EