Future demand for industrial wood products depends on income growth, population growth, technological change, growth in human capital, changes in tastes and preferences,

and institutional and political change (Solberg *et al.*, 1996). Changes in other markets also can influence demand for wood products. For example, increases in the price of substitutes, such as steel and concrete building materials, would increase the demand for industrial timber. In light of these driving factors, recent timber market assessments have predicted that industrial harvests will increase by 1–2% yr⁻¹ (Solberg *et al.*, 1996; Brooks, 1997; FAO, 1997b; Sohngen *et al.*, 1999). These results contrast with those in the SAR (Solomon *et al.*, 1996), which concluded that global demand for industrial fiber would exceed global supply in the next century.

There is some debate about which forests are likely to be harvested in the future. Some authors contend that most supply will come from new industrial plantations, secondary growth forests, and enhanced management, rather than from native forests (FAO, 1997b; Sohngen *et al.*, 1999). The proportion of global timber from subtropical plantations (presently 10%) may increase to 40% by 2050 (Sohngen *et al.*, 1999). Non-native species, such as eucalypts and pines, are favored in these regions because the costs of management and harvesting are low compared to those in temperate and boreal forests (Sedjo and Lyon, 1990; Sedjo, 1999). Recent estimates

use global timber market models that incorporate management responses to prices across a wide range of forests. Under most price scenarios, subtropical plantations with 5- to 20-year rotations are a financially attractive alternative (Sedjo, 1999). However, higher demand still may put pressures on native forests even if plantation establishment and forest management responds to price increases (Solberg *et al.*, 1996; Brooks, 1997).

Policies that raise prices for substitute products, such as non-wood building materials made from steel or plastics, may increase timber demand, increase non-native plantation establishment, and cause additional pressures on native forests. Substituting non-wood products for wood products could increase carbon emissions as well (Marland and Schlamadinger, 1995; Schlamadinger *et al.*, 1997).

Increased reliance on plantations may have positive and negative ancillary consequences. For example, most of the plantations established for industrial purposes involve nonindigenous species, and the environmental effects of these plantations are not fully evident. However, most plantations have been established on former agricultural lands, which begins the process of restoring forests (Lugo *et al.*, 1993). Furthermore, plantations may reduce harvest pressures on natural forests. Despite increased reliance on plantations, however, industrial harvests in native forests along accessible roadways are likely to continue (Johns *et al.*, 1996).

The relationship between income and fuelwood demand is nonlinear. As incomes rise and infrastructure grows, households substitute alternative fuel sources (e.g., natural gas, fuel oil). Brooks *et al.* (1996), for example, suggest that fuelwood harvests will increase by 17% by 2050 under a low-GDP-growth scenario, but only by 4% under a high-growth scenario. Fuelwood harvest depends on the extent of substitution by alternative methods of heating and cooking. Currently, use of wood for energy on a large scale does not appear to be cost-effective relative to other energy sources, but if future energy prices rise, the demand for wood as a source of energy could rise.

5.6.2.4. Land-Use Change

Land-use change, including deforestation, is still considered to be a large pressure on global forests (Alcamo *et al.*, 1998). Several factors contribute to deforestation in tropical regions, including income and population growth, road-building policies, and other government policies (Southgate, 1998). Conversion to agriculture is impractical in boreal systems because of low productivity and high access costs, but some boreal forests continue to be converted to second-growth, managed forests. In temperate regions, conversion of agricultural lands back to forest has increased with agricultural productivity and falling prices (Kuusela, 1992; UN-ECE/FAO, 2000a). There is some evidence that these trends will continue, although at a lower rate (UN-ECE/FAO, 2000a). Factors

affecting these trends include urbanization, agricultural yields and prices, timber prices, access and conversion costs, and subsidy programs (such as those that promote afforestation for environmental reasons, including mitigation of climate change impacts).

5.6.2.5. Other Pressures

Fragmentation of forest landscapes as a result of climate change, land-use practices, and disturbance is expected to take place in advance of larger scale biome shifts (Fahrig and Merriam, 1994; Shriner *et al.*, 1998). Fragmentation can change biodiversity and resiliency (Sala *et al.*, 2000). Fragmentation of the landscape can occur as a result of disturbance (natural or anthropogenic) or more gradually from successional responses to environmental changes (NBIOME SSC, 1992).

Pressures from air pollution and air quality: There is evidence of decline in forest condition as a result of air pollution, especially in areas adjacent to industrial areas and large cities (e.g., deposition of heavy metals, sulfur, nitrogen, and ozone) (Nilsson *et al.*, 1998). Of major concern is increased nitrogen deposition caused by industrial processes and agriculture (Vitousek *et al.*, 1997b). Nitrogen deposition is higher in northern Europe than elsewhere (Vitousek *et al.*, 1997b). Low-level increases in nitrogen deposition associated with air pollution have been implicated in productivity increases over large regions (Schindler and Bayley, 1993; Vitousek *et al.*, 1997b). Temperate and boreal forests, which historically have been nitrogen-limited, appear to be most affected (Townsend and Rastetter, 1996; Vitousek *et al.*, 1997b). In other areas that become nitrogen-saturated, other nutrients are leached from the soil, resulting in forest dieback (Vitousek *et al.*, 1997b)—counteracting, or even overwhelming, any growth-enhancing effects of CO₂ enrichment.

Tropospheric ozone has been shown to impact the structure and productivity of forest ecosystems throughout industrialized countries (Chameides *et al.*, 1994; Weber *et al.*, 1994; Grulke *et al.*, 1998) and is likely to increase in extent with further industrial development and agriculture management (Chameides *et al.*, 1994). It has been suggested that the impact of ozone damage is reduced, but not eliminated, by increasing CO₂ (Tingey *et al.*, 2001).

In developed countries, the major impacts of air pollution on forest services are likely to be on recreation and non-wood products. Air pollution has been shown not to have significant impacts on industrial timber markets in the United States (Haynes and Kaiser, 1990), although European timber market studies suggest potentially larger local effects (Nilsson *et al.*, 1992). Although increasing industrialization in developing countries that have less restrictive air pollution requirements could have effects on local industrial or fuelwood markets, these increases are not expected to have major effects on global timber supply.

5.6.3. Responses by Forests and Woodlands and Impacts on their Goods and Services

Assessment of responses and impacts must distinguish between transient and equilibrium situations. Because forests are composed of long-lived organisms, responses to climate change and resulting impacts may take a long time to propagate through the system. To the extent that global change (climate and land-use change) proceeds faster than the life cycle of many late-succession trees, transient responses will predominate. Forest structure today is the result of activities and events that occurred many years (>100) ago; hence, responses and parameters measured today are not in equilibrium with present conditions. Many state variables, such as carbon pools, are expected to change with a time delay. Furthermore, forest responses to climate change and resulting impacts may extend longer than the change in climate.

5.6.3.1. Responses and Impacts: Carbon Storage

There are numerous ways in which forests respond to climate change and other pressures. These responses affect their ability to store carbon. Responses include changes in species distribution, NPP, NEP, and NBP; pests and disease outbreaks; and elevated CO₂, as well as changes in climate variability and weather extremes.

5.6.3.1.1. Forest and species distribution

Models that predict changes in species distribution suggest reduced forest carbon storage as climate changes (King and Neilson, 1992; Smith and Shugart, 1993; Kirilenko and Solomon, 1998; Woodward *et al.*, 1998), although the change in forest carbon stocks depends on species migration rates (Solomon and Kirilenko, 1997; see also Section 5.2). Where seed availability and dispersal are impeded (e.g., by fragmented landscapes), achieved/realized productivity may remain below the potential for some time (resulting in carbon losses) unless aided by human intervention (Iverson and Prasad, 1998; Sohngen *et al.*, 1998; Iverson *et al.*, 1999). Pitelka and Plant Migration Workshop Group (1997) point out, however, that increases in weed species that take advantage of human mobility may be an adverse effect.

Changes in forest distribution as a result of climate change are likely to occur subtly and nonlinearly (Davis and Botkin, 1985; Prentice *et al.*, 1993; Neilson and Marks, 1994; Tchbekova *et al.*, 1994; Bugmann *et al.*, 1996; Neilson and Drapek, 1998). Prediction of changes in species distribution is complicated by the current lack of precise predictions of environmental changes themselves (especially precipitation) and responses of species to these changes. Price *et al.* (1999b) show that responses to precipitation are greatly dependent on assumptions made about species parameters and the temporal pattern of rainfall. The most rapid changes are expected where they are accelerated by changes in natural and anthropogenic disturbance patterns

(Overpeck *et al.*, 1991; Kurz *et al.*, 1995; Flannigan and Bergeron, 1998).

At the stand level, climate-induced changes in competitive relationships are likely to lead to dieback and replacement of maladapted species, causing changes in stand population and productivity (e.g., Cumming and Burton, 1996; Rehfeldt *et al.*, 1999b). In addition, increases in locally extreme events and disturbances (fires, insects, diseases and other pathogens) developing over different time scales (Wein *et al.*, 1989; Campbell and McAndrews, 1993; Campbell and Flannigan, 2000) also lead to regionally specific increases in mortality and dieback. Resulting changes in age-class distributions and productivity are likely to have short- and long-term impacts on carbon stocks (Kurz *et al.*, 1995; Fleming, 1996; Hogg, 1997, 1999; Fleming and Candau, 1998).

5.6.3.1.2. NPP and NEP

Some modeled responses of forest ecosystems to climate change suggest that forests could increase carbon storage during climate change (Xiao *et al.*, 1997; Prinn *et al.*, 1999). However, recent work has provided new experimental evidence on the response of vegetation uptake (NPP) and ecosystem losses (affecting both NEP and NBP) to observed changes in climate over the past century. The net balance between NPP (usually assumed to increase with warming, though this assumption is challenged by data offered by Barber *et al.*, 2000), heterotrophic respiration (often assumed to increase with warming, though this is challenged, for example, by Giardina and Ryan, 2000, and Liski *et al.*, 1999—at least for mineral soil components) and disturbance releases (often ignored but shown—for example, by Kurz and Apps, 1999—to be important in boreal estimates of NBP) is no longer as clear as the SAR asserts. Present research continues to improve scaling of localized responses (at the stand level, where increases and decreases in NPP and NEP are observed) to the global scale.

Research reported since the SAR confirms the view that the largest and earliest impacts induced by climate change are likely to occur in boreal forests, where changes in weather-related disturbance regimes and nutrient cycling are primary controls on productivity (Kasischke *et al.*, 1995; Kurz *et al.*, 1995; Yarie, 1999). The impacts are exacerbated by characteristic ecosystem time constants (rotation length, mean residence time of SOM, etc.) that are long compared to other forest ecosystems. In boreal forests, recent warming has been shown to change seasonal thaw patterns (Goulden *et al.*, 1998; Osterkamp and Romanovsky, 1999); increase growing season length (Keeling *et al.*, 1996; Myneni *et al.*, 1997); and, if accompanied by summer drought, reduce NPP (Sellers *et al.*, 1997; Barber *et al.*, 2000). These trends are expected to continue on average (see Table 3-10), although short-term modulations will occur (e.g., in association with ENSO events) (Black *et al.*, 2000).

The SAR (Kirschbaum *et al.*, 1996) concludes that in lowland humid tropics, temperatures already are close to optimum

ranges for year-round growth. Hence, an increase in temperature as a result of climate change is likely to have a marginal effect on forest processes. However, research in a lowland tropical forest in Costa Rica has shown that the annual growth in six major species of this forest (with markedly different growth rates and life histories), over a period of 13 years, was highly negatively correlated with annual mean minimum (nighttime) temperatures (Clark and Clark, 1999). Although annual tree growth varied among the six species, there was a highly significant interannual coherence of growth among species.

5.6.3.1.3. Insect herbivory, pests, and diseases

Some evidence suggests that insect populations already are responding to climate change (Fleming and Tatchell, 1995). In general, current forecasts of the response of forest insects and other pathogens to climate change are based on historical relationships between outbreak patterns and climate. These forecasts suggest more frequent or longer outbreaks (Thomson and Shrimpton, 1984; Thomson *et al.*, 1984; Mattson and Haack, 1987; Volney and McCullough, 1994; Carroll *et al.*, 1995; Cerezke and Volney, 1995; Brasier, 1996; Roland *et al.*, 1998). Outbreaks also may involve range shifts northward, poleward, or to higher elevations (Williams and Liebold, 1997). All of these responses will tend to reduce forest productivity and carbon stocks, although the quantitative extent of these changes is hard to predict (see Box 5-10).

5.6.3.1.4. Elevated CO₂

At the time of the SAR, no experiments on intact forest ecosystems exposed to elevated CO₂ had been performed. Since then, several FACE experiments have been implemented and are beginning to show interesting results. In a 13-year-old loblolly pine plantation (North Carolina), CO₂ levels have been maintained at 200 ppm above ambient. After 2 years, the growth rate of the dominant trees increased by about 26% relative to trees under ambient conditions (DeLucia *et al.*, 1999). Litterfall and fine root increment also increased under the CO₂-enriched conditions. Total NPP increased by 25%. The study concludes, however, that stimulation is expected to saturate not only because each forest stand tends toward its maximum carrying capacity (limited by nutrient capital) but also because plants may become acclimated to increased CO₂ levels.

Research on CO₂ fertilization, however, has taken place only over a short fraction of the forest ecosystem's life cycle. Questions of saturation of response can be addressed through longer term experiments on tree species grown under elevated CO₂ in open-top chambers under field conditions over several growing seasons (Norby *et al.*, 1999). A review of such experiments by Norby *et al.* (1999) found that the evidence shows continued and consistent stimulation of photosynthesis, with little evidence of long-term loss of sensitivity to CO₂; the relative effect on aboveground dry mass was highly variable but greater than indicated by seedling studies, and the annual increase in wood

mass per unit of leaf area increased. Norby *et al.* (1999) also found that leaf nitrogen concentrations were lower in CO₂-enriched trees, but not as low as seedling studies indicated, and the leaf litter C/N ratio did not increase. In the majority of CO₂ chamber experiments, the decrease in the percentage of nitrogen in litter was matched by an increase in the percentage of lignin. Moore *et al.* (1999) have suggested, however, that lower litter quality caused by CO₂ fertilization may have offset the expected temperature-induced increase in decomposition. A longer term perspective still is needed because long-term trends cannot be extrapolated directly from relatively short-term experiments on individual trees (Idso, 1999). Field experiments on elevated CO₂ provide inconclusive evidence at this time to predict overall changes in carbon storage in forests.

5.6.3.1.5. Climate-induced changes in variability and weather extremes

The net rate of carbon storage in forests varies as a result of interannual variability in rainfall, temperature, and disturbance regimes. For example, transient simulations with the Terrestrial Ecosystem Model (TEM) suggest that forests of the Amazon basin during hot, dry El Niño years were a net source of carbon (of as much as 0.2 Gt C yr⁻¹), whereas in other years they were a net sink (as much as 0.7 Gt C yr⁻¹) (Tian *et al.*, 1998). Notably, source and sink strength varied across the basin, indicating regional variation. Similarly for the United States, the net rate of carbon storage varied from a net source of about 0.1 Gt C yr⁻¹ to a net sink of 0.2 Gt C yr⁻¹ (Schimel *et al.*, 2000). The rate of carbon accumulation in undisturbed forests of the Amazon basin reported by Tian *et al.* (1998) was approximately equal to the annual source from deforestation in the same area. For the United States, Houghton *et al.* (1999)—using inventory data—estimate a sink of 0.35 Gt yr⁻¹ during the 1980s as a result of forest management and regrowth on abandoned agricultural lands, whereas Schimel *et al.* (2000) indicate that 0.08 Gt yr⁻¹ stored from 1980 to 1993 could have been a result of carbon fertilization and climate effects. Thus, for the United States, the rate of carbon accumulation in forest regrowth on abandoned agricultural and harvested managed forest lands appears to be as large as or larger than the direct effects of CO₂ and climate (Schimel *et al.*, 2000). The SAR (Kirschbaum *et al.*, 1996) suggests that modeled trends described above are unlikely to continue under projected climate change and high elevated CO₂ concentrations. However, climatic variability (including ENSO events) is likely to increase under a changed climate (see Table 3-10), which may increase interannual variation in regional carbon uptake—as demonstrated by Tian *et al.* (1998) and Schimel *et al.* (2000).

5.6.3.2. Responses and Impacts: Timber and Non-Wood Goods and Services

5.6.3.2.1. Response to locally extreme events

In addition to fire and insect predation, other episodic losses may become increasingly important in response to locally

extreme weather events. For example, in Europe, wind-throw damage has appeared to increase steadily from negligible values prior to about 1950; wind-throws exceeding 20 million m³ have occurred 10 times since then (UN-ECE/FAO, 2000b). Losses in 1990 and 1999 were estimated at 120 million and 193 million m³, respectively—the latter equivalent to 2 years of harvest and the result of just three storms over a period of 3 days (UN-ECE/FAO, 2000b). The unusual 1998 icestorms in eastern North America caused heavy damage to infrastructure as well as large areas of forest, the extent of which is still being assessed (Irland, 1998).

Financial returns to forest landowners decline if these episodic events (including fire and insect predation) increase (Haight *et al.*, 1995), although the impact on global timber supply of such episodic losses is unlikely to be significant. Local effects on timber and non-wood goods and services may be significant, although timber loss may be ameliorated through salvage logging. Moreover, the location of the loss is particularly important for non-wood products and services. For example, forest fires in recreational areas are known to have an impact (Englin *et al.*, 1996).

5.6.3.2.2. Industrial timber

Recent industrial timber studies link equilibrium ecological models to economic models to measure market impacts to potential climate change and include adaptation (Joyce *et al.*, 1995; Perez-Garcia *et al.*, 1997; Sohngen and Mendelsohn, 1998; McCarl *et al.*, 2000; Sohngen *et al.*, 2000). Conclusions from regional studies are similar to those in the SAR (Solomon *et al.*, 1996) for temperate regions, suggesting that wood supply in these regions will not be reduced by climate change. Studies in the United States that consider only changes in forest growth find small negative or positive impacts on timber supply (Joyce *et al.*, 1995; McCarl *et al.*, 2000). Studies that consider growth effects and species redistribution effects (dieback of existing forests, followed by redistribution), as well as alternative economic scenarios, find that welfare economic impacts in U.S. timber markets could change by -1 to +11% (Sohngen and Mendelsohn, 1998). Generally, consumers are predicted to benefit from increased supply and lower prices. Producers in some regions of the United States may lose because of lower prices and dieback, although productivity gains could offset lower prices (Sohngen, 2001).

In contrast to the SAR (Solomon *et al.*, 1996), more recent global market studies suggest that climate change is likely to increase global timber supply and enhance existing market trends toward rising market share in developing countries (Perez-Garcia *et al.*, 1997; Sohngen *et al.*, 2000). One study that uses TEM (Melillo *et al.*, 1993) to predict growth changes finds that global timber growth rises, global timber supply increases, prices fall, and consumers and mill owners benefit (Perez-Garcia *et al.*, 1997). Landowners in regions where increased timber growth does not offset lower prices perceive losses. A study using the BIOME3 model (Haxeltine and

Prentice, 1996) suggests that producers in temperate and boreal forests could be susceptible to economic losses from short-term dieback effects and lower prices, although long-term (>50 years) supply from these regions is predicted to increase (Sohngen *et al.*, 2000). Alternatively, studies that do not consider global market forces, timber prices, or adaptation predict that supply in boreal regions is likely to decline (Solomon and Leemans, 1997).

5.6.3.2.3. Recreation and non-wood forest products

There is considerably less published literature available to assess the effects of climate change on nonmarket services from forests (Wall, 1998), including recreation and non-wood forest products. Climate change is likely to have direct effects on forest-based recreation. For example, lengthening of the summer season may increase forest recreation (Wall, 1998). Changes in the mean and variance in daily temperature and precipitation during peak seasons will affect specific activities differently, however. In the United States, some studies suggest that higher temperatures may negatively affect camping, hiking, and skiing but positively affect fishing (Loomis and Crespi, 1999; Mendelsohn and Markowski, 1999; Joyce *et al.*, 2000).

Climate change also will have indirect effects on forest recreation. For example, changes in the structure and function of natural forests that are used for recreation could alter visitation patterns by causing users to substitute alternative sites. Alternatively, some recreational industries may have large adaptation costs—for example, snow-making costs in skiing areas may increase (Irland *et al.*, 2001). In addition, institutional factors are likely to play a strong role in mediating the response of recreation because much of it occurs on public, natural forests where adaptation may be less economically feasible. Many forest-based activities, such as hunting, rely on management decisions by agencies that will have to adapt to climate change as well (Brotton and Wall, 1997).

5.6.4. Adaptation Options and Vulnerability of Goods and Services

5.6.4.1. Adaptation in Timber and Non-Wood Goods and Services

In markets, prices mediate adaptation through land and product management. At the regional and global scales, the extent and nature of adaptation will depend primarily on prices, the relative value of substitutes, the cost of management, and technology (Joyce *et al.*, 1995; Binkley *et al.*, 1997; Perez-Garcia *et al.*, 1997; Skog and Nicholson, 1998; Sohngen and Mendelsohn, 1998). On specific sites, changes in forest growth and productivity will constrain, and could limit, choices of adaptation strategies (Lindner, 1999, 2000).

Forest management has a history of long-term decisions under uncertain future market and biological conditions (e.g., prices,

pest infestations, or forest fires). Most adaptation in land management will occur in managed forests; it will include salvaging dead and dying timber, replanting new species that are better suited to the new climate, planting genetically modified species, intensifying or decreasing management, and other responses (e.g., Binkley, 1988; Joyce *et al.*, 1995; Perez-Garcia *et al.*, 1997; Sohngen and Mendelsohn, 1998; Lindner, 1999). Climate change is not likely to cause humans to convert highly productive agricultural land to forests (McCarl *et al.*, 2000), even with afforestation incentives (e.g., the Kyoto Protocol) (Alig *et al.*, 1997). Adaptation estimates are sensitive to assumed rates of salvage and choices made in regenerating species during climate change (Sohngen and Mendelsohn, 1998; Lindner, 1999). In product management, adaptation includes substituting species in the production process for solid wood and pulpwood products, shifting harvests from one region to another, and developing new technologies and products, such as wood products manufactured with adhesives (McCarl *et al.*, 2000; Irland *et al.*, 2001). In some cases, producers may need to adapt to changes in wood quality (Gindl *et al.*, 2000).

In addition to adaptation through traditional management, agroforestry, small woodlot management, and windrows (or shelterbelts) could provide numerous adaptation options for maintaining tree cover and fuelwood supplies in developing countries. Afforestation in agroforestry projects designed to mitigate climate change may provide important initial steps towards adaptation (Sampson *et al.*, 2000). Although agroforestry is not expected to play a large role in global industrial timber supplies, it may have important regional implications.

Recreation users can adapt by substituting recreational sites as forests respond to climate change, but this will have impacts on recreational industries. Substitution will be easier in regions where transportation networks are well established. Adaptation will be more difficult in regions where recreation depends on particular forest structures (e.g., old-growth forests) that are negatively affected by climate change and for which there are no close substitutes (Wall, 1998).

5.6.4.2. Vulnerability Associated with NPP, NEP, and NBP

Given their inertia, forested systems may exhibit low vulnerability and low climate sensitivity, unless drought and disturbance are driving factors (Peterken and Mountford, 1996). Extant forests may persist and appear to exhibit low vulnerability and low climate sensitivity (see Section 5.2), but they may be climate sensitive in ways that are not immediately apparent. Thus, their vulnerability may occur as a reduction in quality (degradation) even where the forest persists as an entity. Increases in disturbances, however, may lead to rapid structural changes of forests, with replacement by weedy species (Overpeck *et al.*, 1990). For example, an increase in area burned by fire or destroyed by invading insects and disease could rapidly undergo changes in species composition, successional dynamics, rates of nutrient cycling, and many other aspects of forest ecosystems—with impacts on goods and services provided by these forests. From

this perspective, in the context of all of the direct and indirect impacts of climatic change and their interactions, the potential vulnerability of forests is high.

The main processes that determine the carbon balance of forests—photosynthesis, plant and heterotrophic respiration, and disturbance releases—are regulated by different environmental factors. Carbon assimilation is a function mainly of available light, temperature, nutrients, and CO₂, and this function shows a saturation characteristic. Respiration is a function of temperature; it increases exponentially with temperature. Thus, close correlation between GPP and NPP does not exist (allocation plays an important role). Similarly, there is no strict correlation between NPP and NEP (high NEP is possible at high and low rates of assimilation and respiration). Disturbances such as harvest or fire export carbon from forests, bypassing respiration; thus, NBP is not expected to correlate with NEP and NPP. Photosynthesis, plant and heterotrophic respiration, and disturbance are vulnerable in different ways and are quite sensitive to climate change and other global change forces.

5.6.4.3. Vulnerability of Unmanaged Systems

Increases in disturbances such as insect infestations and fires can lead to rapid structural and functional changes in forests (species composition, successional dynamics, rates of nutrient cycles, etc.), with replacement by weedy species. The effects of these vulnerabilities in unmanaged systems on goods and services vary. They are not likely to have large effects on market products given that unmanaged forests constitute an increasingly small portion of timber harvests. They could have large impacts on local provision of timber products, NWFP, and fuelwood. Local services from forests could be highly vulnerable, particularly if the services are tied to specific forest functions that change (e.g., hiking in old-growth forests).

5.6.4.4. Vulnerability in Managed Systems

Managed systems are vulnerable to direct impacts on NPP (related to volume production) and species composition (related to timber quality), as well as market forces. The global supply of market products exhibits low vulnerability because timber markets have high capacity to adapt to change. Temperate and boreal producers are vulnerable to dieback effects and lower prices caused by potential global increases in timber growth. Managed forests in subtropical regions have low vulnerability given their high growth rates and short rotation periods, which provide multiple opportunities to adapt to changes.

5.7. Lakes and Streams

Lake and stream ecosystems include many familiar places: large and small lakes, permanent and temporary ponds, and streams—from tiny, often temporary rivulets at headwaters to powerful floodplain rivers discharging from our continents.

Freshwaters (lakes and rivers), which are so valuable for the sustainability of life as we know it, constitute only 0.0091% of the Earth's surface waters by volume. This is a great deal less than 0.5% for groundwater and 97.3% for oceans (Cole, 1994). Lakes and rivers are used intensively for recreation and are aesthetically valued. These values include fishing, hunting, swimming, boating, skating, and simply enjoying the view.

This section focusses on physical and biological processes and how they affect goods and services from lakes and streams that are regulated by these processes. The emphasis is on food, carbon, and biodiversity. Hydrology and water supply are covered in Chapter 4; oceans and coastal systems are covered in Chapter 6. Hydrological goods and services are covered largely in Chapter 4, but are considered here as an interactive influence of climate change on inland waters. Wetlands are covered in Section 5.8.

5.7.1. Status of Goods and Services

Products from lakes and streams include fisheries (fish, amphibians, crustaceans, and mollusks) and aquaculture; services include biodiversity, recreation, aesthetics, and biogeochemical cycling. A detailed list of services from freshwater ecosystems includes many items that are undervalued in economic terms and often are unrecognized and unappreciated—for example, their role in the carbon cycle.

Reported catches in freshwater and inland fisheries were 7.7 Mt of biomass in 1996 (FAO, 1999b) and 15.1 Mt from aquaculture. China accounts for 80% of aquaculture production. Actual landings in capture fisheries are believed to be two to three times larger owing to nonreporting (FAO, 1999c). About 100 fish species are reported in world catches—primarily cyprinids, cichlids, snakeheads, catfish, and barbs. Asia and China report the largest catches; Africa is second; North America ranks relatively low. River and large reservoir fisheries are important.

Recreational fish catches are included in the foregoing world catches and were reported to be 0.48 Mt in 1990 (FAO, 1992). This is likely to be an underestimate because only 30 (of 200) countries reported recreational catches. Recreational fishing is increasing in developed and developing countries. The number of anglers is estimated at 21.3 million in 22 European countries, 29.7 million in the United States, and 4.2 million in Canada (U.S. Fish and Wildlife Service, 1996; Department of Fisheries and Oceans, Canada, 1998). Total expenditures for recreational angling are in the billions of dollars—for example, \$38 billion in the United States in 1996 (U.S. Fish and Wildlife Service, 1996) and \$4.9 billion in Canada in 1995.

Freshwaters are known for high biodiversity and endemism owing to their island-like nature, which leads to speciation and reduces invasions of competitors and predators. Of about 28,000 fish species known on Earth, 41% are freshwater species and 58% are marine, of which 1% spend part of their lives in

freshwater (Moyle and Cech, 1996). Individual east African Rift Valley lakes contain species flocks of almost 250 cichlid species. In Lake Baikal in Russia, 35% of the plants and 65% of the animals are endemic (Burgis and Morris, 1987). At the global level, biodiversity in many lakes has been decreasing in recent decades, with many species becoming extinct (Naiman *et al.*, 1995b). The trend is likely to continue, with many species that now are listed as endangered or threatened becoming extinct (IUCN, 1996). The causes for these extinctions are likely to be related to the many pressures listed below.

Inland waters play a major role in biogeochemical cycling of elements and compounds such as carbon, sulfur, nitrogen, phosphorous, silica, calcium, and toxic substances. The general roles are storage, transformation, and transport (Stumm and Morgan, 1996). Storage is important because sediments and associated minerals accumulate in the bottom sediments of lakes, reservoirs, and floodplains. Transformation includes organic waste purification and detoxification of various human created compounds such as insecticides. Water movement redistributes these spatially.

Of special interest here is the role of freshwaters in carbon storage and CO₂ and methane (CH₄) release. Organic carbon from primary production in lakes and adjacent riparian lands accumulates in sediments; estimates are that 319 Mt yr⁻¹ are buried in the 3.03 million km² of small and large lakes, reservoirs, and inland seas worldwide (USGS, 1999; see also Stallard, 1998). This estimate excludes amounts for peatlands (96 Mt yr⁻¹). It is three times greater than estimates for the ocean in absolute terms (97 Mt yr⁻¹) even given the relatively small area of inland waters. Lakes also are a source of GHGs. Lakes become supersaturated with dissolved CO₂, and net gas exchange is from the lake to the atmosphere (Cole *et al.*, 1994). For example, during summer in Lake Pääjärvi, Finland, the amount of carbon from respiration in the water column was greater than that produced by phytoplankton and sedimentation combined (Kankaala *et al.*, 1996). Pulses of CO₂ from the water column and CH₄ from sediments are released to the atmosphere during spring and fall mixing of the water column of dimictic lakes (Kratz *et al.*, 1987; Riera *et al.*, 1999; Kortelainen *et al.*, 2001). Methane releases, especially from the littoral zone, can be significant in lakes and reservoirs (Fearnside, 1995, 1997; Alm *et al.*, 1997a; Hyvönen *et al.*, 1998).

Hydroelectric power plants generally are assumed to emit less CO₂ than fossil fuel plants. However, a hydroelectric reservoir may contribute more to GHGs over 100 years of operation than a fossil fuel plant that produces an equivalent amount of electricity (Fearnside, 1997). Emissions are likely to be high in the first few decades and then decrease. This is exemplified by a Brazilian hydroelectric reservoir that is simulated to release a large quantity of CO₂ during the first 10 years after filling (*ca.* 5–27 Mt CO₂ gas yr⁻¹) but relatively low amounts from years 30 to 100. Releases of CH₄ were simulated to be high for at least 100 years (about 0.05–0.1 Mt CH₄ yr⁻¹, with actual estimates for 1990 of 0.09 Mt) (Fearnside, 1995, 1997).

5.7.2. Pressures on Goods and Services

People expect drinkable, swimmable, boatable, and fishable freshwaters. However, rivers and lakes have many pressures. These pressures include land and water use for urbanization, agriculture, and aquaculture; hydrologic engineering structures such as dams, dykes, channelization, and construction of drainage and connecting canals; water extractions for industry, drinking water, irrigation, and power production; water pollution with toxics, excess nutrients, and suspended sediments; capture fisheries; and invasion of exotics. UV-B is an interactive pressure with climate change owing to the change in water clarity influenced by drought. Under these conditions, UV-B penetrates farther and causes more damage in clear waters than in murky waters.

Human demand for water in many areas will increase more rapidly with climate change and population increases and leave fewer waters unmodified by water projects (see Chapter 4). Water projects interact with many aspects of climate change as related to natural resource and environmental management. Additional dams will increase the difficulty of managing migratory fish populations in streams. Sedimentation that occurs above dams will reduce downstream transport of sand, sediments, and toxic substances. Lakes and reservoirs with increased water withdrawals will reduce the suitability of the littoral zone for fish spawning and nursery areas. Diversions of water by canals, ships, or pipes will transport exotics into new watersheds and confound biodiversity and exotics issues.

5.7.3 Responses of Lakes and Streams and Impacts on their Goods and Services

Many responses of lakes and streams to climate change were documented in the SAR by Arnell *et al.* (1996), and more have been added by Cushing (1997) and Domoto *et al.* (2000). Responses include warming of waters; reductions in ice cover; reduction in dissolved oxygen in deep waters; changes in the interaction between waters and their watersheds; changes in biogeochemical cycling; greater frequencies of extreme events, including flood and drought; changes in growth, reproduction, and distribution of organisms; and poleward movement of climate zones for organisms. Only a few are mentioned in the following subsections.

5.7.3.1. Physical Conditions

5.7.3.1.1. Ice cover

To date, the only limnological properties measured or simulated at a global scale are lake and river ice phenologies. Ice-cover durations for inland waters have decreased over the entire northern hemisphere (Magnuson *et al.*, 2000) (see Figure 5-6). Change from 1846 to 1995 averaged 8.7 days later freeze and 9.8 days earlier break-up; these changes correspond to a 1.8°C increase in air temperature. Lake Suwa in Japan, Tornionoki

River in Finland, and Angara River in Siberia have longer records; ice phenologies have been changing in the direction of warming since about the early 1700s, but at slower rates than during 1846–1995. Interannual variability in freeze dates, thaw dates, and ice duration are increasing (Kratz *et al.*, 2001). Interannual variability was greater from 1971 to 1990 than from 1951 to 1970 in 184 lakes in the northern hemisphere.

For the Baltic Sea, which contains freshwater communities near shore and to the north, simulation until 2050 reduced the extent of ice cover from 38% of the area to 10%, and simulation until 2100 reduced ice cover to zero (Haapala and Leppäranta, 1997). For U.S. lakes, ice-on date, ice-off date, ice duration, ice thickness, and the continuity of ice cover all responded to a 2xCO₂ change (Fang and Stefan, 1998). Mean duration at 209 locations distributed evenly across the country declined by 45 days (60%), and ice thickness by 21 cm (62%). Simulated

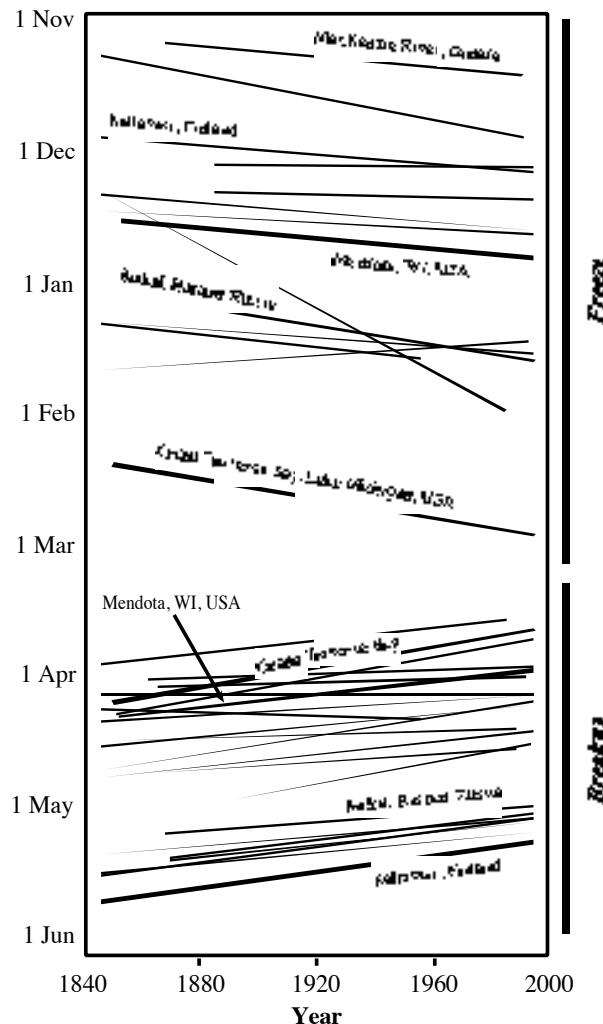

Figure 5-6: Historical trends in freeze and breakup dates of lakes and rivers in the Northern Hemisphere; 37 of the 39 trend slopes are in the direction of warming (modified from Magnuson *et al.*, 2000).

profiles of deepwater oxygen concentrations and water temperatures also changed dramatically in lakes across the United States (Fang and Stefan, 1997).

Lake ice influences biogeochemical cycling, including gas exchange with the atmosphere, fish habitat availability (through changes in pH and dissolved oxygen), biodiversity, and seasonal succession (Arnell *et al.*, 1996; Cushing, 1997). Decreased ice cover should reduce winterkill of fish.

Ice break-up date influences the productivity of diatoms beneath the ice of Lake Baikal (Granin *et al.*, 2001). Seasonal succession of phytoplankton in small lakes is altered partly because of variation in the inoculum of algae beneath the ice in different years (Adrian and Hintze, 2001). The mechanism for enhanced diatom productivity in Lake Baikal is a combination of nutrient enrichment immediately beneath the ice owing to the extrusion of salts as the water freezes and vertical mixing that results from the greater density of the water with extruded salts immediately beneath the ice. Reductions in ice thickness and increases in snow would be expected to reduce diatom production.

River ice plays an important biological role by regulating flow aeration and oxygen concentrations under the ice (Prowse, 1994; Chambers *et al.*, 1997); dissolved oxygen can approach critical levels for river biota (e.g., Power *et al.*, 1993). Decreases in the duration of the river-ice season or increases in the size and frequency of open-water sections where re-aeration can occur will reduce anoxia. Warmer winters favor the formation of mid-winter break-ups produced by rapid snowmelt runoff, particularly those initiated by rain-on-snow events. Such events significantly impact benthic invertebrate and fish populations where late-season break-ups are the norm (Cunjak *et al.*, 1998).

Ecological impacts will be influenced most by changes in break-up timing and intensity. Physical disturbances from break-up scouring and flooding influence nutrient and organic matter dynamics, spring water chemistry, and the abundance and diversity of river biota (Scrimgeour *et al.*, 1994; Cunjak *et al.*, 1998). Ice-induced flooding supplies the flux of sediment, nutrients, and water that are essential to the health of freshwater delta ecosystems (e.g., Lesack *et al.*, 1991; Prowse and Conly, 1998). Even the mesoscale climate of delta ecosystems depends on the timing and severity of break-up flooding (Prowse and Gridley, 1993).

Climate-induced change in ice cover or the timing and severity of its break-up will affect the movement and deposition of sediment and associated contaminants. Stable cover leads to deposition of sediment particles that would remain in suspension without ice cover. Environmental contaminants with an affinity for adsorption to fine-grained sediments are more likely to be deposited during ice-covered, low-flow season than during open-water season. The break-up plume contains the winter-long accumulation of contaminated sediment (Milburn and Prowse, 1996). Sediment deposition zones often are where biological productivity is greatest, such as on river deltas

(Milburn and Prowse, 1998). Because growth rates of aquatic organisms in cold regions are low and because higher trophic level animals are longer lived, potential exists for greater life-long accumulation of contaminants in these aquatic ecosystems than in more temperate regions.

River ice is a key agent of geomorphologic change; it is responsible for creating numerous erosional and depositional features within river channels and on channel floodplains (e.g., Prowse and Gridley, 1993; Prowse, 1994). During break-up, these processes cause channel enlargement and removal and succession of riparian vegetation. Climatic conditions that alter the severity of such events will greatly influence river morphology and riparian vegetation.

5.7.3.1.2. Direct use of water

Intensification in direct uses of water will negatively influence "natural" waters and could seriously reduce services provided by these ecosystems. Some values and services of lakes and rivers would be degraded by human responses to their greater demands for water for direct human use through dam construction, dyke and levee construction, water diversions, and wetland drainage (Postel and Carpenter, 1997). Such activities can alter water temperatures, recreation, pollution dilution, hydropower, transportation, and the timing and quantity of river flows; lower water levels; destroy the hydrologic connection between the river and the river floodplain; reduce natural flood control, nutrient and sediment transport, and delta replenishment; eliminate key components of aquatic environments; and block fish migration. At risk are aquatic habitat, biodiversity habitat, sport and commercial fisheries, waterfowl, natural water filtration, natural floodplain fertility, natural flood control, and maintenance of deltas and their economies (Ewel, 1997).

Water-level increases as well as decreases can have negative influences on lakes and streams. A recent example is from Lake Baikal, where the combined influences of a dam on the outlet and increased precipitation has increased water level by 1.5 m and decreased biodiversity and fishery production (Izrael *et al.*, 1997; ICRF, 1998).

5.7.3.2. Fisheries and Biodiversity

Potential effects of climate change on fisheries are documented in the SAR by Everett *et al.* (1996); freshwater fisheries in small rivers and lakes are considered to be more sensitive to changes in temperature and precipitation than those in large lakes and rivers. Changes in temperature and precipitation resulting from climate change are likely to have direct impacts on freshwater fisheries through changes in abundance, distribution, and species composition. Because current exploitation rates tend to be high or excessive, any impact that concentrates fish will increase their catchability and further stress the population.

Assessing the potential impacts of climate change on aquaculture is uncertain, in part because the aquaculture industry is mobile and in a period of rapid expansion. There is no question that large abundances relative to traditional wild harvests can be produced in small areas and that in many cases these sites can be moved to more favorable locations. Changes in groundwater may be especially significant for aquaculture. In tropical areas, crustaceans are cultured in ponds (Thia-Eng and Paw, 1989); fish frequently are cultured in cages. Commonly cultured species such as carp and tilapia may grow faster at elevated temperatures, but more food is required and there is an increased risk of disease. Temperature is a key factor affecting growth, but other factors relating to water quality and food availability can be important. Modeling studies suggest that for every 1°C average increase, the rate of growth of channel catfish would increase by about 7%, and the most favorable areas for culture would move 240 km northward in North America (McCauley and Beitingen, 1992; see Figure 5-7, right panel). The southern boundary also would move northward as surface water temperatures increase, perhaps exceeding lethal ranges on occasion. Growth would increase from about 13 to 30°C and then fall off rapidly as the upper lethal limit of about 35°C is reached (McCauley and Beitingen, 1992). Thus, aquaculture for traditional species at a specific location may have to switch to warmer water species.

Warmer conditions are more suitable for warmer loving flora and fauna and less suitable for cold-loving flora and fauna. Warmer temperatures, however, lead to higher metabolic rates, and if productivity of prey species does not increase, reductions in growth would occur at warmer temperatures (Arnell *et al.*,

1996; Magnuson *et al.*, 1997; Rouse *et al.*, 1997). Rates of natural dispersal across land barriers of less mobile species poleward or to higher altitudes are not likely to keep up with rates of change in freshwater habitats. Species most affected would include fish and mollusks; in contrast, almost all aquatic insects have an aerial life history stage, thus are less likely to be restricted. Some streams have a limited extent and would facilitate only limited poleward or altitudinal dispersal. This could be especially problematic as impoundments restricting movements of organisms increase in number. Coldwater species and many coolwater species would be expected to be extirpated or go extinct in reaches where temperatures are at the warmer limits of a species range. Many lakes do not have surface water connections to adjacent waters, especially in headwater regions where interlake movement would be limited without human transport of organisms across watershed boundaries.

Exotics will become a more serious problem for lake and stream ecosystems with warming. In the northern hemisphere, for example, range extensions occur along the northern boundaries of species ranges and extinctions occur along the southern boundaries, in natural waters and in aquaculture operations (Arnell *et al.*, 1996; Magnuson *et al.*, 1997). In addition, loss of habitat for biodiversity will result from warmer, drier conditions interacting with increases in impoundment construction.

Distributions of fish are simulated to move poleward across North America and northern Europe. In northern Europe, Lehtonen (1996) forecasts a shrinking range for 11 coldwater species and an expanding range for 16 cool- and warmwater

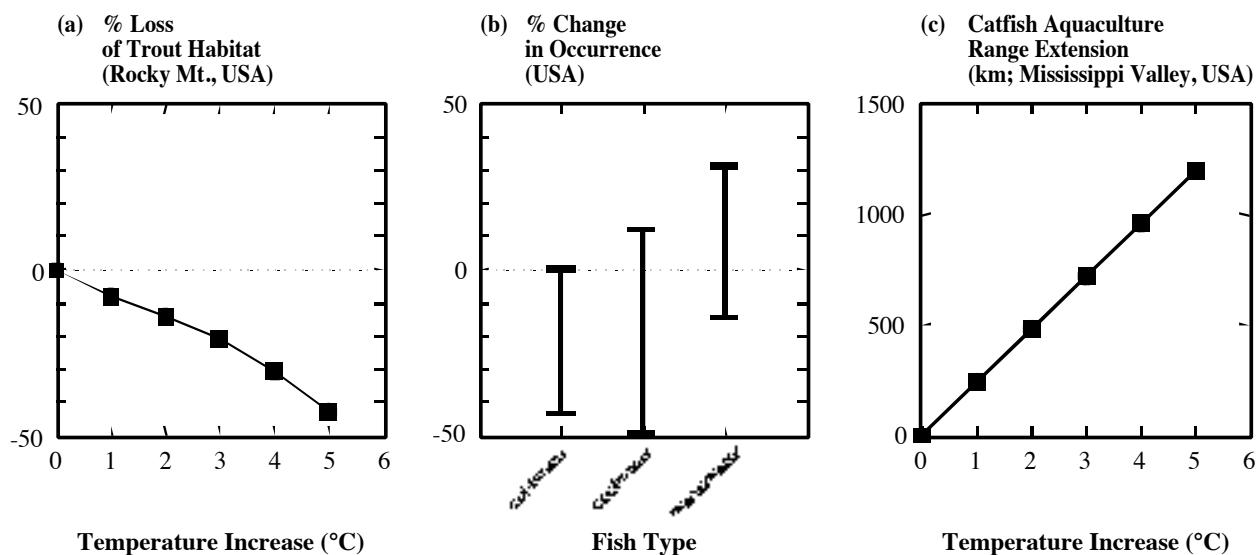

Figure 5-7: Simulated changes in thermal habitat for fish in the continental United States. Left panel is modified from Keleher and Rahel (1996). Center panel is modified from Mohseni and Stefan (2000) and Fang *et al.* (1998). Right panel is modified from McCauley and Beitingen (1992). Simulation is for a 2xCO_2 climate from the Canadian Climate Model and represents air temperature increases of 3– 6.5°C in different parts of the United States. Coldwater fish include trout and salmon; coolwater fish include yellow perch, walleye, northern pike, and white sucker; and warmwater fish include sunfish (black basses, bluegill, pumpkinseed) and common carp.

fish. In simulations for Finland by Lappalainen and Lehtonen (1995), lake whitefish lost habitats progressively toward the north, whereas brown trout did better, at least in the north. Coolwater fish were forecast to spread northward through the country. In simulation studies, boundaries of individual warmwater species ranges were projected to move northward by 400–500 km in Ontario, Canada (Minns and Moore, 1995), and southern boundaries of coldwater fishes were projected to move 500–600 km northward in the southeastern United States (estimated from Fang *et al.*, 1998). In simulations based on an elevated CO₂ scenario using the Canadian Climate Centre model, warmwater fish were projected to benefit in shallow eutrophic and mesotrophic lakes around the United States, owing to reduction in winterkill, but habitable lakes and streams for coolwater fish and especially coldwater fish were projected to decline, owing to summer kill (Fang *et al.*, 1998; Mohseni and Stefan, 2000). Habitat changes from various studies over large regions (see Figure 5-7, center panel) projected 0–43% reductions for coldwater species, 50% reductions to 12% increases for coolwater species, and 14% reductions to 31% increases for warmwater fish. Changes differ among ecosystem types and areas, depending on latitude and altitude.

A dramatic picture of the regional decline in trout habitat in the Rocky Mountain region of the western United States is provided by Keleher and Rahel (1996) (see Figure 5-7, left panel). Even a 1°C increase in mean July air temperatures is simulated to decrease the length of streams inhabitable by salmonid fish by 8%; a 2°C increase causes a reduction of 14%, a 3°C increase causes a 21% decline, a 4°C increase causes a 31% reduction, and a 5°C increase causes a 43% reduction. There also is likely to be increased fragmentation of inhabitable areas for the North Platte River Drainage in Wyoming (Rahel *et al.*, 1996).

5.7.3.3. Biogeochemical Cycling and Pollution

Understanding of interactions of climate change with other human-caused pressures on lakes and streams is still in its infancy. No simulation models have been developed to assess the combined effects of these pressures on these systems.

5.7.3.3.1. Eutrophication

Nutrient cycling would be altered by climate change in ways that could exacerbate existing water quality problems such as eutrophication (see Figure 5-8). Eutrophication of lakes results when nutrient inputs from catchments and recycling from bottom sediments are large. The result is excessive production of algae; blue-green algae reduce water quality for recreation and drinking. Deep coldwater habitats become anoxic, owing to greater rates of decomposition of sinking organic matter (Horne and Goldman, 1994).

Interaction between climate change and eutrophication is complex, and projections are somewhat contradictory (see Figure 5-8)

because climate-influenced processes have interacting and often opposing effects (Magnuson *et al.*, 1997; Schindler, 1997). Consider, for example, phosphate release from anoxic sediments. In a warmer climate, the longer period of summer stratification would increase the likelihood that anoxia develops below the thermocline (Stefan and Fang, 1993); this would increase the solubility of phosphates in sediment and increase nutrient recycling. At the same time, warmer climates would reduce the duration of ice cover in lakes, which would reduce winter anoxia and decrease sediment phosphate release in winter. This is further complicated by water column stability.

In Lake Mendota, Wisconsin (Lathrop *et al.*, 1999), it is not surprising that one-third of observed year-to-year variation in summer water clarity is associated with variability in runoff (see Figure 5-8); more nutrient input leads to higher populations of phytoplankton, which reduce water clarity. Runoff would be influenced by differences in precipitation and the frequency of extreme rainfall events during autumn, winter, and spring. Precipitation trends differ around the world, and there is evidence for increased frequency of extreme rainfall events that may occur in different seasons of the year (see Chapter 4). Wetter climates or climates with more extreme rainfall events would increase export of nutrients and sediment to lakes and streams; drier climates or those with more even rainfall would reduce export to lakes and streams. Extreme rainfall events would export more if they occurred at seasons when the earth was bare in agricultural watersheds.

In Lake Mendota, the other two-thirds of the variation in water clarity also is related to climate (see Figure 5-8). One-third is through climatic influences on vertical mixing, where warmer summers lead to greater water column stability, less recycling from deep water, and greater water clarity. The remaining one-third is related to the abundance of herbivorous zooplankton that eat phytoplankton. A warming climate would allow invasion of new species of fish that forage on the herbivorous zooplankton; in Lake Mendota, it probably would be the gizzard shad that lives in reservoirs south of Wisconsin (see Dettmers and Stein, 1996).

Several other complexities would lead to different results, depending on the change in precipitation patterns. For example, in a drier climate, increases in water residence time (Schindler *et al.*, 1996a) would increase the importance of nutrient recycling within lakes, and storage of nutrients in the sediments of lakes would be reduced (Hauer *et al.*, 1997). This is complicated by changes in light penetration that occur if dissolved organic carbon (DOC) inputs are reduced (Magnuson *et al.*, 1997; Schindler, 1997). DOC can reduce light penetration, so a reduction in DOC input would increase light availability and could lead to increases in primary production in deeper water. This influence would depend on whether climate becomes drier or wetter.

Several empirical and simulation studies support the idea of increased eutrophication with climate change. Results of these studies contradict the expectations of reductions in nutrient

loading from catchments in drier climates and greater stability of the water column in warmer climates.

Empirical relations (Regier *et al.*, 1990; Lin and Regier, 1995) suggest that annual primary production by phytoplankton, zooplankton biomass, and sustained yields of fisheries all increase with temperature. Simulations for Lake Erie (Blumberg and Di Toro, 1990) and smaller lakes (Stefan and Fang, 1993) indicate that climate change leads to more eutrophic conditions with respect to loss of oxygen beneath the thermocline in summer. Ongut-Ongwayo *et al.* (1997) suggest that recent changes in the regional climate of Lake Victoria in Africa may have reduced physical mixing and contributed to

increases in deepwater anoxia and thus nutrient recycling contributing to eutrophication.

5.7.3.3.2. Acidification

Acidification of streams and recovery of acidified lakes would be altered by climate changes (Yan *et al.*, 1996; Magnuson *et al.*, 1997; Dillon *et al.*, 2001). In addition to direct atmospheric deposition of acids, sulfates deposited in the catchment are transported to streams during storm events as pulses of acidity. Lakes would receive less buffering materials in drier climates and more in wetter climates. Lakes high in the landscape that

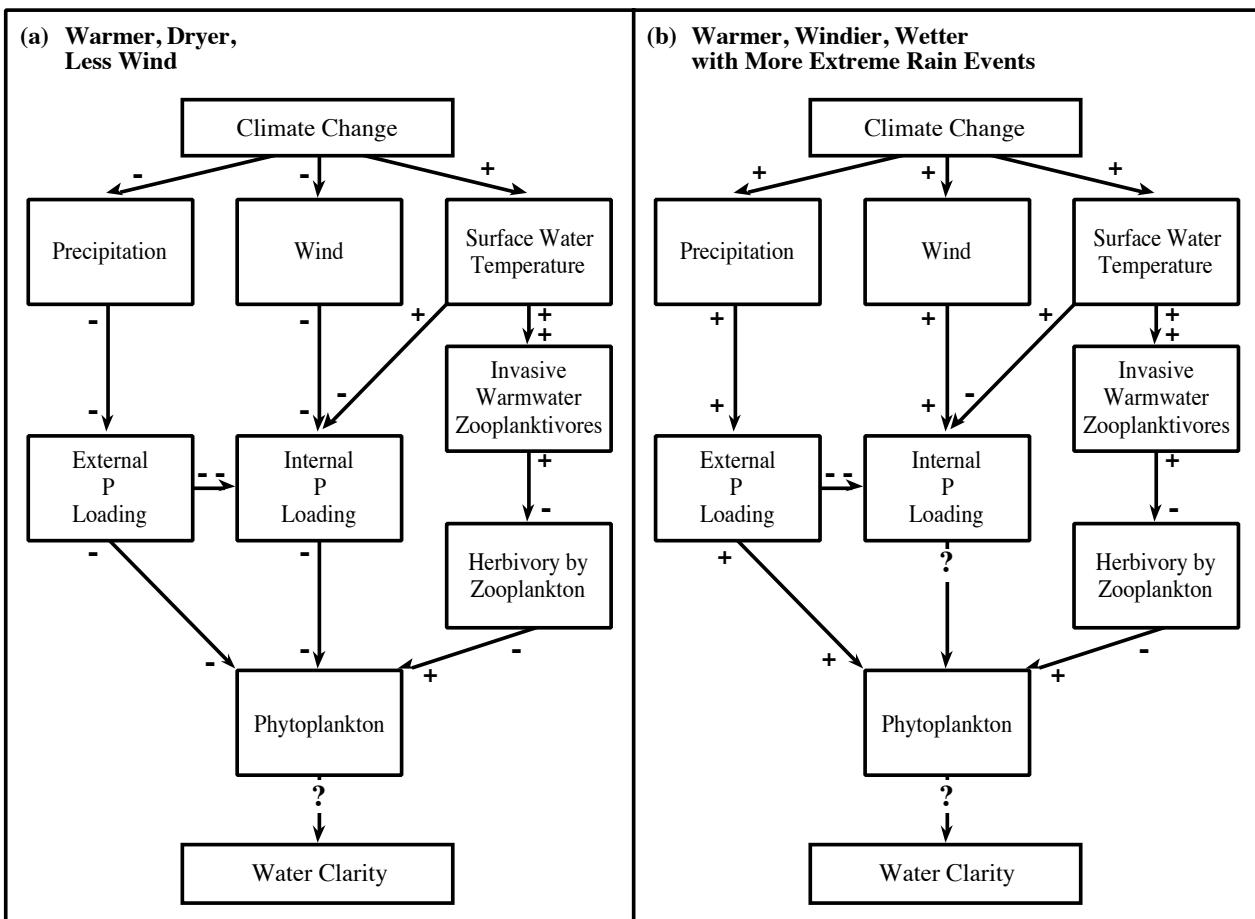

Figure 5-8: Diagram of complex interactions between climate change, watershed and lake processes, and water clarity of a eutrophic lake [modified from Lathrop (1998) and information in Lathrop *et al.* (1999)]. The left panel diagrams a warmer, dryer climate with less wind; the right panel diagrams a warmer, windier, and wetter climate with more extreme rain events. In both cases, the altered climate would be expected to change the water quality of the lake, but the complexity of relations leads to uncertain future water clarities. A “+” means an increase and a “-” means a decrease in the condition or process; a “?” means conflicting expectations. Greater blooms of phytoplankton lead to lower water clarity, and reduced blooms lead to greater clarity. Blooms depend on external and internal loading of phosphorus (P). Drier climates lead to less external loading, whereas wetter climates or more episodic rains lead to more external loading. Warmer climates lead to warmer surface waters and increased vertical stability in the water column, thus less mixing and internal loading. Warmer waters also allow potential invasion by warmer loving, zooplanktivorous fish that can reduce zooplankton species that in turn reduce algal populations. Windier climates result in increased vertical mixing, thus greater internal loading.

receive less groundwater in dry years would be more vulnerable to acidification (Webster *et al.*, 1996).

5.7.3.3.3. Toxics

Climate change would interact with biogeochemical transport and transformation of toxics such as mercury, zinc, and pesticides (see brief reviews in Magnuson *et al.*, 1997; Schindler, 1997; and related physiological understanding in Wood and McDonald, 1997). The expected influences are poorly known as well as complex and variable, depending on the toxin, the organism, and the climate scenario. Enough is known to say that toxic stresses are not independent of climate change.

5.7.3.4. Other

5.7.3.4.1. Recreation

Winter recreational opportunities would decline with warmer climates. Declines in safe ice conditions would reduce all ice-related activities such as ice fishing, ice skating, ice boating, and snowmobiling on lakes and rivers. Recreational uses of lakes that become more eutrophic are likely to be degraded by lower water clarity and increased blooms of noxious blue-green algae. Nonmarket values for water-based recreation are in direct conflict with greater direct uses of that water and a warmer and drier climate. These values ranged from \$3–65 per thousand m³ of water for fishing, rafting, and river recreation in general in Colorado (Postel and Carpenter, 1997).

UV-B radiation can be harmful to freshwater organisms (Bothwell *et al.*, 1994; Williamson and Zagarese, 1994; Williamson *et al.*, 1996). Absorption of UV-B is lower in clearwater lakes. Reduction of colored DOC entering lakes during drier conditions results in greater transmission and thus greater harm to organisms (Schindler *et al.*, 1996a; Yan *et al.*, 1996; Schindler, 1997; Williamson *et al.*, 1996).

5.7.3.4.2. Heterogeneity in response

Responses of lakes and streams to climate change are spatially heterogeneous. Much of the local heterogeneity depends on the type of water body being considered: lake or stream, large or small, shallow or deep, eutrophic or oligotrophic, and so forth. Spatial heterogeneity also results from spatial differences in climate drivers themselves with latitude, altitude, and distance from the coast or a large lake. Inappropriate responses with large expenditures of local resources will result unless the spatial heterogeneity of local responses is understood and can be predicted.

Two ideas that help explain local heterogeneity in responses of lakes and streams to climate change from a landscape perspective are the stream continuum (Vannote *et al.*, 1980; Minshall *et al.*, 1985) and the position of a lake in the landscape (Kratz *et al.*,

1991; Kratz *et al.*, 1997; Magnuson and Kratz, 2000; Riera *et al.*, 2000). Both concepts are geomorphic legacies resulting from the location of the water body in the hydrologic flow field. Headwater streams will be more shielded from warming relative to lowland streams because cool groundwater sources are more important; in forest catchments, they are more shaded from radiation, and in mountain catchments they are at higher, cooler altitudes (Hauer *et al.*, 1997). For lakes, changes in chemical inputs with changes in rainfall will be greater in upland lakes than in lowland lakes. Upland lakes are supplied more by dilute precipitation than by solute-rich groundwater or overland flow. The chemistry of headwater lakes is extremely responsive to climate-driven changes in groundwater inputs because they tend to have smaller volumes and shorter residence times (Krabbenhoft and Webster, 1995).

Differences in the extent of connected wetlands or other sources of DOC contribute to local heterogeneity in responses. Export of DOC to lakes and streams increases in wetter times and decreases during drought. This, in turn, changes light penetration and vertical distribution of solar heating and, in lakes, the depth of thermocline and the relative magnitude of cold and warm thermal habitat for fish (Schindler *et al.*, 1996b). Penetration of UV-B, thus the damaging effects of that radiation (Schindler, 1997), also will differ among lakes. Lakes without large sources of DOC that leach in during wetter periods will respond less to climate changes in these respects.

Shorter term, more stochastic patterns in catchments alter the behavior of lake ecosystems. Consider a drought that increases the likelihood of forest fires in the watersheds of boreal lakes in Ontario (Schindler, 1997). Burned areas typically are patchy and may or may not include the catchment of a given lake. If they do include the lake's watershed, there is an initial increase in the input of solutes to streams and the lake. The lake also is under greater influence of wind mixing with trees gone, which would deepen the thermocline and again alter the relative magnitude of cold and warm thermal habitat for fish.

Predicted responses of threatened anadromous Pacific salmonid stocks in the Columbia basin of the northwestern United States are varied. Climate-related factors that are important to successful reproduction include temperature, the river hydrograph (peak and annual flow), and sedimentation (Neitzel *et al.*, 1991). Based on expected changes in these streams and 60 stocks across the basin, impacts on 23% were judged to be negative, 37% positive, and 40% neutral.

5.7.4. Adaptation Options

Human responses to climate change could further exacerbate the negative impact on aquatic ecological systems. For example, human responses to a warmer climate and the variety of precipitation scenarios, as well as human population increases, are likely to place greater demands on freshwaters to meet water needs for drinking, industry, and irrigation, along with an increase in water management projects (see Chapter 4).

Potential results would include fewer free-flowing streams and greater fluctuations in water level. These changes would cause a loss of ecosystem services and products from “natural/unmodified” lakes and streams. Conflicts between developers and those wishing to reduce development pressure on lakes and streams probably would intensify as freshwater becomes either more scarce or more abundant.

One adaptation to climate change would entail poleward transportation of fish, mollusks, and other less vagile organisms across watershed boundaries to cooler waters (Magnuson *et al.*, 1997). Historical introductions and range expansions of species have resulted in extinction or extirpation of preexisting fauna owing to ecological interactions, especially predation by the invader. Well-known examples include the sea lamprey, alewife, smelt, and zebra mussel to the Laurentian Great Lakes in North America (Mills *et al.*, 1994); the peacock bass in Panama (Zaret and Paine, 1973); and the Nile perch into Lake Victoria (Kaufman, 1992). Other examples being documented include the decline or extirpation of cisco and yellow perch in small Wisconsin lakes in the United States with the arrival of rainbow smelt (Hrabik *et al.*, 1998) and the loss of cyprinids (minnows) and the decline of lake trout with the introduction of black bass and rockbass into Ontario lakes in Canada (Casselman, 2000; Jackson, 2000; Vander Zanden, 2000). The history of invasions exemplifies the homogenization of continental faunas (Rahel, 2000), losses in native organisms, and large changes in ecosystem processes and structure—all with economic consequences.

Fisheries (capture, aquaculture, and recreational) and associated introductions would exacerbate biodiversity and exotic problems in a warming climate. A substantial number of inland fisheries are associated with introduced species and stock enhancement. Tilapia, carp, grass carp, and rainbow trout are commonly introduced or stocked. An estimated 38% of the recreational catch is of non-native fishes. The practice of introducing species apparently has resulted in 1,354 introductions of 237 species into 140 countries from pre-1900 to the mid-1980s (FAO, 1988). Despite recognition of the importance of wild native species and increasing appreciation of the importance of biodiversity, impacts of climate change are likely to be managed by introducing better adapted species, if past management practices prevail. In the United States, an average of 38% of the recreational fishery is for non-native species, 75% of which now reproduce naturally (Horak, 1995). As climate change impacts affect the abundance of native (and non-native) species, it is probable that the past precedent of introducing non-native species would be applied to maintaining catches and recreational fishing stability.

Moving species poleward to adapt to changing climate zones for lakes and streams is fraught with scientific uncertainties and human conflict. The exotic can become a superabundant pest species, with negative effects on native organisms—including extirpation and extinction. The invasion ecology of organisms is not a predictive science; many surprises would be expected. The case has been made that managing with exotics increases

the instability of the fish community and fish management problems and includes many unexpected consequences (Magnuson, 1976). Introduction of warmer water fauna on top of regional fauna that are having increasing problems from warming climates is likely to be a controversial adaptation.

Climate changes may provide development opportunities for aquaculture if traditional wild fisheries are less stable and markets favor the stability of the aquaculture product. Aquaculture represents a mobile technology that potentially can move with changing climate to the best conditions for culture (see Figure 5-7).

5.7.5. Vulnerability

Specific vulnerable elements include reduction and loss of lake and river ice, loss of habitat for coldwater fish, increases in extinctions and invasions of exotics, and potential exacerbation of existing pollution problems such as eutrophication.

Adaptation to climate change may induce other negative effects related to secondary pressures from new hydrologic engineering structures, poleward transport by humans of fauna and flora adapted to warmer lakes and streams, and interactions resulting from increased stocking and relocation of recreational and aquacultural endeavors.

Inland waters are affected hydrologically, physically, chemically, and biologically by climate change (Arnell *et al.*, 1996; Cushing, 1997). One reason for their vulnerability is that lakes, rivers, and wetlands integrate and reflect human and natural events in their watersheds and airsheds (Naiman *et al.*, 1995b). Interactions with changes to their watersheds, riparian shorelines, and human use of water combine to make lake and stream ecosystems vulnerable. Potential changes in quantity and quality of water reduce the ability of these waters to provide goods and services.

5.8. Inland Wetlands

Wetlands are defined here as any area of land where the water table is at or near the surface for some defined period of time, leading to unique physiochemical and biological processes and conditions that are characteristic of shallow flooded systems (Mitch and Gosselink, 1993; Oquist *et al.*, 1996). However, it should be noted that many other definitions also are in use, and care is required in comparing wetland areas in different regions of the world (Lugo *et al.*, 1990; Finlayson and van der Valk, 1995; Finlayson and Davidson, 1999).

Wetlands described in this section include those dominated by forested and nonforested vegetation; those on highly organic soils such as peatlands (partially decomposed plant material); and those on mineral soils, as is often typical of riverine systems. Peatlands are peat-accumulating wetlands and usually are divided into bogs and fens, both of which may be forested.

Peatlands are found at all latitudes, from the Arctic to the tropics. The growing vegetation layer of bogs is totally dependent on atmospheric inputs for their water and solute supply; consequently, surface peat layers are acidic and poor in nutrients. Fens receive additional water from overland flow and/or groundwater and typically have near-neutral pH and higher nutrient levels.

Wetlands provide many services and goods, many of which are indirect values (e.g., recreation, education, biodiversity, wild food) and are difficult to quantify. Key ecosystem services and goods considered here include biodiversity, carbon sinks, food, and fiber (peat and wood).

5.8.1. State of Wetland Services

5.8.1.1. Habitat and Biodiversity

Global estimates for the area of wetlands vary according to the definition of wetland used. Spiers (1999) reports global estimates for natural freshwater wetlands of 5.7 million km². The estimate by Matthews and Fung (1987) is 5.3 million km², which represents approximately 4% of the Earth's land surface, although a more recent estimate by Lappalainen (1996) is somewhat larger, at 6.4 million km². This compares well with Finlayson and Davidson's (1999) estimate of about 7 million km², including 1.3 million km² of rice paddy.

Maltby and Proctor (1996) estimate that peatlands cover about 4 million km² ($\pm 4\%$), constituting about 75% of wetlands. More than 90% of peatlands are in temperate, boreal, and subarctic regions. The total area of tropical peatlands is estimated to be 0.37–0.46 million km² (i.e., approximately 10 % of the global resource), but the full extent is uncertain (Immirzi *et al.*, 1992).

Many wetlands have irregular wetting and drying cycles, driven by climate. To date, little attention has been given to the impact of climate change on these less regular cycles of wetlands in semi-arid and arid regions (Sahagian and Melack, 1998). Changes in the area of these wetlands can be immense but could be monitored by using area-based parameters—for example, functional parameters and wetland extent expressed in terms of ha-days (Sahagian and Melack, 1998).

Species that form wetland plant communities are adapted to varying degrees to life in a flooded environment. These phenomena show large spatial variability, and different species show varying degrees of susceptibility to them, so it is not surprising that wetland vegetation exhibits such a high degree of variation in species composition (Crawford, 1983). Peatland plant communities have been observed to change over long periods of time, reflecting the peat accumulation process and leading to gradually drier conditions. This inherent changeability of wetland communities results largely from their occurrence in environments where a single extremely variable habitat factor—water supply—is predominant (Tallis, 1983). Consequently, land use and climate change impacts on these ecosystems can

be expected to be mediated through changes in the hydrological regime.

Primary production in wetland communities is highly variable (Bradbury and Grace, 1983; Lugo *et al.*, 1988). Generally, wetland communities—which are dominated by trees, sedges, and grasses—have higher production rates than those characterized by shrubs and mosses. Organic matter produced in many wetlands is accumulated partially (2–16%—Päivänen and Vasander, 1994) as peat. A necessary antecedent condition for peat formation and accumulation is an excess of water stored on the mineral soil or sediment surface. This arises in humid climatic regions where precipitation exceeds evaporation (Ivanova, 1981; Clymo, 1984) or in more arid climatic regions where lateral inputs of water via surface runoff and/or groundwater seepage are sufficient to exceed evaporative demand (Glaser *et al.*, 1996).

Tropical peatlands play an important role in maintenance of biological diversity by providing a habitat for many tree, mammal, bird, fish, and reptile species (Prentice and Parish, 1992; Rieley and Ahmad-Shah, 1996; Page *et al.*, 1997); some of these species may be endemic or endangered. In common with other peatlands, tropical systems have a significant scientific value that goes beyond their plant and animal communities.

Within the peat also lies a repository of paleoenvironmental and paleogeochemical information that is extremely important in understanding past climatic conditions. These paleorecords are used to estimate rates of peat formation or degradation, former vegetation, climatic conditions, and depositional environments (Morley, 1981; Cecil *et al.*, 1993; Moore and Shearer, 1997).

5.8.1.2. Carbon Sink

The importance of peat-accumulating wetlands to global change is via the large carbon store accumulated over millennia—and the risk that this store would be released to the atmosphere in conditions modified by global change (e.g., fires). The carbon store in boreal and subarctic peatlands alone has been estimated at 455 Gt with an annual sink of slightly less than 0.1 Gt (Gorham, 1991). Tropical peatlands also are a considerable store (total of 70 Gt), containing as much as 5,000 t C ha⁻¹, compared with an average of 1,200 t C ha⁻¹ for peatlands globally (Immirzi *et al.*, 1992; Diemont *et al.*, 1997). Estimates of the annual sink in tropical peatlands vary from 0.01 Gt (Sorensen, 1993) and 0.06 Gt (Franzen, 1994) to 0.09 Gt (Immirzi *et al.*, 1992)—emphasizing the lack of reliable data.

Optimal conditions for carbon sequestration appear to be in areas with mean annual temperatures between 4 and 10°C (Clymo *et al.*, 1998), which prevail in much of the southern boreal and temperate zones. The present carbon accumulation rate for boreal and subarctic bogs and fens is estimated as 0.21 t C ha⁻¹ yr⁻¹ (Clymo *et al.*, 1998). Rapid carbon accumulation rates also have been estimated for some tropical peatlands (Neuzil, 1997); retrospective values of Indonesian peatlands range from 0.61 to 1.45 t C ha⁻¹ yr⁻¹ (Neuzil, 1997).

Another important long-term (>100 years) sink for carbon in forested wetlands is wood biomass. Based on growth data (Shepard *et al.*, 1998) and conversion factors (Turner *et al.*, 1995) for bottomland hardwood forests, southern U.S. swamps, for example, sequester 0.011 Gt C yr⁻¹.

A small but significant proportion of organic matter in wetland soils is transformed into methane in the metabolism of methanogenic bacteria. Methane production is a characteristic feature in all wetland soils; the rate is governed largely by substrate availability and temperature (Shannon and White, 1994; Mikkelä *et al.*, 1995; Schimel, 1995; Bergman *et al.*, 1998; Komulainen *et al.*, 1998). Part of the methane produced in anoxic soil is oxidized by methanotrophic bacteria in aerobic surface layers.

The ratio of methane production to consumption determines the magnitude of the flux from the soil to the atmosphere; this rate is governed largely by the depth of the aerobic layer (Roulet *et al.*, 1993; Shannon and White, 1994). The role of vascular plants in providing continuous substrate flux for methanogenesis and as a transport pathway to the atmosphere has been stressed (Whiting and Chanton, 1993; Schimel, 1995; Frenzel and Rudolph, 1998). Slow fermentation of organic matter in growing peat layers of bogs has been cited as the factor that theoretically limits the final volume a bog may reach during its development (Clymo, 1984).

5.8.1.3. Food and Fiber Production

Wild berries growing on peatlands are an important natural resource in many regions of the boreal zone (Reier, 1982; Yudina *et al.*, 1986; Salo, 1996). In Finnish peatlands alone, the annual biological yield of wild berries may exceed 150 million kg, of which approximately 10% is picked, with a value of US\$13.5 million (Salo, 1996). In North America, cranberry (*Vaccinium macrocarpon*) is commercially cultivated in peatlands (Johnson, 1985). The use of peatlands for agriculture has a long history; presently, 10,000 km² are under this land use (Immirzi *et al.*, 1992).

The importance of wetlands in North America as waterfowl habitat has long been recognized (Mitch and Gosselink, 1993). The commercial value of these wetlands is not direct; it comes through the added value of the activities of hunters in local economies. Although there are few estimates of this service, much of the wetland conservation effort in North America has focused on conservation, enhancement, and creation of habitat.

Products from tropical forested wetlands include rattans, resins, latex, fungi, fruit, honey, and medicinal plants, sale of which provides revenue for local communities. Exploitation of fish from swamp forests and associated waterways also can supply a modest income and is an important source of protein for local human populations (Immirzi *et al.*, 1996; Lee and Chai, 1996).

Forested wetlands are valuable for wood production, mostly as a result of wetland modification. For example, in Finland, these wetlands produce about 18 million m³ of timber annually—nearly 25% of the total annual increment (Tomppo, 1998). Forested wetlands in the southern United States produce 39 million m³ of timber, of which 33 million m³ are removed annually (Shepard *et al.*, 1998).

Direct harvest of forest resources from tropical peatlands yields several important products, ranging from timber and bark to non-timber products (Immirzi *et al.*, 1996; Lee and Chai, 1996). Southeast Asia's peat swamps yield some of the most valuable tropical timbers—in particular, ramin (*Gonystylus bancanus*) (Ibrahim, 1996).

Peat has been used as a domestic energy source in northwestern and central Europe for centuries (Feehan and O'Donovan, 1996). The present volume of industrial peat harvesting is estimated at 71 million m³, most of it in Finland and Ireland (Asplund, 1996). The peatland area occupied by peat harvesting is rather small in comparison to the area of land uses such as agriculture and forestry; for example, in Finland 24 million m³ of energy peat are harvested from an area of 530 km². Employment aspects may be important in peat harvesting because most peat sites are located in remote areas where few industrial jobs are available. Peat harvesting may offer an estimated 550 permanent/seasonal jobs for each 1 million m³ of produced peat (Nyrönen, 1996). Canada has a small but prosperous peat harvesting industry for horticulture and medical uses (Rubec *et al.*, 1988; Keys, 1992). Between 1986 and 1990, Canadian shipments were 662,000–812,000 t yr⁻¹ (Keys, 1992).

5.8.2. Pressures on Wetland Services

Pressures on wetlands are likely to be mediated through changes in hydrology, direct and indirect effects of changes in temperature, and land-use change. There would be interactions among these pressures and subsequent impacts on services and good from these ecosystems.

5.8.2.1. Changes in Hydrology

Climate change will affect the hydrology of individual wetland ecosystems mostly through changes in precipitation and temperature regimes. Because the hydrology of the surface layer of bogs is dependent on atmospheric inputs (Ingram, 1983), changes in the ratio of precipitation to evapotranspiration may be expected to be the main factor in ecosystem change. However, work on the large peatland complexes of the former Glacial Lake Aggazzi region indicate that the hydrology of bogs cannot be considered in isolation or independent of local and regional groundwater flow systems (Siegel and Glaser, 1987; Branfireun and Roulet, 1998) and that groundwater flow reversals, even in ombrotrophic peatlands, can have an impact on their water storage and biogeochemistry (Siegel *et al.*, 1995;

Devito *et al.*, 1996). From the perspective of assessment of climate variability and change of peatlands, these systems need to be viewed in the broader context of their hydrogeological setting.

Fen, marsh, and floodplain wetlands receive additional water influx from the surrounding basin, including underground sources—sometimes from a considerable distance. This means that climate change impacts are partially mediated through changes in the whole basin area or even further afield where groundwater reserves do not correspond with surface basins. These changes also may affect the geochemistry of wetlands. Recharge of local and regional groundwater systems, the position of the wetland relative to the local topography, and the gradient of larger regional groundwater systems are critical factors in determining the variability and stability of moisture storage in wetlands in climatic zones where precipitation does not greatly exceed evaporation (Winter and Woo, 1990). Changes in recharge external to the wetland may be as important to the fate of the wetland under changing climatic conditions as the change in direct precipitation or evaporation on the wetland itself (Woo *et al.*, 1993).

5.8.2.2. Changes in Temperature

Temperature is an important factor controlling many ecological and physical functions of wetlands. Primary productivity and microbial activity are both controlled to a certain extent by temperature conditions. Temperature also affects evapotranspiration rates and has an impact on the water regime. Because higher temperatures and drying of the surface soil usually occur together and interactively affect the ecosystem processes, it is not always possible to separate their impacts.

Although Gorham (1991) suggests that the effects of temperature will be overshadowed by the impacts of water-level drawdown on northern peatlands, the impacts of temperature increases on wetlands on permafrost may be drastic (Gorham, 1994a). A fairly small increase in temperature might initiate large-scale melting of permafrost, with thermokarst erosion and changed hydrological regimes as a consequence (Billings, 1987). Work by Vitt *et al.* (1994) and Halsey *et al.* (1997) has demonstrated clearly the dynamic association between the distribution of peatlands, peatland types, and the presence or absence of permafrost in North America. This association is strong enough that it has been used as a proxy method for inferring climatic variability during the Holocene (Halsey *et al.*, 1995). This might imply shifts from black spruce/*Sphagnum*/lichen communities on permafrost to wetter fen communities, with subsequent changes in carbon cycling.

5.8.2.3. Land-Use Change

Land-use change may create multiple pressures on wetland habitats. Area estimates of the scale of direct development of tropical peatlands vary and provide only an imprecise picture

of the current situation (Immirzi *et al.*, 1992; Maltby and Immirzi, 1996). In southeast Asia, agriculture and forestry are the major peatland land uses. Toward the end of the 1980s, it was estimated that in Indonesia alone 3.7 Mha (18% of the total peat swamp forest) had undergone some form of development (Silvius *et al.*, 1987).

Cultivation of tropical peatlands involves measures that radically change the hydrological regime and consequently influence vegetation and soil processes. Forests are cleared and effective drainage installed. In many places in southeast Asia, cultivation of horticultural and estate crops has met with mixed success, and some previously converted peatlands have been abandoned, although peat-forming vegetation has failed to reestablish (Immirzi *et al.*, 1992). Reasons for failure include poor water management and persistent infertility of the soil (Rijken *et al.*, 1997).

The total area of tropical peatland drained or otherwise altered during forestry management is not known. Silvius *et al.* (1987) suggest that as much as 0.11 million km² of peatlands in Indonesia (i.e., as much as 50% of the total resource) are possibly being exploited for forestry purposes. In Malaysia, most of the remaining peat swamp forest outside limited conservation areas has been logged (Immirzi *et al.*, 1992). Sustainable-yield forestry is likely to be the most appropriate form of land use for peat swamp forest, but such methods applicable to peat swamps have yet to be developed, let alone implemented (Immirzi *et al.*, 1992).

Use of peatlands for forestry usually brings about smaller changes in the ecosystem. In floodplain swamps and peatlands of the more continental areas of North America, often only tree stands are managed (Dahl and Zoltai, 1997), but in northwestern Europe and the southeastern United States, forestry use includes artificial drainage (Richardson and McCarthy, 1994; Päivinen, 1997). Some 0.15 million km² have been drained for forestry, mostly in Scandinavia and Russia (Päivinen, 1997). In these cases, much of the original vegetation (Laine *et al.*, 1995) and functions (Aust and Lea, 1991; Minkkinen *et al.*, 1999) are preserved during forestry management. About 70% of the expansive peatlands in North Carolina (6,000 km²) have been entirely or partially degraded through draining, ditching, or clearing (Richardson and Gibbons, 1993).

Peat harvesting for energy or horticultural use has the most drastic impact on the ecosystem; vegetation is removed with the topsoil prior to harvesting, and most of the accumulated peat gradually is extracted (Nyrönen, 1996).

5.8.3. Impacts on Wetland Services

Generally, climatic warming is expected to start a drying trend in wetland ecosystems. According to Gorham (1991), this largely indirect influence of climate change, leading to alteration in the water level, would be the main agent in ecosystem change and would overshadow the impacts of rising temperature and

longer growing seasons in boreal and subarctic peatlands. Monsoonal areas are more likely to be affected by more intense rain events over shorter rainy seasons, exacerbating flooding and erosion in catchments and the wetlands themselves. Similarly, longer dry seasons could alter fire regimes and loss of organic matter to the atmosphere (Hogenbirk and Wein, 1991).

5.8.3.1. Habitat and Biodiversity

Climate change may be expected to have clear impacts on wetland ecosystems, but there are only a few studies available for assessing this. There are some laboratory studies concerned with the responses of individual plant species or groups of species (Jauhainen *et al.*, 1997, 1998a,b; van der Heijden *et al.*, 1998). Based on these studies, however, it is difficult to predict the responses of plant communities formed by species with somewhat varying environmental requirements.

The response of wetland plant communities to drought has received some attention in temperate freshwater wetlands (Greening and Gerritsen, 1987; Streng *et al.*, 1989). Stratigraphical studies in peatlands have shown hydroseral succession whereby swamp and fen communities gradually develop into bog communities (Tallis, 1983). These changes are largely autogenic, connected to growth of wetland communities and caused by past climatic variability or artificial drainage. An alternative approach to observe the vegetation-environmental change succession has been to use space as a time substitute by mapping different plant communities onto climatic and hydrological surfaces (Gignac *et al.*, 1991). This approach has shown tight coupling between various peatland plants, climate, hydrology, and resultant chemistry—and even for trace gas exchange (Bubier, 1995)—and has been used to infer certain aspects of peatland development through macrofossil analysis (Gorham and Janssens, 1992; Kuhry *et al.*, 1993).

Much is known about how vegetation changes as a result of water-level drawdown following drainage for forestry in northwestern Europe. Drying of surface soil initiates a secondary succession whereby original wetland species gradually are replaced by species that are typical of forests and heathlands (Laine and Vanha-Majamaa, 1992; Vasander *et al.*, 1993, 1997; Laine *et al.*, 1995). Plants living on wet surfaces are the first to disappear, whereas hummock-dwelling species may benefit from drying of surface soil. In nutrient-poor peatlands, bog dwarf-shrubs dominate after water-level drawdown; at more nutrient-rich sites, species composition develops toward upland forest vegetation (Laine and Vanha-Majamaa, 1992; Minkkinen *et al.*, 1999).

The effect of sea-level rise on wetlands has been addressed in several assessments. In northern Australia, extensive seasonally inundated freshwater swamps and floodplains are major biodiversity foci (Finlayson *et al.*, 1988). They extend for approximately 100 km or more along many rivers but could be all but displaced if predicted sea-level rises of 10–30 cm by 2030 occur and are associated with changes in rainfall in the catchment and tidal/storm surges (Bayliss *et al.*, 1997; Eliot *et al.*,

al., 1999). Expected changes have been demonstrated by using information collected from the World Heritage-listed Kakadu National Park, but the scenario of massive displacement of these freshwater wetlands can be extended further afield given similarities in low relief, monsoonal rainfall, and geomorphic processes (Finlayson and Woodroffe, 1996; Eliot *et al.*, 1999). In fact, the potential outcome of such change can be seen in the nearby Mary River system, where saline intrusion, presumably caused by other anthropogenic events, already has destroyed 17,000 ha of freshwater woodland and sedge/grassland (Woodroffe and Mulrennan, 1993; Jonauskas, 1996).

Mechanisms by which environmental factors and biotic interactions control wetland biodiversity are not well understood (Gorham, 1994b). The effects of water-level drawdown after drainage for forestry indicate that the shift in species composition from bog and fen species to forest species only slightly affects plant species richness of individual sites (Laine *et al.*, 1995). In regions dominated by forests, there would be clear reduction in regional diversity as landscapes become homogenized after drainage (Vasander *et al.*, 1997).

The inherent changeability of wetland communities, resulting from spatial and temporal variability in water supply (Tallis, 1983), may be the key factor in the response of wetland communities to climate change. Because there may be differences between species in adaptation potential, community structures would change, and there would be profound effects on the nature of the affected wetlands, as discussed by Gorham (1994a). The response of wetland plant communities to changing environment may have fundamental effects on the species diversity of these ecosystems.

Because of spatial and temporal variability in ecosystem processes, development of systems models for wetlands is becoming an important assessment tool. A fully coupled peatland-climate model has not yet been developed, but there have been some significant advances in modeling various components of the peatland and/or wetland biogeochemical system (Harris and Frolking, 1992; Roulet *et al.*, 1992; Christensen and Cox, 1995; Christensen *et al.*, 1996; Walter *et al.*, 1996; Granberg, 1998), and several process-level models are now used at the global scale (Cao *et al.*, 1996; Potter *et al.*, 1996; Potter, 1997).

Elevated CO₂ levels will increase photosynthetic rates in some types of vegetation (e.g., C₃ trees and emergent macrophytes) (Bazzaz *et al.*, 1990; Idso and Kimball, 1993; Drake *et al.*, 1996; Megonigal and Schlesinger, 1997; see also Section 5.6.3.1). Responses of nonvascular vegetation, such as sphagnum, have been less clear (Jauhainen *et al.*, 1994, 1997, 1998a; Jauhainen and Silvola, 1999). A study in Alaskan tussock tundra found that photosynthetic rates in *Eriophorum vaginatum* quickly adjusted downward such that rates with elevated and ambient CO₂ were similar after 1 year (Tissue and Oechel, 1987). However, a sustained increase in net ecosystem carbon sequestration was observed when elevated CO₂ treatments were combined with a 4°C increase in temperature (Oechel *et al.*, 1994).

Many C₃ plants respond to elevated CO₂ with a decrease in stomatal conductance (Curtis, 1996), which could reduce transpiration rates. Because transpiration is an important pathway for water loss from many ecosystems (Schlesinger, 1997), including wetlands (Richardson and McCarthy, 1994), reductions in transpiration rate could affect the position of the aerobic-anaerobic interface in wetland soils (Megonigal and Schlesinger, 1997).

5.8.3.2. Carbon Sink

It has been suggested that water-level drawdown and increased temperature will decrease carbon sequestration in subarctic and boreal peatlands, especially in more southern latitudes (Gorham, 1991). However, conclusions are hampered by the diversity of possible responses.

Impacts of climate change on wetland carbon sink can be measured directly by using the eddy covariance method or chamber techniques (Crill *et al.*, 1988; Fowler *et al.*, 1995; Alm *et al.*, 1997b; Aurela *et al.*, 1998) and modeling the balances (Frolking *et al.*, 1998). In recent years, several high quality, continuous, snow-free season time series of net ecosystem exchange have been obtained for wetlands and peatlands in the subarctic zone (Burton *et al.*, 1996; Friberg *et al.*, 1997; Schreder *et al.*, 1998), the boreal zone (Shurpali *et al.*, 1995; Jarvis *et al.*, 1997; Kelly *et al.*, 1997; Lafleur *et al.*, 1997; Roulet *et al.*, 1997; Suyker *et al.*, 1997; Goulden *et al.*, 1998), and the temperate zone (Happell and Chanton, 1993; Pulliam, 1993). Extrapolations of temporally detailed enclosure measurements along with estimates of the export of DOC have been undertaken to derive peatland carbon balances (Waddington and Roulet, 1996; Carroll and Crill, 1997). These studies point out the difficulty of assessing the sink/source strength of a peatland within a reasonable level of certainty because of errors introduced in the scaling process (Waddington and Roulet, 2000).

For northern peatlands, much is known about the effects of water-level drawdown on the carbon balance, based on studies carried out in peatlands drained for forestry (Glenn *et al.*, 1993; Roulet *et al.*, 1993; Laine *et al.*, 1995; Martikainen *et al.*, 1995; Minkkinen and Laine, 1998). These studies may be used cautiously to represent the climate change impact because the effect of drainage on ecosystem structure and functioning is similar to that predicted after drying caused by climate change in northern latitudes (Laine *et al.*, 1996). The change observed in vegetation structure after water-level drawdown directs biomass production to the shrub and tree layer; in most cases, primary production and biomass increased (Laiho and Finér, 1996; Laiho and Laine, 1997; Sharitz and Gresham, 1998). Simultaneously, litter production increased (Laiho and Finér, 1996; Laiho and Laine, 1997; Finér and Laine, 1998), and the litter was more resistant to decomposition (Meentemeyer, 1984; Berg *et al.*, 1993; Couteaux *et al.*, 1998). There is some evidence that part of the carbon from decomposing litter is stored in the peat profile down to 0.5-m depth (Domisch *et al.*,

1998). These alterations to vegetation production and litter flow into soil have been observed to keep the net carbon accumulation rate into the soil of boreal bogs in most cases at the level prior to water-level drawdown, sometimes exceeding this level (Minkkinen and Laine, 1998). However, increased duration and shortened return periods of extreme droughts may have detrimental effects on the peat carbon balance, as indicated by the results of Alm *et al.* (1997b).

Water-level drawdown will cause a decrease in CH₄ emissions as substrate flux to anoxic layers is decreased and consumption of CH₄ in the thicker aerobic layer is enhanced (Glenn *et al.*, 1993; Roulet *et al.*, 1993; Martikainen *et al.*, 1995; Roulet and Moore, 1995). It has been suggested that reduced CH₄ emissions after water-level drawdown, together with an increase in tree biomass and a fairly small change in carbon sequestration into peat, may even decrease the greenhouse effect of these ecosystems (Laine *et al.*, 1996).

Therefore, it is not immediately clear that a warmer, drier climate necessarily will lead to a large loss of stored peat for all peatland types. The feedback between climate and peatland hydrology and the autogenic nature of peatland development is poorly understood. Clymo (1984) first developed this idea, and it has recently been used to show how surface topography on peatlands is preserved (Belyea and Clymo, 1999). Hilbert *et al.* (1998) have expanded on the work of Clymo (1984) and developed a model of peatland growth that explicitly incorporates hydrology and feedbacks between moisture storage and peatland production and decomposition. Their studies suggest that some peatland types (e.g., most bogs) will adjust relatively quickly to perturbations in moisture storage.

Future rates of carbon sequestration in swamps on mineral soils will depend largely on the response of trees to changes in hydrology, temperature, and elevated CO₂ concentrations. The aboveground productivity of temperate zone swamp forests is strongly regulated by the extent of soil saturation and flooding, and the long-term effect of changes in hydrology on growth will depend on the position of forests along the current hydrological gradient (Megonigal *et al.*, 1997). Drier conditions may increase NPP on extensively flooded sites and decrease it on dry and intermediate sites.

The combination of high soil carbon density and rapid warming in peatlands underlain by permafrost have raised concerns that northern peatlands may become net carbon sources rather than sinks (Lal *et al.*, 2000). Indeed, working in tussock and wet tundra, Oechel *et al.* (1993) estimate that these systems are now net sources of 0.19 Gt C, caused mainly by melting of permafrost and lowering of the water table. Botch *et al.* (1995) report that peatlands of the former Soviet Union are net sources of 0.07 Gt C yr⁻¹. Other parts of the boreal zone may have become enhanced sinks as a result of recent warming (Myneni *et al.*, 1997), and continued warming could change the equation to favor net carbon storage—as suggested by warming experiments in arctic ecosystems (Hobbie, 1996).

Higher temperatures may affect carbon cycling of other wetlands as well. Increased photosynthetic activity of deep-rooted wetland plants, such as sedges, may enhance substrate availability for methanogenesis—which, together with higher temperatures, might lead to higher CH₄ emissions (Valentine *et al.*, 1994; Bergman *et al.*, 1998; Segers, 1998) where water level would remain near the soil surface.

Land uses such as agriculture and forestry always change carbon fluxes in ecosystems. High carbon losses have been reported for agricultural crop production on drained wetland in Europe and North America, as much as 10–20 t C ha⁻¹ yr⁻¹ (Armentano and Menges, 1986). Studies have shown that agriculture on peat soils may contribute significantly to nitrous oxide (N₂O) emission (Nykänen *et al.*, 1995a). Kasimir-Klemedtsson *et al.*, (1997) conclude that agricultural practices on organic soils lead to a net increase in emissions of GHGs because of large fluxes of CO₂ and N₂O, over decreases in emissions of CH₄.

As agricultural management fundamentally alters the processes of wetlands and gradually leads to decreases in wetland area (Okruszko, 1996). Large areas of wetlands have been lost in Russia, Europe, and North America by complete drainage and conversion to other land uses. It has been estimated that 53% of the original 89 Mha of wetlands in the coterminous United States were lost by the 1980s (Shepard *et al.*, 1998), much of it to agricultural conversion. Development for agriculture also can have offsite effects—for example, reduced water quality that impacts fisheries (Notohadiprawiro, 1998). Arable agriculture always transforms wetlands into sources of GHGs to the atmosphere (Armentano and Menges, 1986; Okruszko, 1996), with the exception of CH₄.

Consequences of the development of tropical peatlands include lowering of the water table, which promotes peat oxidation and decomposition. Peat loss and subsidence can occur at very fast rates—as much as 0.9 cm per month (Dradjad *et al.*, 1986). Eventually, shrinkage and oxidation may lead to loss of the entire peat profile and exposure of underlying nutrient-poor substrates or potential acid sulphate soils (Maltby *et al.*, 1996; Rieley *et al.*, 1996). In subcoastal situations, this may be followed by marine inundation.

When wetland use for forestry involves only management of existing tree stands, the impacts on functions and processes may be small, and the ecosystem may remain within the wetland concept (Aust and Lea, 1991; Minkkinen *et al.*, 1999). However, if artificial drainage is included, decay of organic matter is enhanced, with consequent increases in CO₂ emissions from peat (Glenn *et al.*, 1993; Silvola *et al.*, 1996). The results of the carbon balance change reported are highly variable, depending on methods used and climatological differences. Losses of peat carbon have been reported by Braekke and Finer (1991) and Sakovets and Germanova (1992), whereas increased post-drainage carbon stores have been reported by Anderson *et al.* (1992) and Vompersky *et al.* (1992). Based on a large cross-sectional data set from forest drainage areas in Finland, it was shown that carbon accumulation in peat soil

increased in southern parts of the country (annual mean temperature 3–4.5°C) but decreased in northern Finland (with mean temperature of 0–1°C). The carbon accumulation increase was clearest for nutrient-poor bog sites (Minkkinen and Laine, 1998). Cannell and Dewar (1995) have concluded that drainage and planting of conifers on organic soils produces little long-term change in soil carbon stores because enhanced organic matter oxidation is compensated by increased litter production of the tree stand.

Water-level drawdown after drainage decreases CH₄ emissions from peatland (Glenn *et al.*, 1993; Roulet *et al.*, 1993; Martikainen *et al.*, 1995; Roulet and Moore, 1995). Increased consumption in the surface soil may even form a small CH₄ sink in some cases (Glenn *et al.*, 1993; Roulet *et al.*, 1993; Fowler *et al.*, 1995; Martikainen *et al.*, 1995; Roulet and Moore, 1995; Komulainen *et al.*, 1998). The effect of drainage on N₂O emissions has been reported to be fairly small and restricted to fen sites (Martikainen *et al.*, 1993).

Forest harvesting in tropical swamp forests can result in changes to the quality and quantity of organic matter inputs from vegetation, and—as the work of Brady (1997) has shown—if tree root mats decline, net accumulation of peat also may decline. Where selective logging is combined with artificial drainage, decomposition and subsidence of peat may proceed at rates of 3.5–6.0 cm yr⁻¹ (Brady, 1997). In contrast with peatlands of the temperate and boreal zone, there has been poor success with establishing forestry plantations on tropical peatlands.

Peat harvesting totally changes the structure and functioning of the original ecosystem by removing the vegetation and finally most of the accumulated peat deposit. This has a fundamental impact on the GHG balances of harvesting sites: CH₄ emissions almost stop (Nykänen *et al.*, 1995b), but the whole accumulated carbon store forms a CO₂ source to the atmosphere during harvesting and combustion (Rodhe and Svensson, 1995), even if peat combustion may replace imported energy in countries with no other major domestic energy sources.

Recent findings have shown that restoration of cut-away peatlands after harvesting soon initiates colonization of peatland plants (Smart *et al.*, 1989; Tuittila and Komulainen, 1995; Campeau and Rochefort, 1996; Wheeler, 1996; Wind-Mulder *et al.*, 1996; Ferland and Rochefort, 1997; LaRose *et al.*, 1997; Price *et al.*, 1998) and may restart carbon accumulation (Tuittila *et al.*, 1999).

Elevated CO₂ is likely to stimulate CH₄ emissions in a wide variety of wetland ecosystems, including freshwater marshes (Megonigal and Schlesinger, 1997) and rice paddies (Ziska *et al.*, 1998). Studies in northern peatlands have been equivocal: One study reports a maximum increase of 250% (Hutchin *et al.*, 1995) and another no increase (Saarnio *et al.*, 1998). Because CH₄ is a more powerful GHG than CO₂, wetlands amplify the greenhouse effect of elevated CO₂ by converting a portion of this gas to CH₄.

Increased nitrogen deposition may alter the species composition of wetland communities (Aerts *et al.*, 1992) and their production, leading to higher production and net accumulation rates in peatlands where production is nitrogen limited (Aerts *et al.*, 1995). There is some indication that nitrogen inputs may affect trace gas emissions from peat soils by increasing emissions of N₂O and sometimes decreasing those of CO₂ and CH₄ (Aerts, 1997; Aerts and Ludwig, 1997; Aerts and Toet, 1997; Regina *et al.*, 1998).

5.8.3.3. Food and Fiber

Services that involve artificial drainage might even benefit from climatic warming and additionally lowered water levels. Moya *et al.* (1998) report that rice biomass and seed yield is increased by CO₂ concentrations of 200 and 300 ppm above ambient, but these increases are diminished or reversed when air temperature is elevated by 4°C. In the northern latitudes of Scandinavia, forest production in drained peatlands clearly is favored by higher temperatures (Keltikangas *et al.*, 1986) and lower water-table levels.

5.8.4. Adaptation Options for Wetlands

Most wetland processes are dependent on catchment-level hydrology, which is being changed by land-use changes at fairly large scales. Thus, it may be very difficult if not impossible to adapt to the consequences of projected climate change. For key habitats, small-scale restoration may be possible if sufficient water is available. In cases where wetlands are used for arable agriculture, the impact on the carbon balance could be controlled by the choice of cropping method, including alternative crops and depth of drainage.

5.8.5. Vulnerability of Functions and Key Services of Wetlands

The types of inland wetlands that are most vulnerable to global change (i.e., experience the largest changes) are difficult to ascertain. As concluded in the SAR, arctic and subarctic ombrotrophic bog communities on permafrost would change drastically after thawing of the frost layer and might be considered prime candidates in the vulnerability assessment, together with more southern depressional wetlands with small catchment areas. The increasing speed of peatland conversion and drainage in southeast Asia will place these areas at a greatly increased risk of fire. This will be one of the principal factors in determining the viability of tropical systems.

Global change impacts on wetlands would cause changes in many of the ecosystem services of wetlands. Especially vulnerable are functions that depend on a high degree of water availability. Services that involve artificial drainage might even benefit from climatic warming and additionally lowered water levels. For instance, in northern latitudes of Scandinavia,

forest production in drained peatlands clearly is favored by higher temperatures (Keltikangas *et al.*, 1986).

5.9. Arctic and Alpine Ecosystems

Arctic and alpine ecosystems are characterized by low human population densities. However, they provide important goods and services locally and globally. At the local scale, they are the resource base of many indigenous cultures and provide recreation, food, and fiber to people in adjacent regions. At the global level, arctic and boreal regions play an important role in the world's climate system. They contain 40% of the world's reactive soil carbon (McGuire *et al.*, 1995); influence global heat transport through their impact on regional water and energy exchange with the atmosphere; and determine freshwater input to the Arctic Ocean, which influences bottom-water formation and thermohaline circulation of the oceans. Alpine regions are important sources of freshwater and hydropower for surrounding lowlands. Changes in these goods and services would have socioeconomic impacts throughout the world.

Chapter 16 presents information on the effects of climate on the physical environment of polar regions. The impacts of climate change on high-mountain systems and arctic tundra are extensively reviewed in the SAR by Beniston and Fox (1996) and Allen-Diaz (1996), respectively. This section emphasizes the effects of climatic change particularly on ecosystem production, carbon stores, biodiversity, and water flow—which, in turn, can affect the productivity especially of alpine ecosystems.

5.9.1. State and Trends of Goods and Services

5.9.1.1. Arctic Ecosystems

Arctic and alpine tundra each occupy 4 million km² (Körner, 1999). Approximately 25% of the tundra is ice-covered, 25% shrub-dominated, and the rest dominated by herbaceous plants. Soil carbon stocks in boreal and tundra peatlands are large (see Sections 5.6 and 5.8).

High-latitude warming that has occurred in the Arctic region since the 1960s (Chapman and Walsh, 1993; Serreze *et al.*, 2000) is consistent with simulations of climate models that predict increased greenhouse forcing (Kattenberg *et al.*, 1996). Climatic change has been regionally variable, with cooling in northeastern North America and warming in northwestern North America and northern Siberia. The warming results from a change in the frequency of circulation modes rather than gradual warming (Palmer, 1999). Precipitation (P) and surface evaporation (E) have increased at high latitudes, with no significant temporal trend in the balance between the two (P-E) (Serreze *et al.*, 2000).

Permafrost underlies 20–25% of the northern hemisphere land area (Brown *et al.*, 1997a). Ice that forms during periods of cold climate frequently constitutes a high proportion (20–30%)

of the volume of these frozen soils (Brown *et al.*, 1997a). Consequently, melting of permafrost can lead to surface collapse of soils forming thermokarst, an irregular topography of mounds, pits, troughs, and depressions that may or may not be filled with water, depending on topography. Permafrost temperatures have warmed in western North America by 2–4°C from 1940 to 1980 (Lachenbruch and Marshall, 1986) and in Siberia by 0.6–0.7°C from 1970 to 1990 (Pavlov, 1994), whereas permafrost cooled in northeastern Canada (Wang and Allard, 1995)—patterns that roughly parallel recent trends in air temperature. However, the magnitude of warming and patterns of interannual variation (roughly 10-year oscillations) in permafrost temperatures are not readily explained as a simple response to regional warming (Osterkamp *et al.*, 1994). Changes in permafrost regime probably reflect undocumented changes in the thickness or thermal conductance of snow or vegetation, in addition to changes in air temperature (Osterkamp and Romanovsky, 1999). Thermokarst features are developing actively in the zone of discontinuous permafrost (Osterkamp and Romanovsky, 1999), particularly in association with fire and human disturbance, but there are no long-term records from which to detect trends in the regional frequency of thermokarst.

In contrast to the long-term trend in tundra carbon accumulation during the Holocene, flux measurements in Alaska suggest that recent warming may have converted tundra from a net carbon sink to a source of as much as 0.7 Gt C yr⁻¹ (Oechel *et al.*, 1993; Oechel and Vourlitis, 1994). The direction and magnitude of the response of carbon exchange to warming may be regionally variable, depending on climate, topography, and disturbance regime (Zimov *et al.*, 1999; McGuire *et al.*, 2000). During recent decades, peak-to-trough amplitude in the seasonal cycle of atmospheric CO₂ concentrations has increased, and the phase has advanced at arctic and subarctic CO₂ observation stations north of 55°N (Keeling *et al.*, 1996). This change in carbon dynamics in the atmosphere probably reflects some combination of increased uptake during the first half of the growing season (Randerson *et al.*, 1999), increased winter efflux (Chapin *et al.*, 1996), and increased seasonality of carbon exchange associated with disturbance (Zimov *et al.*, 1999). This “inverse” approach generally has concluded that mid-northern latitudes were a net carbon sink during the 1980s and early 1990s (Tans *et al.*, 1990; Ciais *et al.*, 1995; Fan *et al.*, 1998; Bousquet *et al.*, 1999; Rayner *et al.*, 1999). At high northern latitudes, these models give a wider range of estimates, with some analyses pointing to a net source (Ciais *et al.*, 1995; Fan *et al.*, 1998) and others to a sink (Bousquet *et al.*, 1999; Rayner *et al.*, 1999).

High-latitude wetlands and lakes account for 5–10% of global CH₄ fluxes to the atmosphere (Reeburgh and Whalen, 1992). These fluxes increase dramatically with thermokarst (Zimov *et al.*, 1997), acting as a potentially important positive feedback to global warming.

Satellite imagery suggests an increase in NDVI (a measure of “greenness”) from 1981 to 1991 (Myneni *et al.*, 1997), although interpretation is complicated by changes in sensor calibration

(Fung, 1997). If these changes in satellite imagery are an accurate reflection of vegetation activity, changes in NDVI could help explain the increase in seasonal amplitude in atmospheric CO₂ observed at high northern latitudes (Keeling *et al.*, 1996; Randerson *et al.*, 1999). This also is consistent with the increased biomass of shrubs in the arctic tundra (Chapin *et al.*, 1995).

5.9.1.2. Alpine Ecosystems

Climatic changes observed in alpine areas generally have paralleled climatic patterns in surrounding regions, with the most pronounced warming at high latitudes, in the Alps, and in Asia and the least pronounced changes in tropical alpine regions (Diaz and Bradley, 1997). Precipitation generally has increased, with the most pronounced changes in winter, leading to increased snow depth (Beniston, 1997).

Regional trends in climate have led to shrinkage of alpine and subpolar glaciers, equivalent to a 0.25 ± 0.1 mm yr⁻¹ of sea-level change or 16% of the sea-level rise in the past 100 years (Dyurgerov and Meier, 1997). This trend has been regionally variable, with Asia contributing 45% of this sea-level rise and arctic islands an additional 18%. The net mass reduction of the alpine glaciers has been most pronounced since 1980, when regional warming was greatest.

Climatic warming observed in the Alps has been associated with upward movement of some plant taxa of 1–4 m per decade on mountaintops and loss of some taxa that formerly were restricted to high elevations (Braun-Blaunquet, 1956; Grabherr *et al.*, 1994). In general, direct human impacts on alpine vegetation from grazing, tourism, and nitrogen deposition are so strong that climatic effects on goods and services provided by alpine ecosystems are difficult to detect (Körner, 1999). Soil carbon stocks per unit area in alpine ecosystems are only one-third as great as those in the arctic because greater topographic relief promotes greater drainage and decomposition than in the arctic (Körner, 1995b).

5.9.2. Responses of Arctic and Alpine Ecosystems and Impacts on their Goods and Services

5.9.2.1. Impacts Resulting from Changes in Climate on Arctic Ecosystems

Changes in climate are likely to be the greatest cause of changes in goods and services in the arctic (Walker *et al.*, 2001). Projected climatic warming of 4–10°C by the end of the century probably would cause substantial increases in decomposition, nutrient release, and primary production. The net effect on the carbon balance will depend primarily on soil moisture (McKane *et al.*, 1997; McGuire *et al.*, 2000), which cannot be projected with confidence. In general, surface soils on slopes are expected to become drier as thaw depth increases. Lowlands may experience substantial thermokarst, impoundment of water, and reduced aeration.

Plant production frequently is limited in the arctic by excessive moisture and slow turnover of nutrients in soils, and warming and drying of soils is likely to enhance decomposition, nutrient mineralization, and productivity. Many of these changes in productivity may be mediated by changes in species composition and therefore are likely to lag changes in climate by years to decades (Chapin *et al.*, 1995; Shaver *et al.*, 2000). Threshold changes in productivity associated with poleward movement of the treeline is likely to experience time lags of decades to centuries because of limitations in dispersal and establishment of trees (Starfield and Chapin, 1996; Chapin and Starfield, 1997).

The net effect of warming on carbon stores in high-latitude ecosystems depends on changes in the balance between production and decomposition. Decomposition initially may respond more rapidly than production, causing trends toward net carbon efflux (Shaver *et al.*, 1992; Smith and Shugart 1993).

Warming-induced thermokarst is likely to increase CH₄ flux to the atmosphere in lowlands, particularly peatlands of northern Canada and western Siberia (Gorham, 1991; Roulet and Ash, 1992; see also Section 5.8) and the loess-dominated "yedoma" sediments of central and eastern Siberia (Zimov *et al.*, 1997). Fires and other disturbances are likely to affect the thermokarsts; however, the role of these disturbances—which can be mediated with changes in regional climate in inducing thermokarst—are poorly understood.

Changes in community composition associated with warming are likely to alter feedbacks to climate. Tundra has a three- to six-fold higher winter albedo than boreal forest, but summer albedo and energy partitioning differ more strongly among ecosystems within tundra or boreal forest than between these two biomes (Betts and Ball, 1997; Eugster *et al.*, 2000). If regional surface warming continues, changes in albedo and energy absorption during winter are likely to act as positive feedbacks to regional warming as a result of earlier melting of snow and, over the long term, poleward movement of the treeline. Surface drying and a change in dominance from mosses to vascular plants also would enhance sensible heat flux and regional warming in tundra (Lynch *et al.*, 1999; Chapin *et al.*, 2000).

Poleward migration of taxa from boreal forest to the Arctic tundra will depend not only on warming climate but also on dispersal rates, colonization rates, and species interactions and therefore may exhibit substantial time lags. The arctic historically has experienced fewer invasions of weeds and other exotic taxa than other regions (Billings, 1973). Some of the most important changes in diversity in the arctic may be changes in the abundance of caribou, waterfowl, and other subsistence resources (see also Section 5.4). Changes in community composition and productivity may be particularly pronounced in the high arctic, where much of the surface currently is unvegetated and is prone to establishment and expansion of additional vegetation (Wookey *et al.*, 1993; Callaghan and Jonasson, 1995).

5.9.2.2. Impacts of Land-Use Change

Extraction of oil and mineral resources is likely to be the greatest direct human disturbance in the arctic. Although the spatial extent of these disturbances is small, their impacts can be far-reaching because of road and pipeline systems associated with them (Walker *et al.*, 1987). Roads in particular open previously inaccessible areas to new development, either directly related to tourism and hunting or to support facilities for resource extraction.

Changes in goods and services in alpine ecosystems are likely to be dominated by changes in land use associated with grazing, recreation, and other direct impacts, as a result of their proximity to population centers (Körner, 1999; Walker *et al.*, 2001). Many of the alpine zones with greatest biodiversity, such as the Caucasus and Himalayas, are areas where human population pressures may lead to most pronounced land-use change in alpine zones (Akakhanjanz and Breckle, 1995). Direct impacts from human activities are likely to be most pronounced in lower elevational zones that are most accessible to people (Körner, 1999). Improved road access to alpine areas often increases human use for recreation, mining, and grazing and increased forestry pressure at lower elevations (Miller *et al.*, 1996). Overgrazing and trampling by people and animals may tend to destabilize vegetation, leading to erosion and loss of soils that are the long-term basis of the productive capacity of alpine ecosystems.

Alpine areas that are downwind of human population or industrial centers experience substantial rates of nitrogen deposition and acid rain (Körner, 1999). Continued nitrogen deposition at high altitudes, along with changes in land use that lead to soil erosion, can threaten provision of clean water to surrounding regions. Nitrogen deposition occurs primarily during the winter and is transmitted directly to streams during snowmelt, so it readily enters water supplies (Körner, 1999). Many places that use water from alpine areas depend on slow release of the water by melting of snowfields in spring and summer. Warming is likely to create a shortened snowmelt season, with rapid water release creating floods and, later, growing-season droughts. These changes in seasonality, combined with increased harvest in montane forests, would amplify floods.

5.9.3. Adaptation Options

Opportunities for adapting to expected changes in high-latitude ecosystems are limited because these systems will respond most strongly to globally induced changes in climate rather than to regionally controlled and regulated factors. The effects of climate and disturbance regime on regional productivity and carbon balance may be difficult to alter at the local or regional scale. The most important opportunities for mitigation will be protection of peatlands, yedoma sediments, and other carbon-rich areas from large-scale hydrological change. It is unlikely that expected changes in fire or thermokarst regime can be altered except in areas of high population densities. Adaptation

options for forests that occur in these areas are presented in Section 5.6.

The most important opportunities for adaptation in arctic ecosystems may exist for culturally important resources such as reindeer, caribou, waterfowl, and specific plant taxa (see Section 5.4). Careful management of these resources could minimize climatic impacts on indigenous peoples. Another adaptation option is diversification. Many high-latitude regions depend strongly on one or a few resources—such as timber, oil, reindeer, or wages from fighting fires. Economic diversification would reduce the impacts of large changes in the availability or economic value of particular goods and services.

In alpine regions, major opportunities for adaptation relate to protection from large-scale changes in land use or pollutant levels. Because these causes of change are local to regional, wise management could minimize changes.

5.9.4. Vulnerability

Goods and services provided by many arctic regions depend on the physical integrity of permafrost and therefore are vulnerable to warming-induced thermokarst. The large carbon stocks in these regions are vulnerable to loss to the atmosphere as CO₂ or CH₄, which could act as positive feedbacks to global warming. A few key taxa of animals—such as reindeer, caribou, and waterfowl—are critical cultural resources. Often these taxa are concentrated in particular habitats, such as riparian areas or high-Arctic oases. Ecological changes that modify the population dynamics of these species or modify the impact on their habitats could have important social consequences.

High levels of endemism in many alpine flora and their inability to migrate upward mean that these species are most vulnerable. In addition, alpine soils are vulnerable to losses from erosion, which would radically reduce the goods and services that these regions could provide.

5.10. Research Needs across Ecosystems

Most of the foregoing sections mention the need for further research in many areas. Results are needed for future assessments of the impacts of climate change on goods and services provided by ecosystems, adaptation options, or identification of vulnerable systems or regions. It also is clear that most of the research to date has focused on impacts and some on adaptation, with little effort on the vulnerability of systems or regions. Key areas where research is needed to improve future assessments and decrease uncertainties in existing knowledge are as follows (order does not imply priority):

- Long-term monitoring of agricultural processes for detection of impacts of climate change and climate variability and development of possible adaptations to these impacts

- Coupling of pest and crop/animal process modeling to estimate climate-induced pest impacts on crops and livestock
- Pest and disease interaction with climate change and the impact of these interactions on many ecosystems
- Development of coupled biophysical-economic modeling of farm-level decisionmaking under climate change
- Improved understanding of agricultural vulnerability and adaptive capacity
- Improved understanding of interactive effects of climate change and management on carbon source-sink relations in many ecosystems
- Determination of mechanisms that create the often complex changes in wildlife populations, through a systems-type approach to problemsolving such as strategic cyclical scaling (SCS)³
- Development of better understanding of the link between biodiversity and ecosystems functions (role each species plays in ecosystem goods and services is necessary to understand the risks and possible surprises associated with species loss)
- The impact of land-use change on biodiversity and the consequence of these impacts on good and services from ecosystems
- The impact of the added stress of climate change on many ecosystems that are under pressure from human activities
- Exploration of management options (including individual species range) that could be used to adapt to the impacts of global change (allowing ecosystems to continue to provide essential goods and services in a changed and rapidly changing world)
- Exploration of the role of integrated management as a means for providing better management options for many ecosystems
- Long-term experiments on intact natural ecosystems across their native range to study the interactive effect of climate change, elevated CO₂, nutrient/pollution deposition, soil moisture, and WUE of plants
- The interaction of elevated CO₂, increased temperature, and changes in soil moisture with nitrogen deposition and land-use change in influencing the goods and services provided by ecosystems
- Valuation of nonmarket goods and services, such as recreation and NWFP
- Management of exotics and achieving desired community structures (research and alternative models for such activities needed in terrestrial and aquatic systems)

³SCS has three basic steps: detection, attribution, and validation (Root and Schneider, 1995). Many types of ecological data would improve the ability to conduct studies based on the SCS approach. First, additional monitoring systems are needed that would allow long-term data to be collected over a broad scale. Such data would provide the means to detect patterns of change more efficiently. Second, specific small-scale studies examining possible cause of a shifting pattern are needed. After several such studies are completed, these data could be used to validate the cause or mechanism.

- Development of a predictive approach for identifying and dealing with spatial heterogeneity, since responses to climate change differ greatly in adjacent areas (increasing the risk of inappropriate actions with large expenditures of local resources)
- Development of systems models for peatlands, including analysis and modeling of the dynamic interactions between climate change impacts, vegetation development, and carbon exchange between wetland ecosystems and the atmosphere at several spatial scales (from stands to regions to the globe)
- The role of fire and other disturbances on many ecosystems and their role in trace-gas budgets
- Time lags by which productivity, decomposition, and disturbance in ecosystems respond to climatic change
- Assessment of the vulnerability of unique biological resources that are culturally important to many indigenous peoples.

Acknowledgments

Thanks to Mark O'Brien, Kimberley Reade Hall, Alison Saunders, Margo Davies, Rukshika Parera, Sophie Maupin, Mary McKenney Easterling, the Center for Integrated Regional Assessment, and many more for their assistance. Thanks to all our families for their tolerance and understanding while the authors worked long hours as "volunteers" to complete this chapter. Thanks to the numerous reviewers for being so thorough in their reading and their constructive comments.

EXECUTIVE SUMMARY

Global climate change will affect the physical, biological, and biogeochemical characteristics of the oceans and coasts, modifying their ecological structure, their functions, and the goods and services they provide. Large-scale impacts of global warming on the oceans will include:

- Increases in sea level and sea-surface temperature
- Decreases in sea-ice cover
- Changes in salinity, alkalinity, wave climate, and ocean circulation.

Feedbacks to the climate system will occur through changes in ocean mixing, deep water production, and coastal upwelling. Collectively, these changes will have profound impacts on the status, sustainability, productivity, and biodiversity of the coastal zone and marine ecosystems.

Scientists recently have recognized the persistence of multi-year climate-ocean regimes and shifts from one regime to another. Changes in recruitment patterns of fish populations and the spatial distribution of fish stocks have been linked to climate-ocean system variations such as the El Niño-Southern Oscillation (ENSO) and decadal-scale oscillations. Fluctuations in fish abundance increasingly are regarded as a biological response to medium-term climate-ocean variations, and not just as a result of overfishing and other anthropogenic factors. Of course, such factors can exacerbate natural fluctuations and damage fish stocks. Global warming will confound the impact of natural variation and fishing activity and make management more complex.

Growing recognition of the role of understanding the climate-ocean system in the management of fish stocks also is leading to new adaptive strategies that are based on the determination of stock resilience and acceptable removable percentages of fish. We need to know more about these interactions. Climate-ocean-related changes in the distribution of fish populations suggest that the sustainability of the fishing industries of many countries will depend on increasing flexibility in bilateral and multilateral fishing agreements, coupled with international stock assessments and management plans.

Marine mammals and seabirds are large consumers of fish and have been shown to be sensitive to inter-annual and longer term variability in oceanographic and atmospheric parameters. Several marine mammal and bird species, including polar bears and some seabirds, may be threatened by long-term climate change.

Marine aquaculture production has more than doubled since 1990 and is expected to continue its upward trend. However, aquaculture may be limited if key fish species used in feed production are negatively impacted by climate change. Increases in seawater temperature may directly impact aquaculture; such increases already have been associated with increases in diseases and algal blooms.

The adaptive capacities of marine and coastal ecosystems varies among species, sectors, and geographical regions. In the broader oceans, marine organisms will be relatively free to move to new geographical areas; organisms in enclosed seas and coastal zones are more constrained by the physical features of the shore, making natural adaptation more difficult.

Coastal zones are among the world's most diverse and productive environments. With global warming and sea-level rise, many coastal systems will experience:

- Increased levels of inundation and storm flooding
- Accelerated coastal erosion
- Seawater intrusion into fresh groundwater
- Encroachment of tidal waters into estuaries and river systems
- Elevated sea-surface and ground temperatures.

Tropical and subtropical coastlines, particularly in areas that are already under stress from human activities, are highly susceptible to global warming impacts. Particularly at risk are the large delta regions—especially in Asia, where vulnerability was recognized more than a decade ago and continues to increase. Mid-latitude temperate coasts often comprise coastal plains and barriers and soft sedimentary cliffs and bluffs that have been the subject of historical and model studies, virtually all of which confirm the high vulnerability of these coasts. High-latitude coastlines also are susceptible, although the impacts in these areas have been less studied. A combination of accelerated sea-level rise, increased melting of ground ice, decreased sea-ice cover, and associated more energetic wave conditions will have severe impacts on coastal landforms, settlements, and infrastructure.

Coastal areas also include complex ecosystems such as coral reefs, mangrove forests, and salt marshes. In such environments, the impact of accelerated sea-level rise will depend on vertical accretion rates and space for horizontal migration, which may be limited by the presence of infrastructure. Many mangrove forests are under stress from excessive exploitation, and salt

marshes are under stress from reclamation. Many coral reefs already are degraded. In such situations, ecosystem resilience will be greatly reduced through human impacts as well as rising sea levels, increasing sea temperatures, and other climate-ocean-related changes, including prevailing wave activity and storm waves and surges.

Progress in evaluating the potential effects of climate change and sea-level rise on socioeconomic systems has not been as substantial as that relating to biogeophysical impacts. With reference to coastal zones, socioeconomic impacts have been considered in several ways, including:

- As a component of vulnerability assessment of natural systems
- With an emphasis on market-oriented or nonmarket-oriented approaches
- With a focus on costs for infrastructure and adaptation options.

Three coastal adaptation strategies have been identified previously: protect, accommodate, and retreat. In the past few years, structural shore-protection measures have been reevaluated, and there has been greater interest in managing coastal retreat.

Enhancement of biophysical and socioeconomic resilience in coastal regions is increasingly regarded as a desirable adaptive strategy but appears not to be feasible in many of the world's coastal zones. Additional insights can be gained by understanding adaptation to natural variability.

Although some countries and coastal communities have the adaptive capacity to minimize the impacts of climate change, others have fewer options; the consequences may be severe for them. Geographic and economic variability leads to inequity in the vulnerability of coastal communities and potentially in intergenerational access to food, water, and other resources. Techniques for the integration of biophysical and socioeconomic impact assessment and adaptation are developing slowly, while human population growth in many coastal regions is increasing socioeconomic vulnerability and decreasing the resilience of coastal ecosystems.

Integrated assessment and management of open marine and coastal ecosystems and a better understanding of their interaction with human development will be important components of successful adaptation to climate change. Also important will be integration of traditional practices into assessments of vulnerability and adaptation.

6.1. Introduction and Scope

The oceans cover 70% of the Earth's surface and play a vital role in the global environment. They regulate the Earth's climate and modulate global biogeochemical cycles. They are of significant socioeconomic value as suppliers of resources and products worth trillions of dollars each year (IPCC, 1998). Oceans function as areas of recreation and tourism, as a medium for transportation, as a repository of genetic and biological information, and as sinks for wastes. These functions are shared by the coastal margins of the oceans.

Approximately 20% of the world's human population live within 30 km of the sea, and nearly double that number live within the nearest 100 km of the coast (Cohen *et al.*, 1997; Gommess *et al.*, 1998). Nicholls and Mimura (1998) have estimated that 600 million people will occupy coastal floodplain land below the 1,000-year flood level by 2100.

Any changes associated with global warming should be considered against the background of natural variations, such as long-term variations caused by solar and tectonic factors, as well as short- and mid-term changes related to atmospheric and oceanic conditions. Climate change will affect the physical, biological, and biogeochemical characteristics of the oceans and coasts at different time and space scales, modifying their ecological structure and functions. These changes, in turn, will exert significant feedback on the climate system. The world's oceans already are under stress as a result of a combination of factors—such as increased population pressure in coastal areas, habitat destruction, and increased pollution from the atmosphere, from land-based sources, and from river inputs of nutrients and other contaminants (Israel and Tsyban, 1983). These factors, along with increased UV-B radiation resulting from stratospheric ozone depletion, are expected to impair the resilience of some marine ecosystems to climate change.

This chapter reviews the potential impacts of climate change on the coastal zone, marine ecosystems, and marine fisheries. It provides an assessment of the latest scientific information on impacts and adaptation strategies that can be used to anticipate and reduce these impacts. Emphasis is placed on scientific work completed since 1995. This chapter builds on earlier IPCC reports but differs in several significant ways. First, the content of the present chapter was covered in three separate chapters in the Second Assessment Report (SAR: Chapter 8, Oceans; Chapter 9, Coastal Zones and Small Islands; Chapter 16, Fisheries) and in two chapters in the First Assessment Report (FAR: World Oceans and Coastal Zones, Working Group II; Coastal Zone Management, Working Group III). Second, in the *Special Report on Regional Impacts of Climate Change* (IPCC, 1998), impacts on the oceans and coasts were considered in each of the regional chapters; those on the Small Island States and the Arctic and Antarctic were of particular relevance to the present chapter. Third, whereas previous IPCC reports highlighted sea-level rise, vulnerability assessment, biogeophysical effects, and single-sector impacts, this chapter covers several other topics—including a range of methodologies;

climate-change parameters; physical, biological, and socioeconomic sensitivities; and adaptation mechanisms. Additional and regionally specific coastal and marine details are included in the regional chapters of this Third Assessment Report (TAR).

6.2. State of Knowledge

In the past decade there has been considerable improvement in our knowledge of the impacts of climate change on coastal zones and marine ecosystems. This improvement has been far from uniform, either thematically or in regional coverage, and there are still substantial gaps in our understanding.

The First and Second Assessment Reports on ocean systems (Tsyban *et al.*, 1990; Ittekkot *et al.*, 1996) conclude that global warming will affect the oceans through changes in sea-surface temperature (SST), sea level, ice cover, ocean circulation, and wave climate. A review of the global ocean thermohaline circulation system—for which the term “ocean conveyor belt” has been coined (Broecker, 1994, 1997)—emphasizes the role of the global ocean as a climate regulator. Ittekkot *et al.* (1996) notes that the oceans also function as a major heat sink and form the largest reservoir of the two most important greenhouse gases [water vapor and carbon dioxide (CO₂)], as well as sustaining global biogeochemical cycles.

Climate-change impacts on the ocean system that were projected with confidence by Ittekkot *et al.* (1996) include SST-induced shifts in the geographic distribution of marine biota and changes in biodiversity, particularly in high latitudes; future improvement of navigation conditions in presently ice-infested waters; and sea-level changes resulting from thermal expansion and changes in terrestrial ice volume. Regional variations caused by dynamic processes in the atmosphere and ocean also were identified with some confidence. Less confident predictions include changes in the efficiency of carbon uptake through circulation and mixing effects on nutrient availability and primary productivity; changes in ocean uptake and storage capacity for greenhouse gases; and potential instability in the climate system caused by freshwater influx to the oceans and resultant weakening of the thermohaline circulation.

The SAR includes a comprehensive review of climate-change impacts on fisheries (Everett *et al.*, 1996). Principal impacts are believed to be compounded by overcapacity of fishing fleets, overfishing, and deterioration of aquatic habitats. The authors also note that the impacts of natural climate variability on the dynamics of fish stocks is being considered as an important component of stock management, although the nature and magnitude of that variability are not clear.

In the present report, we identify new information about the impacts of climate change that has accumulated since the SAR. We include assessments of impacts on fisheries, marine mammals, sea birds, aquaculture, and marine diseases. We show that more recent information identifies natural multi-year climate-ocean trends as an essential consideration in fisheries

management and stewardship of marine ecosystems. We point out that separating the impacts of natural climate variability and regime shifts from those associated with long-term climate change will be important, although distinguishing between the two will be a difficult task.

The potential impacts of sea-level rise on coastal systems have been emphasized in recent years. Much less attention has been given to the effects of increases in air and sea-surface temperatures; and changes in wave climate, storminess, and tidal regimes. There are at least two reasons for this lack of attention. First, low-lying coastal areas such as deltas, coastal plains, and atoll islands are regarded as particularly vulnerable to small shifts in sea level. Second, global sea-level rise is regarded as one of the more certain outcomes of global warming and already is taking place. Over the past 100 years, global sea level has risen by an average of 1–2 mm yr⁻¹, and scientists anticipate that this rate will accelerate during the next few decades and into the 22nd century.

The FAR (Tsyban *et al.*, 1990) regards sea-level rise as the most important aspect of climate change at the coast and identifies seven key impacts:

- 1) Lowland inundation and wetland displacement
- 2) Shoreline erosion
- 3) More severe storm-surge flooding
- 4) Saltwater intrusion into estuaries and freshwater aquifers
- 5) Altered tidal range in rivers and bays
- 6) Changes in sedimentation patterns
- 7) Decreased light penetration to benthic organisms.

In the SAR, Bijlsma *et al.* (1996) acknowledge the importance of these impacts and further conclude, with high confidence, that natural coastal systems will respond dynamically to sea-level rise; responses will vary according to local conditions and climate; and salt marshes and mangroves may survive where vertical accretion equals sea-level rise—but built infrastructure limits the potential for landward migration of coastal habitats. That report also provides summaries of national and global vulnerability assessments, focusing on numbers of people, land areas, and assets at risk. Several coastal adaptation strategies are identified. The importance of resilience in coastal systems is hinted at and subsequently has become an important consideration in vulnerability analysis of sectors and geographical regions.

6.3 Marine Ecosystems

6.3.1. Habitat

The oceans have significant adaptive capacity to store heat and are the largest reservoir of water vapor and CO₂, although the storage capacity for CO₂ in the Southern Ocean recently has been questioned (Caldeira and Duffy, 2000). In the oceans, climate change will induce temperature changes and associated adjustments in ocean circulation, ice coverage, and sea level. Changes in

the frequency of extreme events also may be expected. These changes, in turn, will affect marine ecosystem structure and functioning, with feedback to global biogeochemical cycles and the climate system.

Recent investigations have shown that there has been a general warming of a large part of the world ocean during the past 50 years (Levitus *et al.*, 2000). Analysis of historical SST data by Cane *et al.* (1997) shows an overall increase associated with land-based global temperature trends. Regional differences exist such that over the past century a cooling was observed in the eastern equatorial Pacific, combined with a strengthening of the zonal SST gradient.

Global mean sea-level has risen by about 0.1–0.2 mm yr⁻¹ over the past 3,000 years and by 1–2 mm yr⁻¹ since 1900, with a central value of 1.5 mm yr⁻¹. TAR WGI Chapter 11 projects that for the full range of the six illustrative scenarios in the IPCC's *Special Report on Emissions Scenarios*, sea level will rise by 0.09–0.88 m between 1990 and 2100. This range is similar to the total range of projections given in the SAR of 0.13–0.94 m. Higher mean sea level will increase the frequency of existing extreme levels associated with storm waves and surges.

The El Niño-Southern Oscillation is a natural part of the Earth's climate. A major issue is whether the intensity or frequency of ENSO events might change as a result of global warming. Timmermann *et al.* (1999) suggested an increased frequency of El Niño-like conditions under future greenhouse warming and stronger “cold events” in the tropical Pacific Ocean. Cooling has been observed in the eastern equatorial Pacific, not reproduced in most GCMs, and has been explained by an increase in upwelling from the strengthening of trade winds because of a uniform warming of the atmosphere (Cane *et al.*, 1997). If temperature differences between the tropics and polar regions are reduced, however, a weakening of the atmospheric circulation patterns that cause upwelling could be expected.

In recent years there have been several studies of global ocean wind and wave climates (e.g., Young, 1999), but analyses of changes over the past few decades have been limited to a few regions. In the past 30 years there has been an increase in wave height over the whole of the North Atlantic, although scientists are not certain that global change is the cause of this phenomenon (Guley and Hasse, 1999). Similarly, analyses of wave buoy data along the entire west coast of North America demonstrate that the heights of storm-generated waves have increased significantly during the past 3 decades (Komar *et al.*, 2000). On the U.S. east coast, analyses have shown that there has been no discernible long-term trend in the number and intensity of coastal storms during the past century, although there has been considerable interdecadal variation (Zhang *et al.*, 2000). The sensitivity of storm waves to a hypothetical sea-level rise and increase in wind strength recently has been modeled for Uruguay (Lorenzo and Teixeira, 1997).

Projected changes in tropical cyclone frequency and intensity remain inconclusive, although some studies have suggested

that the maximum intensity of tropical cyclones may rise by 10–20% (Henderson-Sellars *et al.*, 1998; Knutson *et al.*, 1998). Walsh and Pittock (1998) and Walsh and Katzfey (2000) also suggest that once formed, tropical cyclone-like vortices might travel to higher latitudes and persist for longer as a result of increased SST.

Increased precipitation intensity in extreme events is suggested by climate models under doubled CO₂ for Europe (Jones *et al.*, 1997) and the United States (Mearns *et al.*, 1995), and there is firm evidence that moisture in the atmosphere is increasing over China, the Caribbean region, and the western Pacific (Trenberth, 1999). Heavy rainfall increased during the 20th century in the United States (Karl and Knight, 1998), and there is evidence for increased precipitation rates in Japan and Australia (Iwashima and Yamamoto, 1993; Suppiah and Hennessy, 1998). Changes in the probability of heavy precipitation also are regarded as important indicators of climate change.

Globally, oceanic thermohaline circulation plays an important role in controlling the distribution of heat and greenhouse gases. This circulation is driven by differences in seawater temperature and salinity. There is some evidence that the global thermohaline circulation will weaken as a result of climate change, although views on this issue are still evolving.

Sea ice covers about 11% of the ocean, depending on the season. It affects albedo, salinity, and ocean-atmosphere thermal exchange. The latter determines the intensity of convection in the ocean and, consequently, the mean time scale of deep-ocean processes affecting CO₂ uptake and storage. Projected changes in climate should produce large reductions in the extent, thickness, and duration of sea ice. Major areas that are now ice-bound throughout the year are likely to have lengthy periods during which waters are open and navigable. Observations in the northern hemisphere already have shown a significant decrease in spring and summer sea-ice extent by about 10–15% since the 1950s. It also has been suggested that the decline in ice volume is underestimated because of significant thinning of sea ice in the Arctic (Rothrock *et al.*, 1999). Evidence from whaling records implies a decline in Antarctic ice extent by as much as 25% between the mid-1950s and the early 1970s (de la Mare, 1997).

The foregoing physical responses in the ocean-climate system have implications for habitat and ecology in the oceans and coastal seas. Projected climate changes have the potential to become a major factor affecting marine living resources over the next few decades. The degree of the impact is likely to vary within a wide range, depending on the species and community characteristics and the regional specific conditions. Smith *et al.* (1999) review the sensitivity of marine ecosystems to climate change.

6.3.2. Biological Processes

Marine biota have an important role in shaping climate. Marine biological processes sequester CO₂ and remove carbon from

surface waters to the ocean interior through the settling of organic particles and as ocean currents transport dissolved organic matter. This process, which is called the biological pump, reduces the total carbon content of the surface layers and increases it at depth. This process may be partially offset by biocalcification in reefs and organisms in the open ocean, which increases surface layer CO₂ by reducing bicarbonate alkalinity.

Projected global warming through the 21st century is likely to have an appreciable effect on biological processes and biodiversity in the ocean. A rise in temperature will result in acceleration of biodegradation and dispersal of global organic pollutants (petroleum and chlorinated hydrocarbons, for example). This process would promote their removal from the photic zone of the ocean, as has been demonstrated by Tsyban (1999a) for the Bering and Chukchi Seas.

Physiochemical and biological processes regulate uptake and storage of CO₂ by oceans. The Arctic Ocean, for instance, is an important CO₂ source in winter and sink in summer (Tsyban, 1999b). Climate change is expected to affect the processes that control the biogeochemical cycling of elements. Uptake and storage of CO₂ by the ocean via the biological pump therefore may change. Any changes that do occur are expected to feed back into the carbon cycle (Ittekkot *et al.*, 1996).

Photosynthesis, the major process by which marine biota sequester CO₂, is thought to be controlled by the availability of nutrients and trace elements such as iron (de Baar *et al.*, 1995; Behrenfeld *et al.*, 1996; Coale *et al.*, 1996; Falkowsky *et al.*, 1998). Changes in freshwater runoff resulting from climate warming could affect the inputs of nutrients and iron to the ocean, thereby affecting CO₂ sequestration. Impacts are likely to be greatest in semi-enclosed seas and bays.

Climate change can cause shifts in the structure of biological communities in the upper ocean—for example, between coccoliths and diatoms. In the Ross Sea, diatoms (primarily *Nitzschia subcurvata*) dominate in highly stratified waters, whereas *Phaeocystis antarctica* dominate when waters are more deeply mixed (Arrigo *et al.*, 1999). Such shifts alter the downward fluxes of organic carbon and consequently the efficiency of the biological pump.

6.3.3. Marine Carbon Dioxide Uptake

The oceans are estimated to have taken up approximately 30% (with great uncertainties) of CO₂ emissions arising from fossil-fuel use and tropical deforestation between 1980 and 1989, thereby slowing down the rate of greenhouse global warming (Ittekkot *et al.*, 1996). An important process in the oceans is burial of organic carbon in marine sediments, which removes atmospheric CO₂ for prolonged time periods. Studies of the Southern Ocean by Caldeira and Duffy (2000) have shown high fluxes of anthropogenic CO₂ but very low storage. Model results imply that if global climate change reduces the density

of surface waters in the Southern Ocean, isopycnal surfaces that now outcrop may become isolated from the atmosphere, which would tend to diminish Southern Ocean carbon uptake.

Using models of the effects of global warming on ocean circulation patterns, Sarmiento and Le Quéré (1996) analyzed the potential for changes in oceanic CO₂ uptake. They found that a weakening of the thermohaline circulation could reduce the ocean's ability to absorb CO₂ whereby, under a doubled-CO₂ scenario, oceanic uptake of CO₂ dropped by 30% (exclusive of biological effects) over a 350-year period. In simulations with biological effects under the same CO₂ conditions and time frame, they found that the oceanic uptake was reduced only by 14%. Confirmation that a collapse of global thermohaline circulation could greatly reduce the uptake of CO₂ by the ocean has been reported by Joos *et al.* (1999).

Sarmiento *et al.* (1998) modeled carbon sequestration in the ocean with increasing CO₂ levels and changing climate from 1765 to 2065. They found substantial changes in the marine carbon cycle, especially in the Southern Ocean, as a result of freshwater inputs and increased stratification, which in turn reduces the downward flux of carbon and the loss of heat to the atmosphere.

6.3.4. Marine Fish

Climatic factors affect the biotic and abiotic elements that influence the numbers and distribution of fish species. Among the abiotic factors are water temperature, salinity, nutrients, sea level, current conditions, and amount of sea ice—all of which are likely to be affected by climate change. Biotic factors include food availability and the presence and species composition of competitors and predators. Clearly the relationship between climatic factors and the fish-carrying capacity of the marine environment is complicated, although water temperature can be used as a basis for forecasting the abundance and distribution of many species (Lehodey *et al.*, 1997). Water temperature also can have a direct effect on spawning and survival of larvae and juveniles as well as on fish growth, by acting on physiological processes. Sea temperature also affects the biological production rate thus food availability in the ocean, which is a powerful regulator of fish abundance and distribution.

The question of large-scale, long-term fluctuations in the abundance of marine organisms, primarily those of considerable commercial importance, recently has gained attention. Research has shown that variations (with cycles of 10–60 years or more) in the biomass volume of marine organisms depend on sea temperature and climate (Ware, 1995). Examples include periodic fluctuations in the climate and hydrographic regime of the Barents Sea, which have been reflected in variations in commercial production over the past 100 years. Similarly, in the northwest Atlantic Ocean results of fishing for cod during a period of 300 years (1600–1900) showed a clear correlation between water temperature and catch, which also involved changes in the population structure of cod over cycles of 50–60 years.

Shorter term variations in North Sea cod have been related to a combination of overfishing and warming over the past 10 years (O'Brien *et al.*, 2000).

From 1987 to 1996, the world catch of all marine fishes averaged 74.5 Mt. From 1987 to 1993, catches were relatively stable, ranging between 71.6 and 75.9 Mt. There was a small increase over the period 1994–1996, ranging from 77.1 to 78.6 Mt (FAO, 1998). The 10 species with the largest landings represented 37.4% of the catch in 1996 and the next 10 species an additional 10.9%. Fluctuations in abundance of species representing the 10 largest landings often have been considered to result from overfishing and occasionally from a combination of ocean environment changes and fishing effects. However, there is increasing evidence to suggest that the impacts of climate variations are also having an important effect (O'Brien *et al.*, 2000).

The collapse of the Peruvian anchovy (*Engraulis ringens*) fishery from the mid-1970s to the mid-1980s was widely accepted as an example of overfishing and poor management. The increases in recent years, to catches slightly smaller than the large catches prior to the collapse, provide an example of the important impact of natural fluctuations and the difficulty of sorting out the impacts of fishing and climate-ocean-induced changes. Caddy and Rodhouse (1998) reported an increase in world cephalopod landings as world marine fish catches stabilized. These increases were believed to be related to reduced predation from overfishing of groundfish stocks, although warmer oceans were considered an important factor. These examples emphasize the importance of considering the ecosystem impacts of climate variations, as well as changes for individual species.

McGowan *et al.* (1998) show that there are large-scale biological responses in the ocean to climate variations. Off California, the climate-ocean regime shift in 1976–1977 (Ebbesmeyer *et al.*, 1991) resulted in a reduced rate of supply of nutrients to a shallower mixing layer, decreasing productivity and zooplankton and causing reductions in kelp and sea birds. Although there is no question that fishing has impacts on the dynamics of fish populations, the recent evidence of climate-related impacts is beginning to confound past interpretations of fishing effects. McGowan *et al.* (1998) point out that the success of future fish stock assessments would depend, to a large extent, on the ability to predict the impacts of climate change on the dynamics of marine ecosystems. The assumption that marine ecosystems are stable is no longer acceptable, which raises questions about the definition of sustained yield (O'Brien *et al.*, 2000).

Weather impacts and seasonal rhythms have long been recognized by the global fishing industry, but decadal-scale regime changes have been acknowledged only recently as a factor in fish and ocean ecosystem dynamics. The concept of distinct states in climate-ocean environments, which after periods of persistence switch abruptly to other states, have been called regimes and regime shifts, respectively. More formally, regimes (Steele, 1996) can be defined as multi-year periods of linked recruitment patterns in fish populations or as a stable mean in physical

Table 6-1: Largest marine fisheries in 1996 (FAO, 1998).

Species	Landings (t)	% of Total
Peruvian anchovy (<i>Engraulis ringens</i>)	8,864,000	11.3
Walleye pollock (<i>Theragra chalcogramma</i>)	4,533,000	5.8
Chilean Jack mackerel (<i>Trachurus murphyi</i>)	4,379,000	5.8
Atlantic herring (<i>Clupea harengus</i>)	2,331,000	3.0
Chub mackerel (<i>Scomber japonicus</i>)	2,168,000	2.8
Capelin (<i>Mallotus villosus</i>)	1,527,000	1.9
South American pilchard (<i>Sardinops sagax</i>)	1,494,000	1.9
Skipjack tuna (<i>Katsuwonus pelamis</i>)	1,480,000	1.9
Atlantic cod (<i>Gadus morhua</i>)	1,329,000	1.7
Largehead hairtail (<i>Trichiurus lepturus</i>)	1,275,000	1.6

data. A regime shift is a change in the mean of a data series. The existence of decadal-scale regimes in the environment has been documented (e.g., Gargett, 1997; Gu and Philander, 1997; Mantua *et al.*, 1997). States even longer than the decadal-scale may exist (Ware, 1995; Marsh *et al.*, 1999). Adkinson *et al.* (1996) and Beamish *et al.* (1997) have documented a large-scale response in fish populations to regimes and regime shifts for Pacific salmon.

Among the most important groups of marine fishes are herrings (*Clupea sp.*), sardines and pilchards (*Sardinops sp.*), and anchovies (*Engraulis sp.*) (see Table 6-1). These fish tend to be short-lived species that mature at an early age. Large fluctuations in abundance have been associated with changes in the climate-ocean environment, although it has not been possible to discover the mechanisms that link climate-ocean changes to recruitment (Cole and McGlade, 1998). One of the most convincing relationships of large-scale, synchronous responses in major fisheries resulting from changes in climate-ocean states exists for sardine (*Sardinops sp.*). The decadal variability in the Japanese sardine catch was synchronous with decadal-scale variability in the ocean and climate of the North Pacific; these phenomena also were synchronous with the fluctuations of sardine catches off Chile and California (Kawasaki, 1991; Hiyama *et al.*, 1995) and with trends in Pacific salmon catches (Beamish *et al.*, 1999) (see Box 6-1).

Fluctuations in the abundance and distribution of herring (*Clupea harengus*) and sardine (*Sardinella pilchardus*) in the North and Baltic Seas have been linked to variations of the North Atlantic Oscillation and the resulting strength and pattern of southwesterly winds (Alheit and Hagen, 1997).

Most fishing regime changes can be related directly to sea-temperature changes, but changes in other physical attributes also can have an impact. For instance, a decrease in wind stress off Tasmania that reduced large zooplankton production affected the density of Jack mackerel (*Trachurus declivis*), which eliminated the possibility of a commercially viable mackerel fishery (Harris *et al.*, 1992).

The aforementioned climate-related fluctuations in the Japanese sardine occurred at the same time as shifts in the

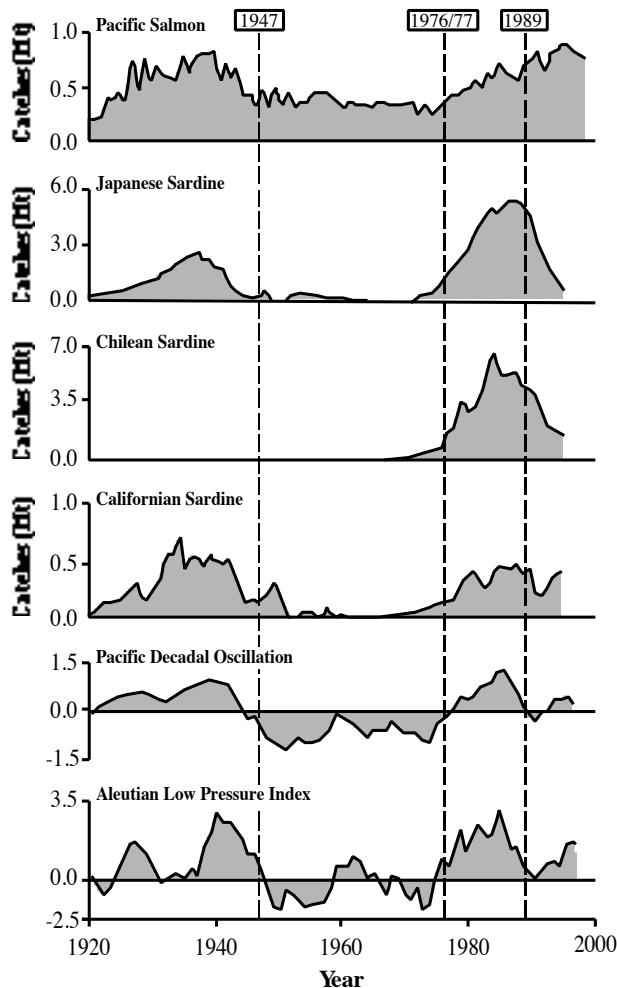

migratory patterns of the northern bluefin tuna (*Thunnus thynnus*), with a higher proportion of bluefin remaining in the western Pacific when sardine abundance was high (Polovina, 1996). The migratory pattern of albacore tuna (*T. alalunga*) also was altered by decadal-scale climate changes (Kimura *et al.*, 1997).

Nearly 70% of the world's annual tuna harvest comes from the Pacific Ocean. In 1996, Skipjack tuna (*Katsuwonus pelamis*) was the eighth-largest marine fishery in the world (see Table 6-1). Catches of skipjack are highest in the western equatorial Pacific warm pool; Lehodey *et al.* (1997) have shown that major spatial shifts in the skipjack population can be linked to large zonal displacements of the warm pool (see Box 6-2).

Welch *et al.* (1998) propose that continued warming of the North Pacific Ocean would compress the distributions of Sockeye salmon (*Oncorhynchus nerka*), essentially squeezing them out of the North Pacific and into the Bering Sea. Some modeling of future impacts of greenhouse gas increases, however, has shown an intensification of the Aleutian Low, which has been associated with mid-ocean cooling (Deser *et al.*, 1996) and increased Pacific salmon production. The warmer surface waters could reduce growth if bioenergetic costs are higher and less food is available as a consequence of ocean habitat changes. The potential impact of climate change on Pacific salmon is expected to occur in freshwater and ocean situations (Hinch *et al.*, 1995). This fact is important because production of more juveniles in hatcheries would not mitigate changes in the ocean carrying capacity for Pacific salmon. The most effective strategy to manage the impacts of climate change on Pacific salmon may be to ensure that wild salmon are preserved and protected, rather than to produce more salmon through artificial enhancement. It is possible that the variety of life history types and genetic traits of the wild stocks are inherent biological solutions to changing freshwater and marine habitats (Bisbal and McConnaha, 1998).

The potential deepening of the Aleutian Low and increase in the amplitude of the Pacific Decadal Oscillation would result in major changes in marine ecosystems (Mantua *et al.*, 1997).

Box 6-1. Regimes and Regime Shifts: Salmon and Sardine Catch

As the figure to the left shows, catches (Mt) of Pacific salmon (*Oncorhynchus sp.*) and sardines (*Sardinops sp.*) fluctuate synchronously with large-scale climate-ocean changes in the North Pacific, as indicated by the Aleutian Low Pressure Index and SST as expressed in the Pacific Decadal Oscillation both of which are shown as a 5-year running average (data from Beamish *et al.*, 1999, and Mantua *et al.*, 1997). Persistent states or regimes are separated by regime shifts, which occurred about 1947, 1976–1977, and 1989. These shifts are shown by the vertical dashed lines. The well-documented 1976–1977 regime shift has been associated with changing abundance trends of other marine organisms such as plankton. It also has been related to an abrupt change in the southernmost extent of sea ice in the Bering Sea, in turn affecting the distribution of Walleye pollock (*Theragra chalcogramma*) and Arctic cod (*Boreogadus saida*) (Wyllie-Echeverria and Wooster, 1998).

The concepts of regimes, regime shifts, and natural trends in the abundance of animals indicates that it is important to assess the potential impact of global warming on decadal-scale processes as well as on species specific responses.

As ecosystems change, there may be impacts on the distribution and survival of fishes. Any changes in natural mortality would be associated with increased predation and other factors such as disease. Improved growth in the early life stages would improve survival, whereas decreased growth could facilitate increased mortality.

Sea temperature is an important regulator of fish behaviors. Wood and McDonald (1997) provide examples of how climate change could induce temperature responses in fish, but there are several areas where less certainty exists. The effect that global climate change will have on trends in the Aleutian Low Pressure system in the Pacific Ocean is an example. Although there are clear linkages between the intensity and position of the low and production trends of many of the commercially important fish species (Kawasaki *et al.*, 1991; Polovina *et al.*, 1995; Gargett, 1997; Mantua *et al.*, 1997; Francis *et al.*, 1998), a reduction in equator-to-pole temperature gradients would probably weaken winds and consequently reduce open-ocean

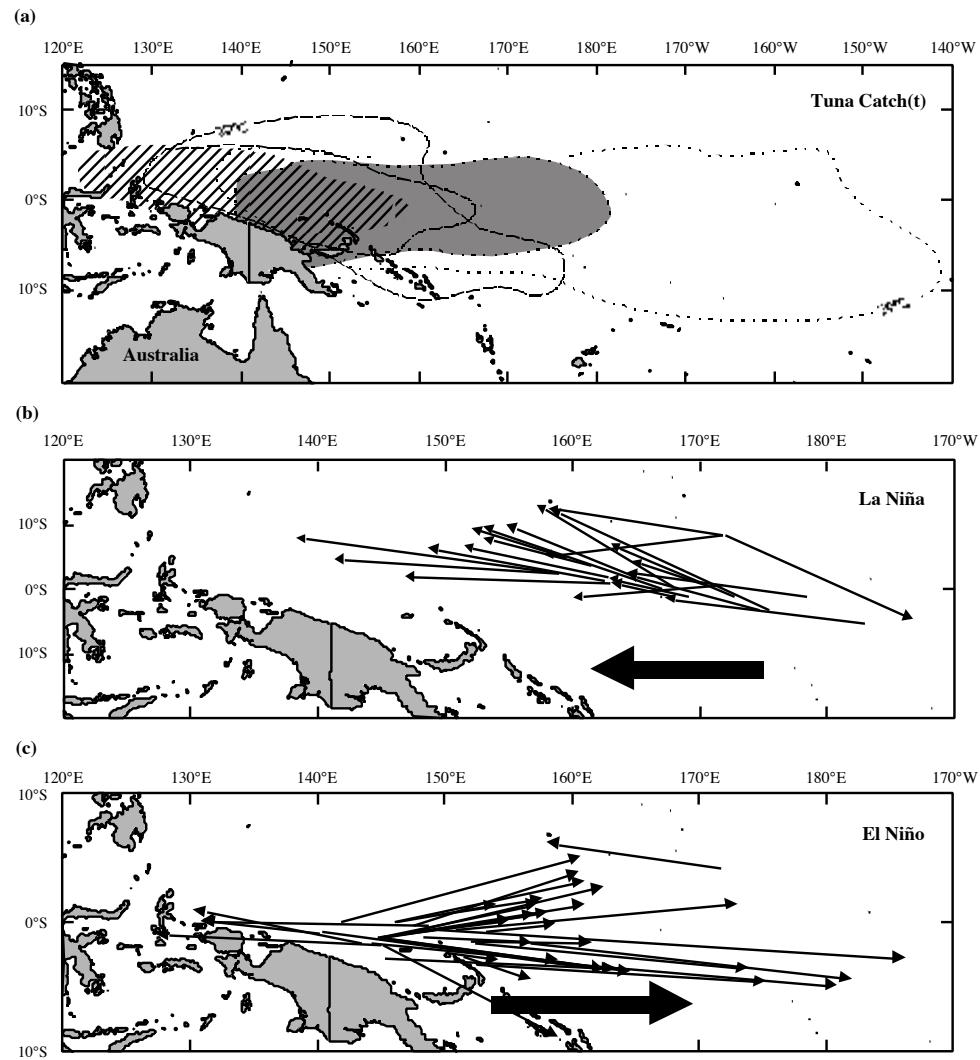

upwelling. Important changes in species distributions in surface waters could result.

There is now a cautious acceptance that climate change will have major positive and negative impacts on the abundance and distribution of marine fish. Thus, the impacts of fishing and climate change will affect the dynamics of fish and shellfish such as abalone in Mexico (Shepherd *et al.*, 1998). Fishing impacts may be particularly harmful if natural declines in productivity occur without corresponding reductions in exploitation rates. Changes in fish distributions and the development of aquaculture may reduce the value of some species, however—as it has for wild Pacific salmon—and these changes may reduce fishing pressures in some areas.

Key to understanding the direction of change for world fisheries is the ability to incorporate decadal-scale variability into general circulation models (GCMs). Although progress has occurred, it still is not possible to assess regional responses to shifts in climate

Box 6-2. Tuna Migration and Climate Variability

Skipjack tuna (*Katsuwonus pelamis*) dominate the world's catch of tuna. The habitat supporting the densest concentrations of skipjack is the western equatorial Pacific warm pool, with SST of 29°C and warmer. Panel (a) clearly shows the association of skipjack tuna catch (shaded and cross-hatched areas indicate January–June catch of 200,000+ t) and mean SST [data from Lehodey *et al.* (1997)].

records of a large-scale skipjack tagging program carried out by the Secretariat of the Pacific Community (SPC). The illustrations are from Lehodey *et al.* (1997, 1998).

The close association of skipjack tuna catch and ENSO is evidence that climate variability profoundly affects the distribution pattern of tuna and resulting fishing opportunities. Scientists do not know how projected climate changes will affect the size and location of the warm pool in the western and central Pacific, but if more El Niño-like conditions occur an easterly shift in the center of tuna abundance may become more persistent.

(1997)]. The figure also shows that the location of the warm pool is linked to ENSO and that it changes during El Niño and La Niña events. For instance, the catch area in the first half of 1989 (La Niña period), which is shown by cross-hatch, was centered around Palau and the Federated States of Micronesia; in the first half of 1992 (El Niño period), the center of abundance had shifted to the east, to the Marshall Islands and Kiribati (shown by shading).

Panels (b) and (c) indicate the scale of tuna migration during a La Niña period and an El Niño period, respectively. These figures were compiled from

trends, and it is unknown if a general warming will increase or decrease the frequency and intensity of decadal-scale changes in regions where national fisheries occur. Recent studies have not produced evidence to change the conclusion from the SAR (Everett *et al.*, 1996) that future saltwater fisheries production

is likely to be about the same as at present, though changes in distribution could affect who catches a particular stock. However, if aquaculture becomes the major source of fish flesh and management of fisheries becomes more precautionary, the exploitation rate of wild marine fish may decrease in some areas.

6.3.5. Aquaculture

Marine aquaculture production more than doubled from 4.96 Mt in 1990 to 11.14 Mt in 1997. Similar trends were exhibited in freshwater aquaculture, with increases from 8.17 Mt in 1990 to 17.13 Mt in 1997, while yields from marine and freshwater fisheries remained relatively constant. The net result was that aquaculture production represented approximately 30% of total fish and shellfish production for human consumption in 1997. Aquaculture production is expected to continue its upward trend in the foreseeable future, although in many areas (such as in Thailand) there is a boom and bust pattern to aquaculture.

About 30% (29.5 Mt) of the world fish catch is used for nonhuman consumption, including the production of fishmeal and fish oils that are employed in agriculture, in aquaculture, and for industrial purposes. Fishmeal and fish oils are key diet components for aquaculture production; depending on the species being cultured, they may constitute more than 50% of the feed. Climate change could have dramatic impacts on fish production, which would affect the supply of fishmeal and fish oils. Unless alternative sources of protein are found, future aquaculture production could be limited by the supply of fishmeal or fish oils if stocks of species used in the production of fishmeal are negatively affected by climate change and live-fish production. The precise impacts on future aquaculture production also will depend in part on other competing uses for fishmeal and fish oils. Usage of other sources of protein or developments in synthetic oils for industrial applications could reduce demands on fishmeal and fish oils, thereby reducing potential impacts on aquaculture.

Climate change is expected to have physical and ecosystem impacts in the freshwater and marine environments in which aquaculture is situated. Water and air temperatures in mid- to high latitudes are expected to rise, with a consequent lengthening of the growing season for cultured fish and shellfish. These changes could have beneficial impacts with respect to growth rate and feed conversion efficiency (Lehtonen, 1996). However, increased water temperatures and other associated physical changes, such as shifts in dissolved oxygen levels, have been linked to increases in the intensity and frequency of disease outbreaks and may result in more frequent algal blooms in coastal areas (Kent and Poppe, 1998). Any increases in the intensity and frequency of extreme climatic events such as storms, floods, and droughts will negatively impact aquaculture production and may result in significant infrastructure damage. Sea-level rise can be expected to have a negative effect on pond walls and defenses.

Elevated temperatures of coastal waters also could lead to increased production of aquaculture species by expanding their range. These species could be cultivated in higher latitudes as well as in existing aquafarms as a result of a longer warm season during which water temperature will be near optimal. A decrease in sea-ice cover could widen the geographical boundaries, allowing cultivation of commercially valuable species in areas hitherto not suitable for such developments.

6.3.6. Ocean Ranching

Ocean ranching is used to increase the production of several fish species. The primary difference between ocean ranching and aquaculture is that in ocean ranching the fish are cultured for only a portion of their life cycle and then released prior to maturity. The cultured fish are then captured as “common property” in a variety of fisheries. These cultured or “enhanced” fish interact with the wild fish in the ecosystem and compete for the finite food and habitat resources available (often referred to as “carrying capacity”). Climate change will alter carrying capacity, but the impacts associated with ocean ranching or stock enhancement activities also need to be considered when examining overall changes to the ecosystem.

Although the precise impacts are species-dependent, the addition of billions of enhanced fish into the marine ecosystem may have significant consequences from genetic and ecological perspectives. In the Pacific, for example, large numbers of salmon are released from hatcheries in Russia, Japan, Canada, and the United States (Mahnken *et al.*, 1998). Beamish *et al.* (1997) estimate that 83% of the catch of chum salmon by all countries is from hatchery production. If climate change increases SST and reduces winter wind mixing in the upper layers of the ocean, the feeding areas for salmon may be less productive because of increased surface layer stability. Reductions in overall production and catches of salmon—and likely other species—would result (Gargett, 1997).

6.3.7. Marine Mammals and Seabirds

Marine mammals and seabirds are sensitive indicators of changes in ocean environments. Springer (1998) concluded that synchrony in extreme fluctuations of abundance of marine birds and mammals across the North Pacific and Western Arctic were a response to physical changes, including climate warming. The linkages with climate change were compelling enough for Springer to suggest that fluctuations in marine bird and mammal populations in the North Pacific are entirely related to climate variations and change.

The climate variations beginning in the 1990s and associated with El Niño conditions (Trenberth and Hoar, 1996), in combination with overfishing, have been linked to behavioral changes in killer whales. These changes drastically reduced sea otter abundance along the Aleutian Islands, which in turn changed the ecology of the kelp forests (Estes *et al.*, 1998). The changes in prey resulting from persistent changes in climate appear to be one of the important impacts of a changing climate on the marine mammals that feed from the top of the food chain.

Climate change also may have an effect on access to prey among marine mammals. For instance, extended ice-free seasons in the Arctic could prolong the fasting of polar bears (*Ursus maritimus*), with possible implications for the seal population (Stirling *et al.*, 1999). Reduced ice cover and access to seals would limit hunting success by polar bears and foxes, with

resulting reductions in bear and fox populations. This dynamic could have negative effects on the lifestyle, food, and health standards of some indigenous peoples (Hansell *et al.*, 1998). Because global climate change is likely to have profound impacts on sea-ice extent and duration, it is in this habitat where the initial impacts on marine mammals may be first evident. Reductions in sea ice have been predicted to alter the seasonal distributions, geographic ranges, migration patterns, nutritional status, reproductive success, and ultimately the abundance of Arctic marine mammals (Tynan and DeMaster, 1997). Studies recognizing multi-year to decadal variability in marine biotic systems include Mullin (1998) on zooplankton over 5 decades in the eastern Pacific (with connections to El Niño), and Tunberg and Nelson (1998) on soft bottom macrobenthic communities in the northeast Atlantic (with connections to the North Atlantic Oscillation). Sagarin *et al.* (1999) have argued that changes in the distribution of intertidal macroinvertebrates on rocky shores in California over the past 60 years have been caused by climate change.

Seabirds are an integral part of marine ecosystems, where they may consume vast amounts of fish. It has been estimated that seabirds consume 600,000 t yr⁻¹ of food in the North Atlantic (Hunt and Furness, 1996). Modeling studies have shown that in several marine ecosystems, seabirds eat 20–30% of the annual pelagic fish production. The dependence on some species of fish, particularly during breeding, and their large abundance make seabirds a good indicator of ecosystem change. Where changes in breeding success or mortality occur, however, distinguishing the climate impact from fishing impacts can be difficult (Duffy and Schneider, 1994). Very few decadal-scale studies of seabirds are available to assess the impacts of long-term variations in climate, however.

In general, seabirds have evolved to adapt to weather patterns (Butler *et al.*, 1997). The ability of a species to alter its migration strategy appears to be important to survival in a changing climate. Food resources appear to be critical to general survival, especially for young seabirds. Dolman and Sutherland (1994) proposed that feeding rate affects the ability of individuals to survive winter. The change in marine ecosystem described by Roemmich and McGowan (1995) was associated with a mortality resulting in a 40% decline in seabird abundance within the California current system from 1987 to 1994 (Veit *et al.*, 1996). The decline was largely related to a dramatic (90%) decline of sooty shearwaters (*Puffinus griseus*), but the response in the ecosystem was not characterized only by declines. There was a northward movement of some species, and in offshore waters the abundance of the most common species, Leach's storm petrels (*Oceanodroma leucorhoa*), increased over the same period. The authors were careful to note that the changes in abundance they described could not be related directly to population dynamics because of complex migratory patterns and the size of the habitat.

Such changes are evidence of the sensitivity of seabirds to climate-ocean changes and that survival and distribution impacts will occur as climates shift. The anomalous cold surface waters

that occurred in the northwest Atlantic in the early 1990s changed the fish species composition in the surface waters on the Newfoundland shelf. These changes were readily detected in the diets of northern gannet (*Sula bassana*). The sensitivity of the distribution patterns of the pelagic prey of fish-feeding and plankton-feeding seabirds imply to Monteverchi and Myers (1997) that small changes in the ocean environment resulting from climate changes could affect seabird reproductive success. Changes in fish-feeding seabird abundance in the eastern Bering Sea are related to the abundance of juvenile pollock (Springer, 1992). It has been argued that long lifespans and genetic variation within populations enable seabirds to survive adverse short-term environmental events, as evidenced by the response to El Niño and La Niña events in the tropical Pacific (Ribic *et al.*, 1997). However, small populations tied to restricted habitat, such as the Galapagos Penguin (*Spheniscus mendiculus*), may be threatened by long-term climate warming (Boersma, 1998).

6.3.8. Diseases and Toxicity

Changes in precipitation, pH, water temperature, wind, dissolved CO₂, and salinity can affect water quality in estuarine and marine waters. Some marine disease organisms and algal species are strongly influenced by one or more of these factors (Anderson *et al.*, 1998). In the past few decades there has been an increase in reports of diseases affecting closely monitored marine organisms, such as coral and seagrasses, particularly in the Caribbean and temperate oceans. The worldwide increase in coral bleaching in 1997–1998 was coincident with high water temperatures associated with El Niño, but Harvell *et al.* (1999) suggest that the demise of some corals might have been accelerated by opportunistic infections affecting the temperature-stressed reef systems. Talge *et al.* (1995) report a new disease in reef-dwelling foraminifera, with implications for coastal sedimentation.

ENSO cycles and increased water temperatures have been correlated with Dermo disease (caused by the protozoan parasite *Perkinsus marinus*) and MSX (multinucleated spore unknown) disease in oysters along the U.S. Atlantic and Gulf coasts. In addition to affecting marine hosts, several viruses, protozoa, and bacteria affected by climatic factors can affect people, by direct contact or by seafood consumption. Many of the reported cases of water-borne diseases involve gastrointestinal illnesses; some can be fatal in infants, elderly people, and people with weakened immune systems (ASM, 1998).

The bacterium *Vibrio vulnificus*, which is found in oysters and is potentially lethal to humans with immune-system deficiencies, becomes more abundant as water temperature increases (Lipp and Rose, 1997). The incidence and severity of cholera (*Vibrio cholerae*) epidemics associated with marine plankton also has been linked with prolonged elevated water temperature. Annual epidemics of cholera in Bangladesh have been correlated with increased SST and sea-surface height (Harvell *et al.*, 1999).

6.4. Coastal Systems

6.4.1. General Considerations

Coastal environments occupy one of the most dynamic interfaces on Earth, at the boundary between land and sea, and they support some of the most diverse and productive habitats. These habitats include natural ecosystems, in addition to important managed ecosystems, economic sectors, and major urban centers. The existence of many coastal ecosystems is dependent on the land-sea connection or arises directly from it (e.g., deltas and estuaries). Coastal ecosystems can encompass a wide range of environmental conditions over short distances, particularly of salinity (from fresh to hypersaline) and energy (from sheltered wetlands to energetic wave-washed shorelines). At a much coarser geographical scale, there is a spectrum of climate types—from tropical to polar—with concomitant broad-scale differences in biogeophysical processes and features. Coastal environments, settlements, and infrastructure are exposed to land-sourced and marine hazards such as storms (including tropical cyclones), associated waves and storm surges, tsunamis, river flooding, shoreline erosion, and influx of biohazards such as algal blooms and pollutants. All of these factors need to be recognized in assessing climate-change impacts in the coastal zone.

A summary of potential impacts appears in Box 6-3. Note, however, that owing to the great diversity of coastal environments; regional and local differences in projected relative sea level and climate changes; and differences in the resilience and adaptive capacity of ecosystems, sectors, and countries, the impacts summarized here will be highly variable in time and space and will not necessarily be negative in all situations.

Some natural features of the shore zone provide significant coastal protection, including coral reefs (the most extensive, massive, and effective coastal protection structures in the world); sand and gravel beaches, which function as wave energy sinks; and barrier beaches, which act as natural breakwaters. Coastal dunes form natural buffers and sand repositories, from which sand may be extracted during storms without major shoreline retreat; coastal vegetation often absorbs wind or wave energy, retarding shoreline erosion. Even the value of salt marsh as a sea defense (King and Lester, 1995) and mangroves as a sediment trap (Solomon and Forbes, 1999) have been recognized. These functions of natural coastal systems contribute to resilience, as discussed in Section 6.6.2.

Bijlsma *et al.* (1996) and the various regional reports in IPCC (1998) identify the areas of greatest sensitivity to accelerated sea-level rise. These areas comprised low-elevation coral atolls and reef islands, as well as low-lying deltaic, coastal plain, and barrier coasts, including sandy beaches, coastal wetlands, estuaries, and lagoons. To this list can be added coarse gravel beaches and barriers, especially if sediment-starved; cliffted coasts in unlithified deposits, particularly where the proportion of sand and gravel is limited; and ice-rich cliffted coasts in high latitudes. Bold and rock-dominated coasts are relatively less

Box 6-3. Potential Impacts of Climate Change and Sea-Level Rise on Coastal Systems

Biophysical impacts can include the following:

- Increased coastal erosion
- Inhibition of primary production processes
- More extensive coastal inundation
- Higher storm-surge flooding
- Landward intrusion of seawater in estuaries and aquifers
- Changes in surface water quality and groundwater characteristics
- Changes in the distribution of pathogenic microorganisms
- Higher SSTs
- Reduced sea-ice cover.

Related socioeconomic impacts can include the following:

- Increased loss of property and coastal habitats
- Increased flood risk and potential loss of life
- Damage to coastal protection works and other infrastructure
- Increased disease risk
- Loss of renewable and subsistence resources
- Loss of tourism, recreation, and transportation functions
- Loss of nonmonetary cultural resources and values
- Impacts on agriculture and aquaculture through decline in soil and water quality.

vulnerable but often include coastal reentrants with beaches, estuaries, or deltas, which may represent areas of localized vulnerability. On such coasts, wave runup and overtopping can be a factor that threatens infrastructure situated well above mean sea level (Forbes, 1996).

It is important to recognize that vulnerable coastal types in many parts of the world already are experiencing relative sea-level rise, from a combination of subsidence and the global component of sea-level rise identified to date. Submergence rates of 2.5 mm yr^{-1} or more are not uncommon, and higher rates apply locally, such as in parts of China (Ren, 1994), the United States (Dean, 1990), Canada (Shaw *et al.*, 1998a), and Argentina (Codignotto, 1997). Although this sea-level rise implies enhanced vulnerability, it also provides a basis for assessing coastal response to various rates of relative sea-level rise, where similar coastal types, boundary conditions, and system properties can be identified. Numerous studies along the U.S. Atlantic coast, where relative sea level is rising at rates of $2\text{--}4 \text{ mm yr}^{-1}$, have demonstrated common patterns of barrier beach retreat by washover and ephemeral inlet processes (Leatherman *et al.*, 2000). More rapid retreat is recorded in delta-margin settings characterized by rapid subsidence (e.g., Stone and McBride, 1998).

In addition to submergence, seawater intrusion into freshwater aquifers in deltaic and nondeltaic areas is an increasing problem with rising sea level (Moore, 1999). This intrusion has been documented in diverse environments such as the arid Israeli coast, the humid Thailand coast, the Chinese Yangtze Delta, the Vietnamese Mekong Delta, and low-lying atolls (e.g., Melloul and Goldberg, 1997; Chen and Stanley, 1998; Singh and Gupta, 1999).

Although some low, sediment-starved, gravel barrier beaches show rapid retreat under rising sea level, this process is highly nonlinear and in some cases is more closely related to storm event frequency and severity (Forbes *et al.*, 1997a). The response of coasts to storm-related sea-level variations around the North Sea has not been determined, although past increases in the winter means of high water levels of the order of 1–2 mm yr⁻¹ have taken place (Langenberg *et al.*, 1999).

6.4.2. Beaches, Barriers, and Cliff Coasts

Sandy coasts shaped and maintained primarily by wave and tidal processes occupy about 20% of the global coastline (Bird, 1993). A smaller proportion consists of gravel and cobble-boulder beaches and related landforms, occurring in tectonically active and high-relief regions and in mid- to high-latitude areas of former glaciation. Coral rubble beaches and islands are common in low-latitude reefal areas. Any analysis of climate-change impacts on the coastal zone should include beaches and barriers of sand and/or gravel as well as coastal cliffs and bluffs.

Over the past 100 years or so, about 70% of the world's sandy shorelines have been retreating, about 20–30% have been stable, and less than 10% have been advancing. Bird (1993) argues that with global warming and sea-level rise there will be tendencies for currently eroding shorelines to erode further, stable shorelines to begin to erode, and accreting shorelines to wane or stabilize. Local changes in coastal conditions and particularly in sediment supply may modify these tendencies, although Nicholls (1998) has indicated that accelerated sea-level rise in coming decades makes general erosion of sandy shores more likely.

Previous discussions of shoreline response to climate change have considered the well-known simple relations between sea-level rise and shoreline retreat of Bruun (1962). This two-dimensional model assumes maintenance of an equilibrium nearshore profile in the cross-shore direction as sea level rises. Some papers have supported this approach for long-term shoreline adjustment (Mimura and Nobuoka, 1996; Leatherman *et al.*, 2000); others have suggested various refinements (Komar, 1998a). Although the model's basic assumptions are rarely satisfied in the real world (Bruun, 1988; Eitner, 1996; Trenhaile, 1997), its heuristic appeal and simplicity have led to extensive use in coastal vulnerability assessments for estimating shoreline retreat under rising sea levels, with varying degrees of qualification (Richmond *et al.*, 1997; Lanfredi *et al.*, 1998; Stewart *et al.*, 1998). Erroneous results can be expected in many

situations, particularly where equilibrium profile development is inhibited, such as by the presence of reefs or rock outcrops in the nearshore (Riggs *et al.*, 1995). Moreover, Kaplin and Selivanov (1995) have argued that the applicability of the Bruun Rule, based on an equilibrium approach, will diminish under possible future acceleration of sea-level rise.

Few models of shoreline response incorporate large-scale impacts of sea-level rise coupled to changes in sediment availability. Efforts to address this shortcoming have been pioneered by Cowell and Thom (1994) for sandy barrier-dune complexes and Forbes *et al.* (1995) for gravel barriers. Although these parametric models incorporate sediment supply as well as sea-level change, they are still in the early stages of development and are useful primarily to indicate general patterns of response. A multifaceted approach is needed to incorporate other factors such as longshore and cross-shore variability in shore-zone morphology, sediment supply, texture and composition, nonlinear shore-zone response to storms and storm sequences (Forbes *et al.*, 1995), tectonic history of the site, and the presence or absence of biotic protection such as mangroves or other strand vegetation.

Impact assessment, adaptation actions, and other management decisions must consider all of these factors within a coastal systems context. Temporal variation in storminess and wind climate can produce significant coastal adjustments (Forbes *et al.*, 1997a). Another important component of analysis involves historical trends of shoreline change, including variability caused by storms or other anomalous events (Douglas *et al.*, 1998; Gorman *et al.*, 1998). This analysis can provide essential baseline data to enable comparisons in the future, albeit prior to anticipated climate-change impacts.

Field studies and numerical simulation of long-term gravel barrier evolution in formerly glaciated bays of eastern Canada (Forbes *et al.*, 1995) have revealed how sediment supply from coastal cliffs may be positively correlated with the rate of relative sea-level rise. In this case, rising relative sea level favors barrier progradation, but the system switches to erosional retreat when the rate of sea-level rise diminishes, cliff erosion ceases, and no new sediment is supplied to the beach. Along the South American coast, El Niño events are linked to higher-than-average precipitation causing increased sediment discharge to the Peruvian coast, leading to the formation of gravel beach-ridge sequences at several sites (Sandweiss *et al.*, 1998).

In assessing coastal response to sea-level rise, the relevant sedimentary system may be defined in terms of large-scale coastal cells, bounded by headlands or equivalent transitions—typically one to several tens of kilometers in length and up to hundreds of kilometers in some places (Wijnberg and Terwindt, 1995). Within such cells, coastal orientation in relation to dominant storm wind and wave approach direction can be very important (Héquette *et al.*, 1995; Short *et al.*, 2000), and sediment redistribution may lead to varying rates and/or directions of shoreline migration between zones of sediment erosion and deposition.

Changes in wave or storm patterns may occur under climate change (Schubert *et al.*, 1998). In the North Atlantic, a multi-decadal trend of increased wave height is observed, but the cause is poorly understood and the impacts are unclear. Changing atmospheric forcing also has been suggested as a process contributing to increases in mean water level along the North Sea coast, independent of eustatic and isostatic contributions to relative sea level. Changes in large-scale ocean-atmospheric circulation and climate regimes such as ENSO and the Pacific Decadal Oscillation have implications for coastal beach and barrier stability (see Box 6-4).

Erosion of unlithified cliffs is promoted by rising sea levels but may be constrained or enhanced by geotechnical properties and other antecedent conditions (Shaw *et al.*, 1998a; Wilcock *et al.*, 1998). Bray and Hooke (1997) review the possible effects of sea-level rise on soft-rock cliffs over a 50- to 100-year planning scale. They evaluate different methods of analyzing historical recession rates and provide simple predictive models to estimate cliff sensitivity to sea-level rise in southern England. Historical observations of cliff erosion under an accelerating sea level suggest, however, that the results of such methods must be interpreted carefully.

If El Niño-like conditions become more prevalent (Timmermann *et al.*, 1999), increases in the rate of cliff erosion may occur along the Pacific coasts of North and South America (Kaminsky *et al.*, 1998; Komar, 1998a,b). For example, El Niño events raise sea level along the California coast and are marked by the presence of larger than average, and more damaging, waves and increased precipitation. These conditions and the changed direction of wave attack combine to increase sea-cliff erosion on the central California coast, particularly on southerly or southwesterly facing cliffs. An increase in El Niño-like conditions with global warming would very likely increase sea-cliff erosion along this section of coast and endanger infrastructure and property (Storlazzi and Griggs, 2000).

6.4.3. Deltaic Coasts

In addition to increasing erosion, many of the world's low-lying coastal regions will be exposed to potential inundation. Deltas that are deteriorating as a result of sediment starvation, subsidence, and other stresses are particularly susceptible to accelerated inundation, shoreline recession, wetland deterioration, and interior land loss (Biljsma *et al.*, 1996; Day *et al.*, 1997).

River deltas are among the most valuable, heavily populated, and vulnerable coastal systems in the world. Deltas develop where rivers deposit more sediment at the shore than can be carried away by waves. Deltas are particularly at risk from climate change—partly because of natural processes and partly because of human-induced stresses. Deltaic deposits naturally dewater and compact as a result of sedimentary loading. When compaction is combined with isostatic loading or other tectonic effects, rates of subsidence can reach 20 mm yr⁻¹ (Alam, 1996). Human activities such as draining for agricultural development;

levee building to prevent flooding; and channelization, damming, and diking of rivers to impede sediment transfers have made deltas more vulnerable to sea-level rise. Examples of sediment starvation include the Rhone and Ebro deltas (Jimenez and Sanchez-Arcilla, 1997) and polder projects in the Ganges-Brahmaputra (Jelgersma, 1996). Sediment transport by the Nile, Indus, and Ebro Rivers has been reduced by 95% and in the Mississippi by half in the past 200 years, mostly since 1950 (Day *et al.*, 1997). Further stress has been caused by subsurface fluid withdrawals and draining of wetland soils. In the Bangkok area of the Chao Phraya delta, groundwater extraction during 1960–1994 increased average relative sea-level rise by 17 mm yr⁻¹ (Sabhasri and Suwarnarat, 1996). Similar severe land subsidence has been experienced in the Old Huange and Changjiang deltas of China (Chen, 1998; Chen and Stanley, 1998). In the latter case, groundwater removal was curtailed, leading to a reduction in subsidence rates.

Where local rates of subsidence and relative sea-level rise are not balanced by sediment accumulation, flooding and marine processes will dominate. Indeed, Sanchez-Arcilla and Jimenez (1997) suggest that in the case of largely regulated deltas, the main impacts of climate change will be marine-related because impacts related to catchment areas will be severely damped by river regulation and management policies. In such cases, significant land loss on the outer delta can result from wave erosion; prominent examples include the Nile (Stanley and Warne, 1998), Mackenzie (Shaw *et al.*, 1998b), and Ganges (Umitsu, 1997). In South America, large portions of the Amazon, Orinoco, and Paraná/Plata deltas will be affected if sea-level rise accelerates as projected (Canziani *et al.*, 1998). If vertical accretion rates resulting from sediment delivery and *in situ* organic matter production do not keep pace with sea-level rise, waterlogging of wetland soils will lead to death of emergent vegetation, a rapid loss of elevation because of decomposition of the belowground root mass, and, ultimately, submergence and erosion of the substrate (Cahoon and Lynch, 1997).

In some situations, saltwater intrusion into freshwater aquifers also is a potentially major problem, as demonstrated by a three-scenario climate change and sea-level rise model study of the Nile delta (Sherif and Singh, 1999). In other places, saltwater intrusion is already taking place (Mulrenna and Woodroffe, 1998). In the Yangtze delta, one consequence of saltwater incursion will be that during dry seasons shortages of freshwater for agriculture are likely to be more pronounced and agricultural yields seriously reduced particularly around Shanghai (Chen and Zong, 1999).

6.4.4. Coastal Wetlands

An estimate by Nicholls *et al.* (1999) suggests that by the 2080s, sea-level rise could cause the loss of as much as 22% of the world's coastal wetlands. Although there would be significant regional variations (Michener *et al.*, 1997), such losses would reinforce other adverse trends of wetland loss resulting primarily from direct human action—estimated by DETR (1999) to be

Box 6-4. Changes in Wave Climate, Storm Waves, and Surges

Over the long term, beaches and coastal barriers are adjusted in plan shape, profile morphology, and geographical position to factors such as sediment type and availability; wave climate, including prevailing wave energy and direction; and episodic storm waves and storm surge events. Few studies have been made of potential changes in prevailing ocean wave heights and directions as a consequence of climate change and sea-level rise, even though such changes can be expected. Similarly, changes in the magnitude of storm waves and surges with a higher sea level can be expected to reach to higher elevations on land than at present, as well as to extend further inland. Changes cannot be expected to be uniform, however, and impacts will vary locally and regionally.

The following case studies illustrate these points and highlight variations in prevailing storm wave/surge trends, differences in attribution and in the nature of past and potential coastal erosion and accretion impacts.

Changes in wind generated ocean waves in North Atlantic Ocean

Over the past 30 years, visual estimates from merchant ships and instrumental records suggest that significant wave height increases of 0.1–0.3 m have occurred over the whole of the North Atlantic except the west and central subtropics. The coastal response to this change in wave climate has not been documented.

Changes in extreme storm surges off Western Europe: The recent record

Storm surge activity in the Irish Sea and North Sea during the 1960s and 1970s reached levels unprecedented since the 1900s. These levels were followed by a sharp decline in the 1980s, taking the number of surges back to the levels of decades before the 1960s. Changes in pressure conditions could be a manifestation of shifts in storm tracks. Changes are part of natural variability on decadal time scales rather than long-term climate change resulting from anthropogenic influences.

Source: Holt (1999).

Changes in waves and storm activity off Western Europe with climate change

A high-resolution climate change experiment mimicking global warming resulted in a weak increase in storm activity and extreme wave heights in the Bay of Biscay and the North Sea; waves and storm action decreased slightly along the Norwegian coast. A weak increase in storm surges in the North Sea can be expected.

Beach rotation and the Southern Oscillation in eastern Australia

Beach profiles measured at monthly intervals along Narrabeen Beach (Sydney) from 1976 to 1999 suggest a cyclic beach oscillation, with two cycles over the 23-year period; the profiles also suggest that the beach is rotating in a cyclic pattern around a central point. These changes have been related to ENSO. When the Southern Oscillation Index (SOI) is positive, there is a greater prevalence of east to northerly waves; these waves help build out the southern beach. When the SOI is negative, southerly waves dominate the wave climate, leading to a northerly shift of sand, thus feeding beach accretion in the north while the south end of the beach is eroded. If more El Niño-like conditions prevail in the future, a net change in shoreline position can be expected.

Venice and the northern Adriatic coast: reduction in storm surges as a result of recent climate change?

Coastal flooding and damaging storm surges generated by the *bora* and other easterly winds affect the northern Adriatic Sea. Analysis of wind records from Trieste (1957–1996) show a decline in frequency of such winds. This decline may be caused in part by interdecadal variability, though their persistence suggests that it may be a consequence of recent global warming and less frequent drifts of polar cold air toward middle latitudes.

Sensitivity of storm waves in Montevideo (Uruguay) to future climate change

Outputs from a simple storm wave generation model that uses real-time wind data for the 1980s have been compared with simulations representing a 10% higher wind strength and a 1-m sea-level rise. Under this scenario, storm waves would increase in height; their angle of incidence would remain unchanged.

about 40% of 1990 values by the 2080s. Stabilization scenarios developed by DETR (1999) show a large reduction in wetland losses—to 6–7%, compared with unmitigated emissions (13%). Two main types of tidal wetland—mangrove forest and salt marsh—are considered here, although serious impacts on other coastal vegetation types, including subtidal seagrasses, can be expected (Short and Neckles, 1999).

Mangrove forests often are associated with tropical and subtropical deltas, but they also occur in low- to mid-latitude lagoon and estuary margins, fringing shorelines from Bermuda in the north to northern New Zealand in the south. Mangroves have important ecological and socioeconomic functions, particularly in relation to seafood production, as a source of wood products, as nutrient sinks, and for shoreline protection (Rönnbäck, 1999). Moreover, different kinds of mangrove provide different goods and services (Ewel *et al.*, 1998). The function and conservation status of mangroves has been considered in special issues of two journals, introduced by Field *et al.* (1998) and Saenger (1998).

Many mangrove forests are being exploited and some are being destroyed, reducing resilience to accommodate future sea-level rise. In Thailand, 50% of mangrove has been lost in the past 35 years (Aksornkoea, 1993); yet with greatly increased sediment supply to the coastal zone in some places, mangrove colonization has expanded seaward in suitable habitats (Panapitukkul *et al.*, 1998). As for other shore types, this example emphasizes the importance of sediment flux in determining mangrove response to sea-level rise. Ellison and Stoddart (1991), Ellison (1993), and Parkinson *et al.* (1994) suggest that mangrove accretion in low- and high-island settings with low sediment supply may not be able to keep up with future sea-level rise, whereas Snedaker *et al.* (1994) suggest that low-island mangroves may be able to accommodate much higher rates of sea-level rise. This ability may depend on stand composition and status (e.g., Ewel *et al.*, 1998; Farnsworth, 1998) and other factors, such as tidal range and sediment supply (Woodroffe, 1995, 1999; Miyagi *et al.*, 1999). In some protected coastal settings, inundation of low-lying coastal land may promote progressive expansion of mangroves with sea-level rise (Richmond *et al.*, 1997). In contrast, Alleng (1998) predicts the complete collapse of a mangrove wetland in Jamaica under rapid sea-level rise.

The response of tidal marshes to sea-level rise is similarly affected by organic and inorganic sediment supply and the nature of the backshore environment (Brinson *et al.*, 1995; Nuttle *et al.*, 1997). In general, tidal marsh accretion tracks sea-level rise and fluctuations in the rate of sea-level rise (e.g., van de Plassche *et al.*, 1998, 1999; Varekamp and Thomas, 1998). Marsh accretion also reflects marsh growth effects (Varekamp *et al.*, 1999). Bricker-Urso *et al.* (1989) estimate a maximum sustainable accretion rate of 16 mm yr⁻¹ in salt marshes of Rhode Island (assuming that vertical accretion rates are controlled mainly by *in situ* production of organic matter); this rate is an order of magnitude higher than rates reported by others. Orson *et al.* (1998) also emphasizes the effects of variability between marsh species types.

Temporal and spatial variability in rates of relative sea-level rise also is important. Stumpf and Haines (1998) report rates of >10 mm yr⁻¹ in the Gulf of Mexico over several years, where the long-term mean rate of relative sea-level rise is 2 mm yr⁻¹ or less. Forbes *et al.* (1997b) report multi-year fluctuations in sea-level rise at Halifax, Nova Scotia, of as much as 10 mm yr⁻¹ and occasionally higher, superimposed on a long-term mean of 3.6 mm yr⁻¹. Thus, short-term fluctuations in sea-level rise may approach the maximum limit of accretion, although the drowning of marsh surfaces is unlikely to be a major concern. Higher local rates of sea-level change have been recorded over the past 100 years or so in a few places, one of which is the Caspian Sea. Here, the response of riparian vegetation to the sea-level fall in the early part of the 20th century was a rapid seaward progression of vegetation. This progression ceased with the rise in Caspian sea level averaging 120 mm yr⁻¹ from 1978 to 1996, but it did not result in a similar rapid regression of vegetation. Instead, the vegetation consolidated its position, which has been partly explained by the wide flooding tolerance of the major emergent plant species, with floating vegetation increasing in extent with more favorable (higher water level) conditions (Baldina *et al.*, 1999).

In some areas, the current rate of marsh elevation gain is insufficient to offset relative sea-level rise. For instance, model results from a wetland elevation model designed to predict the effect of an increasing rate of sea-level rise on wetland sustainability in Venice Lagoon revealed that for a 0.48-m rise in the next 100 years, only one site could maintain its elevation relative to sea level; for a 0.15-m rise, seven sites remained stable (Day *et al.*, 1999).

Maintenance of productive marsh area also depends on horizontal controls discussed by Nuttle *et al.* (1997) and Cahoon *et al.* (1998). For example, in settings with sufficient sediment influx, the wetland may expand toward the estuary, while also expanding landward if the backshore slope is sufficiently low and not backed by fixed infrastructure (Brinson *et al.*, 1995). If sediment supply is low, however, marsh front erosion may occur (Dionne, 1986).

Although determining the threshold for such erosion is difficult, this erosion is regarded as a negative impact on many wetlands, particularly those constrained by artificial structures on the landward side. Nicholls and Branson (1998) use the term “coastal squeeze” to describe the progressive loss and inundation of coastal habitats and natural features located between coastal defenses and rising sea levels. They believe that intertidal habitats will continue to disappear progressively, with adverse consequences for coastal biological productivity, biodiversity, and amenity value. Where sediment influx is insufficient to sustain progradation, there is potential for significant loss of coastal wetlands. After considering two “what if” climate change scenarios, Mortsch (1998) found that key wetlands around the Great Lakes of Canada-USA are at risk—particularly those that are impeded from adapting to the new water-level conditions by artificial structures or geomorphic conditions.

6.4.5. Tropical Reef Coasts

Coral reefs occur in a variety of fringing, barrier, and atoll settings throughout the tropical and subtropical world. Coral reefs constitute important and productive sources of biodiversity; they harbor more than 25% of all known marine fish (Bryant *et al.*, 1998), as well as a total species diversity containing more phyla than rainforests (Sale, 1999). Reefs also represent a significant source of food for many coastal communities (Wilkinson *et al.*, 1999). Coral reefs serve important functions as atoll island foundations, coastal protection structures, and sources of beach sand; they have economic value for tourism (which is increasingly important for many national economies) and support emerging opportunities in biotechnology. Moberg and Folke (1999) have published a comprehensive list of goods and ecological services provided by coral reef ecosystems.

The total areal extent of living coral reefs has been estimated at about 255,000 km² (Spalding and Grenfell, 1997). As much as 58% (rising locally to >80% in southeast Asia) are considered at risk from human activities, such as industrial development and pollution, tourism and urbanization, agricultural runoff, sewage pollution, increased sedimentation, overfishing, coral mining, and land reclamation (Bryant *et al.*, 1998), as well as predation and disease (e.g., Antonius, 1995; Richardson *et al.*, 1998). In the past these local factors, together with episodic natural events such as storms, were regarded as the primary cause of degradation of coral reefs. Now, Brown (1997), Hoegh-Guldberg (1999), and Wilkinson (1999), for instance, invoke global factors, including global climate change, as a cause of coral reef degradation.

Previous IPCC assessments have concluded that the threat of sea-level rise to coral reefs (as opposed to reef islands) is minor (Bijlsma *et al.*, 1996; Nurse *et al.*, 1998). This conclusion is based on projected rates of global sea-level rise from Warrick *et al.* (1996) on the order of 2–9 mm yr⁻¹ over the next 100 years. Reef accretion at these rates has not been widely documented, largely because most reefs have been growing horizontally under stable or falling sea levels in recent years (Wilkinson and Buddemeier, 1994). Schlager (1999) reports an approximate upper limit of vertical reef growth during the Holocene of 10 mm yr⁻¹, suggesting that healthy reef flats are able to keep pace with projected sea-level rise. The situation is less clear for the large numbers of degraded reefs in densely populated regions of south and southeast Asia, eastern Africa, and the Caribbean (Bryant *et al.*, 1998), as well as those close to population centers in the Pacific (Zann, 1994).

Positive trends of SST have been recorded in much of the tropical ocean over the past several decades, and SST is projected to rise by 1–2°C by 2100. Many coral reefs occur at or close to temperature tolerance thresholds (Goreau, 1992; Hanaki *et al.*, 1998), and Brown (1997) has argued that steadily rising SST will create progressively more hostile conditions for many reefs. This effect, along with decreased CaCO₃ saturation state (as CO₂ levels rise), represent two of the most serious threats to reefs in the 21st century (Hoegh-Guldberg, 1999; Kleypas *et al.*, 1999).

Several authors regard an increase in coral bleaching as a likely result of global warming. However, Kushmaro *et al.* (1998) cite references that indicate it is not yet possible to determine conclusively that bleaching episodes and the consequent damage to reefs are caused by global climate change. Corals bleach (i.e., pale in color) because of physiological shock in response to abrupt changes in temperature, salinity, and turbidity. This paling represents a loss of symbiotic algae, which make essential contributions to coral nutrition and clarification. Bleaching often may be temporary, with corals regaining color once stressful environmental conditions ameliorate. Brown *et al.* (2000) indicate that some corals in the Indian Ocean, Pacific Ocean, and Caribbean Sea are known to bleach on an annual basis in response to seasonal variations in temperature and irradiance. Major bleaching events can occur when SSTs exceed seasonal maximums by >1°C (Brown *et al.*, 1996). Mortality for small excursions of temperature is variable and, in some cases, apparently depth-related (Phongsuwan, 1998); surviving coral has reduced growth and reproductive capacity. More extensive mortality accompanies temperature anomalies of 3°C or more over several months (Brown and Suharsono, 1990). Hoegh-Guldberg (1999) found that major episodes of coral bleaching over the past 20 years were associated with major El Niño events, when seasonal maximum temperatures were exceeded by at least 1°C.

Corals weakened by other stresses may be more susceptible to bleaching (Glynn, 1996; Brown, 1997), although Goreau (1992) found in Jamaica that anthropogenically stressed areas had lower bleaching frequencies. More frequent and extensive bleaching decreases live coral cover, leading to reduced species diversity (Goreau, 1992; Edinger *et al.*, 1998) and greater susceptibility to other threats (e.g., pathogens and emergent diseases as addressed by Kushmaro *et al.*, 1996, 1998; Aronson *et al.*, 2000). In the short term, this bleaching may set back reef communities to early successional stages characterized by noncalcifying benthos such as algae, soft corals, and sponges (Done, 1999). Reefs affected by coral bleaching may become dominated by physically resilient hemispherical corals because branching corals are more susceptible to elevated SST, leading to a decrease in coral and habitat diversity (Brown and Suharsono, 1990). Differential susceptibility to bleaching among coral taxa has been reported during the large-scale event in 1998 on the Great Barrier Reef (Marshall and Baird, 2000).

The 1998 bleaching event was unprecedented in severity over large areas of the world, especially the Indian Ocean. This event is interpreted by Wilkinson *et al.* (1999) as ENSO-related and could provide a valuable indicator of the potential effects of global climate change. However, the 1998 intense warming in the western Indian Ocean has been associated with shifts in the Indian dipole rather than ENSO.

Attempts to predict bleaching have met with variable success. Winter *et al.* (1998) compared a 30-year record of SST at La Parguera, Puerto Rico, with coral bleaching events at the same location but could not forecast coral bleaching frequency from the temperature record. On the other hand, analyses of

recent sea temperature anomalies, based on satellite data, have been used to predict the mass coral bleaching extent during 1997–1998 (Hoegh-Guldberg, 1999).

Recently it has been suggested that a doubling of CO₂ levels could reduce reef calcification, but this effect is very difficult to predict (Gattuso *et al.*, 1999). Kleypas *et al.* (1999) argue that such effects could be noticed by 2100 because of the decreased availability of CaCO₃ to corals. In combination with potentially more frequent bleaching episodes, reduced calcification could impede a reef's ability to grow vertically in pace with sea-level rise.

The implications for reef-bound coasts in terms of sediment supply, shore protection, and living resources may be complex, either positive or negative, and are difficult to predict at a global scale. However, there have been suggestions that fishing yields will be reduced as reef viability decreases, leading to reduced yields of protein for dependent human populations, and that the effects of reducing the productivity of reef ecosystems on birds and marine mammals are expected to be substantial (Hoegh-Guldberg, 1999).

6.4.6. High-Latitude Coasts

High-latitude coasts are highly susceptible to a combination of climate change impacts in addition to sea-level rise, particularly where developed in ice-bonded but otherwise unlithified sediments. In this context, atmospheric warming affects ground-surface temperatures and thaw, as well as SST and sea ice.

Ground temperatures determine the presence of perennially frozen ground (permafrost), which often contains large volumes of excess ice that may occur in the form of massive ice. The seasonal cycle of ground and nearshore seawater temperatures determines the depth of the seasonally active thaw layer in high-latitude beaches and the nearshore, with implications for limiting beach scour during storms (Nairn *et al.*, 1998). Deepening of the active layer (Vyalov *et al.*, 1998) also can lead to melting of near-surface massive ice and may trigger additional coastal slope failure (Dallimore *et al.*, 1996; Shaw *et al.*, 1998b).

Rapid coastal retreat already is common along ice-rich coasts of the Beaufort Sea in northwestern Canada (e.g., Dallimore *et al.*, 1996), the United States, and the Russian Arctic (e.g., Are, 1998). Where communities are located in ice-rich terrain along the shore, warmer temperatures combined with increased shoreline erosion can have a very severe impact. For example, at Tuktoyaktuk—the main community, port, and offshore supply base on the Canadian Beaufort sea coast—many structures are located over massive ice along eroding shore (Wolfe *et al.*, 1998).

Coastal recession rates along the Arctic coast also are controlled by wave energy during the short open-water season. An early study based on historical records of shoreline recession, combined with hindcast waves derived from measured wind and observed ice distributions, showed that coastal recession rates at several

sites are correlated with open-water fetch, storminess, and wave energy. Using estimates of less extensive ice distribution under a doubled-CO₂ atmosphere, Solomon *et al.* (1994) were able to demonstrate an increase in coastal erosion rates to a mean value comparable to the maximum observed rates under present climate conditions. In the Canadian Arctic Archipelago region, where many fine-grained (mud and sand) shorelines and deltas now experience almost zero wave energy (e.g., Forbes and Taylor, 1994), any increase in open water will lead to rapid reworking and potentially substantial shoreline retreat.

Sea ice may erode the seabed in the nearshore zone, but it also may supply shoreface sediments to the nearshore and beach (Reimnitz *et al.*, 1990; Héquette *et al.*, 1995). Thinner ice or later freeze-up resulting from climate warming may lead to changes in nearshore ice dynamics and associated sediment transport. Warmer temperatures and associated changes in winter sea-ice distribution at mid-latitudes are expected to have a negative impact on coastal stability. Rapidly eroding sandy coasts in the southern Gulf of St. Lawrence are partially protected in winter by development of an icefoot and nearshore ice complex. The strongest storms and most persistent onshore winds occur in winter, partially overlapping the ice season. Severe erosion in recent years has been linked to warmer winters with late freeze-up—an anticipated outcome of greenhouse warming (Forbes *et al.*, 1997b).

6.5. Socioeconomic Impacts of Climate Change

In the past decade, some progress has been made in evaluating potential socioeconomic impacts of climate change and sea-level rise on coastal and marine systems. This progress, however, has not been as substantial as that relating to biogeophysical impacts; nor has it been especially comprehensive (Turner *et al.*, 1995, 1996). To date, emphasis has been in three areas. First, research has focused on the coastal zone itself (we are not aware of any studies of the socioeconomic impact of climate change on open-ocean marine ecosystems). Second, there has been an emphasis on the potential socioeconomic impact of sea-level rise but little on any other climate change variables. Third, emphasis has been on economic effects, not on impacts on social and cultural systems. These emphases are evident in the following review, in which we consider socioeconomic impacts initially as a component of the methodology for vulnerability assessment and then through economic cost-benefit analyses of coastal zones in general and infrastructure developments in particular. In these cases, “benefits” derive from the inclusion of adaptation options—primarily shore protection—into the analyses to derive some net cost. Finally, we consider attempts that have been made to “value” natural systems, as well as the potential social and cultural impacts of climate change.

6.5.1. Socioeconomic Impacts as Part of Vulnerability Assessment

In the SAR, Bijlsma *et al.* (1996) reviewed several country case studies that had applied the IPCC Common Methodology

for assessing the vulnerability of coastal areas to sea-level rise. These case studies offered important insights into potential impacts and possible responses. Many of the assessments emphasized the severe nature of existing coastal problems such as beach erosion, inundation, and pollution, as well as the effects of climate change acting on coastal systems that already are under stress.

The Common Methodology defined *vulnerability* as a country's degree of capability to cope with the consequences of climate change and accelerated sea-level rise. The methodology of seven consecutive analytical steps allowed for identification of coastal populations and resources at risk and the costs and feasibility of possible responses to adverse impacts. The SAR also identified the strengths and weaknesses of the Common Methodology. More recently, Klein and Nicholls (1999) have evaluated the IPCC's approach and results, concluding that the Common Methodology has contributed to understanding the consequences of sea-level rise and encouraged long-term thinking about coastal zones. They went on to develop a new conceptual framework for coastal vulnerability assessment that identifies the main components of the natural system and the socioeconomic system, as well as the linkages between them and climate change and other change variables. This framework is outlined in Box 6-5.

In the SAR, data on socioeconomic impacts were derived from country and global vulnerability assessment studies. Figures for several countries were given relating to the population affected, capital value at loss, and adaptation/protection costs (Bijlsma *et al.*, 1996, Table 9-3). For the coastal zone, the authors concluded that:

- There will be negative impacts on several sectors, including tourism, freshwater quality and supply, fisheries and aquaculture, agriculture, human settlements, financial services, and human health.
- The number of people potentially affected by storm-surge flooding is expected to double (or triple) in the next century, ignoring potential adaptation and population growth.
- Protection of low-lying island states and nations with large deltaic areas is likely to be very costly.
- Adaptation to sea-level rise and climate change will involve important tradeoffs, which may include environmental, economic, social, and cultural values.

Since the SAR, there have been several summaries of the socioeconomic results of the vulnerability assessment studies, presenting data at local, regional, and global levels. Examples include case studies of Poland and Estonia (Kont *et al.*, 1997; Zeider, 1997), the Philippines (Perez *et al.*, 1999), Bangladesh (Ali, 1999), Egypt (El-Raey *et al.*, 1999), and The Gambia and Abidjan (Jallow *et al.*, 1999), as well as the regional analyses and global synthesis of Nicholls and Mimura (1998). The initial global vulnerability assessment has been revised on the basis of scenarios for global sea-level rise derived from the Hadley Centre's HadCM2 ensemble simulations and HadCM3 simulations for

GHG-only forcing (Nicholls *et al.*, 1999). This assessment indicated that by the 2080s, the potential number of people flooded by storm surge in a typical year will be more than five times higher than today (using a sea-level rise of 0.38 m from 1990 to 2080) and that between 13 million and 88 million people could be affected even if evolving protection is included. Broadly similar results are given in the study undertaken by DETR (1999). However, they note that the flood impacts of sea-level rise are reduced by emissions scenarios that lead to stabilization of CO₂. By the 2080s, the annual number of people flooded is estimated to be 34 million under the 750-ppm scenario and 19 million under the 550-ppm scenario.

Klein and Nicholls (1999) have categorized the potential socioeconomic impacts of sea-level rise as follows

- Direct loss of economic, ecological, cultural, and subsistence values through loss of land, infrastructure, and coastal habitats
- Increased flood risk of people, land, and infrastructure and the aforementioned values
- Other impacts related to changes in water management, salinity, and biological activities.

They also developed a methodology that has not yet been applied in any case studies.

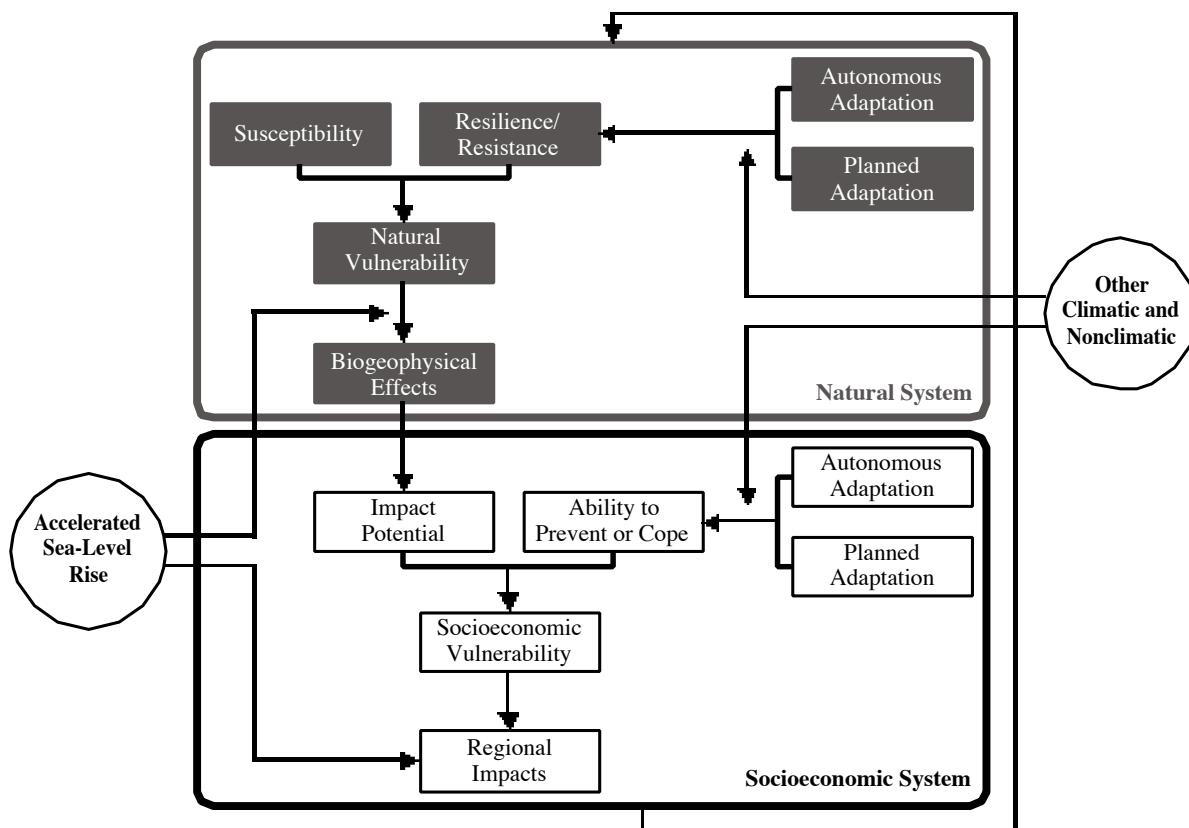

6.5.2. Economic Costs of Sea-Level Rise

In the early 1990s, several studies examined the cost of sea-level rise in the United States, based on uniform national response strategies of holding back the sea (Titus *et al.*, 1992) or not holding back the sea (Yohe, 1990). A series of nationwide studies in other countries (see Bijlsma *et al.*, 1996) followed much the same approach. Turner *et al.* (1995) attempted to assess the cost of sea-level rise in general. Yohe *et al.* (1996) analyzed the economic cost of sea-level rise for developed property in the United States. They conclude that their cumulative figure of US\$20.4 billion (1990 US\$) cumulative is much lower than earlier estimates because those estimates had not considered offsetting factors, such as the cost-reducing potential of natural, market-based, adaptation measures or the efficiency of discrete decisions to protect (or not to protect) small tracts of property on the basis of individual economic merit. In most analyses, those "offsetting factors," or adaptations, are shore protection works. The expected economic cost of protection or abandonment in the United States also has been assessed (Yohe and Schlesinger, 1998).

Saizar (1997) assesses the potential impacts of a 0.5-m sea-level rise on the coast of Montevideo, Uruguay. Given no adaptive response, the cost of such a rise is estimated to be US\$23 million, with a shoreline recession of 56 m and loss of only 6.8 ha of land. Olivo (1997) determined the potential economic impacts of a sea-level rise of 0.5 m on the coast of Venezuela. At six study sites, he identified land and infrastructure at risk—such

Box 6-5. Conceptual Framework for Coastal Vulnerability Assessment

In the scheme illustrated below, analysis of coastal vulnerability starts with a notion of the natural system's *susceptibility* to the biogeophysical effects of sea-level rise and its capacity to cope with these effects (*resilience* and *resistance*). Susceptibility reflects the coastal system's potential to be affected by sea-level rise; resilience and resistance determine the system's robustness or ability to continue functioning in the face of possible disturbance. Together, these factors determine the *natural vulnerability* of the coastal zone.

Resilience and resistance are functions of the natural system's capacity for *autonomous adaptation*, which represents the coastal system's natural adaptive response. Resilience and resistance often are affected by human activities, which need not only be negative: *Planned adaptation* can reduce natural vulnerability by enhancing the system's resilience and resistance, thereby adding to the effectiveness of autonomous adaptation.

The biogeophysical effects of sea-level rise impose a range of potential socioeconomic impacts. This *impact potential* is the socioeconomic equivalent of susceptibility; it is dependent on human influences. *Socioeconomic vulnerability* is determined by the impact potential and society's technical, institutional, economic, and cultural ability to prevent or cope with these impacts. As with the natural system's resilience and resistance, the potential for *autonomous adaptation* and *planned adaptation* determines this ability to prevent or cope.

Dynamic interaction takes place between natural and socioeconomic systems. Instead of being considered as two independent systems, they are increasingly regarded as developing in a co-evolutionary way, as shown by the feedback loop from the socioeconomic system to the natural system.

Sources: Klein and Nicholls (1999); Mimura and Harasawa (2000).

as oil infrastructure, urban areas, and tourist infrastructure—and, after evaluating four scenarios, concludes that Venezuela cannot afford the costs of sea-level rise, either in terms of land and infrastructure lost under a no-protection policy or in terms of the costs involved in any of three protection policies. In Poland, Zeider (1997) estimates the total cost of land-at-loss at US\$30 billion; the cost of full protection for the 2,200 km of coast would be US\$6 billion.

Several different methods have been used to estimate economic costs. Yohe and Neumann (1997) focus attention on the cost-benefit procedures applied by coastal planners to evaluate shoreline protection projects in relation to sea-level rise. They develop three alternative adaptive responses to the inundation threat from climate-induced sea-level rise: cost-benefit with adaptation foresight (CBWAF), cost-benefit absent adaptation (CBA), and protection guaranteed (PG). On economic grounds, CBWAF became the preferred option; CBA conforms most closely with the routine application of existing procedures. “Adaptation foresight” in Yohe and Neumann’s cost-benefit procedures assumes that erosion resulting from sea-level rise is a gradual process and that storm impacts do not change as sea level rises. West and Dowlatabadi (1999) suggest, however, that although a rise in sea level may be gradual and predictable, the effects of storms on coastal shorelines and structures are often stochastic and uncertain, in part because of sea-level rise effects.

Sea-level rise can increase the damage caused by storms because mean water level (the base level for storm effects) is higher, waves can attack higher on the shore profile, and coastal erosion often is accelerated, bringing structures nearer the shoreline and potentially removing protection offered by dunes and other protective features. The Heinz Center (2000) estimates that roughly 1,500 homes in the United States will be lost to coastal erosion each year for several decades, at a cost to property owners of US\$530 million yr⁻¹. Most of the losses over the next 60 years will be in low-lying areas that also are subject to flooding, although some damage will be along eroding bluffs or cliffs. West *et al.* (2001) estimate that the increase in storm damage because of sea-level rise increases the direct damages of sea-level rise from erosion of the shoreline by 5%, but storm damage could be as much as 20% of other sea-level rise damages. They also developed a method for evaluating the effects of investor decisions to repair storm damage on the net economic impacts of rising sea level in the United States. Neumann *et al.* (2000) have estimated that a 0.5-m sea-level rise by 2100 could cause cumulative impacts to U.S. coastal property of US\$20 billion to US\$150 billion and that more extensive damage could result if climate change increases storm frequency or intensity.

Morisugi *et al.* (1995) attempt to evaluate the household damage cost in Japan from increased storm surges and the potential benefit generated by countermeasures, using a microeconomic approach. In this approach, household utility is expressed as a function of disaster occurrence probability, income, and other variables, and the change of utility level from sea-level rise and/or countermeasures is translated into monetary terms. For

a 0.5-m sea-level rise, the damage cost without countermeasures in Japan would be about US\$3.4 billion yr⁻¹, based on the comparison of the utility level between no sea-level rise and a 0.5-m sea-level rise without countermeasures. When the utility level is calculated for the case with countermeasures, the damage cost is reduced to about –US\$1.3 billion yr⁻¹, which means that a benefit is created. Therefore, the benefit created by countermeasures for a 0.5-m sea-level rise, which is defined as the decrease of damage cost, would be about US\$4.7 billion yr⁻¹ at the national level. Because the annual expense for countermeasures is estimated to be about US\$1.9 billion yr⁻¹ (Mimura *et al.*, 1998), the countermeasures are still beneficial after expenses are considered. This and other examples given here suggest that more robust assessments of the economic impacts of sea-level rise are possible and that they can improve the quality of adaptation strategies.

6.5.3. Impacts on Coastal Infrastructure

A large portion of the human population now lives in coastal areas, and the rate of population growth in these areas is higher than average (Cohen *et al.*, 1997; Gommess *et al.*, 1998). Many large cities are located near the coast (e.g., Tokyo, Shanghai, Jakarta, Bombay, New York), and Nicholls and Mimura (1998) have argued that the future of the subsiding megacities in Asia, particularly those on deltas, is among the most challenging issues relating to sea-level rise. People in developed coastal areas rely heavily on infrastructure to obtain economic, social, and cultural benefits from the sea and to ensure their safety against natural hazards such as high waves, storm surges, and tsunamis. Their well-being is supported by systems of infrastructure that include transportation facilities, energy supply systems, disaster prevention facilities, and resorts in coastal areas. Significant impacts of climate change and sea-level rise on these facilities would have serious consequences (see Chapter 7). This analysis applies not only in highly developed nations but in many developing economies and small island states (Nunn and Mimura, 1997). The vulnerability of waste facilities, septic systems, water quality and supply, and roads is a particular concern in many places (Solomon and Forbes, 1999).

Mimura *et al.* (1998) summarize Japanese studies on the impacts on infrastructure. Several studies suggested that disaster prevention facilities such as coastal dikes, water gates, and drainage systems and coastal protection structures such as seawalls, breakwaters, and groins will become less functional because of sea-level rise and may lose their stability. A common concern relates to the bearing capacity of the soil foundation for structures. For instance, the increased water table resulting from sea-level rise decreases the bearing capacity of the soil foundation and increases the possibility of liquefaction, which results in higher instability of coastal infrastructures to earthquakes (Shaw *et al.*, 1998a). In the United Kingdom, sea defenses and shore protection works around 4,300 km of coast cost approximately US\$500 million yr⁻¹ to maintain at present—a figure that Turner *et al.* (1998) suggest will continue to rise in the future.

Port facilities are another type of infrastructure that will be affected by climate change and sea-level rise. Higher sea level probably will decrease the effectiveness of breakwaters against wave forces, and wharves may have to be raised to avoid inundation. When such effects are anticipated, countermeasures can be implemented to maintain function and stability. Therefore, the real impacts will occur as an additional expenditure to reinforce the infrastructure. The total expenditure to keep the present level of functions and stability for about 1,000 Japanese ports is estimated to be US\$110 billion for a 1-m sea-level rise (Mimura *et al.*, 1998).

6.5.4. Socioeconomic Impacts and Natural Systems

Turner *et al.* (1995) assert that relationships between the physical impacts of climate change and socioeconomic implications in the coastal zone have not been fully encompassed in recent work. This statement remains valid to date. Some attempts have been made to express the value of coastal features that are normally regarded as nonmarket goods (Costanza *et al.*, 1997; Alexander *et al.*, 1998). Several assessments of mangrove and reef ecosystems have highlighted their economic value on the basis of ecosystem goods and services, as well as natural capital value (e.g., Moberg and Folke, 1999).

Estimates of the monetary value of wetlands and information about attitudes toward wetland conservation can be used in policy decisions (e.g., Söderqvist, 2000). “Use” and “non-use” values may be determined (Stein *et al.*, 2000). For example, Rönnbäck (1999) suggests that mangrove systems alone account for US\$800–16,000 ha⁻¹ in seafood production. Streever *et al.* (1998) sought public attitudes and values for wetland conservation in New South Wales, Australia, and found that a conservative estimate of the aggregate value of these wetlands, based on willingness-to-pay criteria, was US\$30 million yr⁻¹ for the next 5 years. They also refer to an earlier study on the value of marketable fish in mangrove habitats of Moreton Bay, Queensland, estimated at more than US\$6,000 ha⁻¹ yr⁻¹ (Marton, 1990). Stein *et al.* (2000) have developed a framework for crediting and debiting wetland values that they suggest provides an ecologically effective and economically efficient means to fulfill compensatory mitigation requirements for impacts to aquatic resources.

Climate change impacts on natural systems can have profound effects on socioeconomic systems (Harvey *et al.*, 1999). One example cited by Wilkinson *et al.* (1999) is the 1998 coral bleaching event in the Indian Ocean. This event was unprecedented in severity; mortality rates reached as high as 90% in many shallow reefs, such as in the Maldives and the Seychelles. Such severe impacts are expected to have long-term socioeconomic consequences as a result of changed fish species mix and decreased fish stocks and negative effects on tourism as a result of degraded reefs. Degradation of reefs also will lead to diminished natural protection of coastal infrastructure against high waves and storm surges on low-lying atolls. Wilkinson *et al.* (1999) estimate the costs of the 1998 bleaching event to be

between US\$706 million (optimistic) and US\$8,190 million (pessimistic) over the next 20 years. The Maldives and the Seychelles are identified as particularly affected, because of their heavy reliance on tourism and fishery.

Some economic impacts of marine diseases and harmful algal blooms influenced by climate variations have been evaluated since the SAR. An outbreak in 1997 of the toxic dinoflagellate *Pfiesteria piscida*, which has been associated with increased nutrients and SSTs, caused large fish kills on the U.S. Atlantic coast that resulted in public avoidance and economic losses estimated at US\$60 million (CHGE, 1999). A persistent brown tide bloom in the Peconic Estuary system of New York blocked light and depleted oxygen in the water column, severely affecting seagrass beds and reducing the value of the Peconic Bay scallop fishery by approximately 80% (CHGE, 1999). Harmful algal blooms associated with increased SST and the influx of nutrients into an estuary can result in economic harm through shellfish closures, impacts on tourism, reduction of estuarine primary productivity, deterioration of fishery habitat (e.g., seagrass beds), and mortality of fish and shellfish.

6.5.5. Social and Cultural Impacts

In some coastal societies, the significance of cultural values is equal to or even greater than that of economic values. Thus, some methodologies have been developed that include traditional social characteristics, traditional knowledge, subsistence economy, close ties of people to customary land tenure, and the fact that these factors are intrinsic components of the coastal zone (e.g., Kay and Hay, 1993). As such, they must be taken into account in certain contexts, including many South Pacific island countries (e.g., Yamada *et al.*, 1995; Solomon and Forbes, 1999) and indigenous communities in northern high latitudes (e.g., Peters, 1999), among other examples.

Patterns of human development and social organization in a community are important determinants of the vulnerability of people and social institutions to sea-level rise and other coastal hazards. This observation does not mean that all people in a community share equal vulnerability; pre-event social factors determine how certain categories of people will be affected (Heinz Center, 1999). Poverty is directly correlated with the incidence of disease outbreaks (CHGE, 1999) and the vulnerability of coastal residents to coastal hazards (Heinz Center, 1999).

Examples of inequitable vulnerability to coastal hazards include population shifts in Pacific island nations such as Tonga and Kiribati. In Tonga, people moving from outer islands to the main island of Tongatapu were forced to settle in low-lying areas, including the old dumping site, where they were proportionally more vulnerable to flooding and disease (Fifita *et al.*, 1992). Storm-surge flooding in Bangladesh has caused very high mortality in the coastal population (e.g., at least 225,000 in November 1970 and 138,000 in April 1991), with the highest mortality among the old and weak (Burton *et al.*, 1993). Land that is subject to flooding—at least 15% of the

Bangladesh land area—is disproportionately occupied by people living a marginal existence with few options or resources for adaptation.

El-Raey *et al.* (1997, 1999) studied the effects of a 0.5-m sea-level rise on the Nile delta. In addition to economic costs from loss of agricultural land and date palms, they identify social and cultural impacts. Under a no-protection policy, El-Raey *et al.* (1997) predict that the population would suffer from the loss of residential shelter (32% of urban areas flooded) and employment (33.7% of jobs lost). In addition, a substantial number of monuments and historic sites would be lost (52%).

6.6. Adaptation

6.6.1. Evolution of Coastal Adaptation Options

In the SAR, Biljsma *et al.* (1996) identified three possible coastal response options:

- *Protect*, which aims to protect the land from the sea so that existing land uses can continue, by constructing hard structures (e.g., seawalls) as well as using soft measures (e.g., beach nourishment)
- *Accommodate*, which implies that people continue to occupy the land but make some adjustments (e.g., elevating buildings on piles, growing flood- or salt-tolerant crops)
- *Retreat*, which involves no attempt to protect the land from the sea; in an extreme case, the coastal area is abandoned.

An evaluation of such strategies was regarded as a crucial component of the vulnerability assessment Common Methodology. Klein and Nicholls (1999) argue, however, that as far as adaptation is concerned, that methodology has been less effective in assessing the wide range of technical, institutional, economic, and cultural elements in different localities. Indeed, they indicated that there has been concern that the methodology emphasizes a protection-oriented response rather than consideration of the full range of adaptation options.

Klein *et al.* (2000) develop a methodology that seeks to address some of these comments. They argue that successful coastal adaptation embraces more than just selecting one of the technical options to respond to sea-level rise; it is a more complex and iterative process, with a series of policy cycles. Four steps can be distinguished in the process of coastal adaptation:

- 1) Information collection and awareness raising
- 2) Planning and design
- 3) Implementation
- 4) Monitoring and evaluation.

In reality, however, adaptive responses often are undertaken reactively rather in a step-wise, planned, and anticipatory fashion.

The process of coastal adaptation can be conceptualized by showing that climate change and/or climate variability, together with other stresses on the coastal environment, produce actual and potential impacts. These impacts trigger efforts of mitigation, to remove the cause of the impacts, or adaptation to modify the impacts. Biljsma *et al.* (1996) noted that climate-related changes represent potential additional stresses on systems that already are under pressure. Climate change generally will exacerbate existing problems such as coastal flooding, erosion, saltwater intrusion, and degradation of ecosystems. At the same time, nonclimate stresses can be an important cause of increasing coastal vulnerability to climate change and variability. Given such interactive effects, adaptation options to be most effective should be incorporated with policies in other areas, such as disaster mitigation plans, land-use plans, and watershed resource plans. In other words, adaptation options are best addressed when they are incorporated in integrated coastal management and sustainable development plans.

Policy criteria and coastal development objectives condition the process of adaptation. Other critical influences include values, awareness, and factors such as historical legacies, institutions, and laws. There is growing recognition of the need for researchers, policymakers, residents, and other key stakeholders to work together to establish a framework for adaptation that is integrated within current coastal management processes and practices and takes a broader view of the subject. Collaborative efforts of this kind can support a process of shared learning and joint problem solving, thereby enabling better understanding, anticipation of, and response to climate change. Cash and Moser (2000) identify some of the deficiencies in integrating science and policy. They suggest the following guidelines for meeting the challenge: Use “boundary organizations” that can link researchers and decisionmakers at various scales, capitalize on particular scale-specific capabilities, and develop adaptive assessment and management strategies through long-term iterative processes of integrated assessment and management.

6.6.2. Resilience and Vulnerability

In the context of climate change and coastal management, vulnerability is now a familiar concept. On the other hand, the concept of coastal resilience is less well known but has become much more important in recent years (Box 6-5). Coastal resilience has ecological, morphological, and socioeconomic components, each of which represents another aspect of the coastal system’s adaptive capacity to external disturbances. We have identified several natural features that contribute to resilience of the shore-zone by providing ecological buffers, including coral reefs, salt marsh, and mangrove forest and morphological protection in the form of sand and gravel beaches, barriers, and coastal dunes.

Socioeconomic resilience is the capability of a society to prevent or cope with the impacts of climate change and sea-level rise, including technical, institutional, economic, and cultural ability (as indicated in Box 6-5). Enhancing this resilience is equivalent

to reducing the risk of the impacts on society. This resilience can be strengthened mainly by decreasing the probability of occurrence of hazard (managed retreat or protection); avoiding or reducing its potential effects (accommodation or protection), and facilitating recovery from the damages when impacts occur. Among these options, managed retreat has gained some prominence in the past 2 decades (see Box 6-6); Clark (1998) has argued that flood insurance is an appropriate management strategy to enhance coastal resilience in the UK.

Technological capacity is a component of social and economic resilience, although adaptation strategies may involve more than engineering measures. Technological options can be implemented efficiently only in an appropriate economic, institutional, legal, and sociocultural context. A list of technologies that could be effective for adaptation appears in Klein *et al.* (2000). Indigenous (traditional) technologies should be considered as an option to increase resilience and, to be effective, must fit in with traditional social structures (Veitayaki, 1998; Nunn *et al.*, 1999).

Enhancing coastal resilience in these ways increasingly is regarded as an appropriate way to prepare for uncertain future changes, while maintaining opportunities for coastal development (although some tradeoffs are involved, and the political discourse is challenging). In short, enhancing resilience is a potentially powerful adaptive measure.

6.6.3. Adaptation in the Coastal Zone

The purpose of adaptation is to reduce the net cost of climate change and sea-level rise, whether those costs apply to an economic sector, an ecosystem, or a country. A simple schematic of the objective of adaptation appears in Figure 6-1.
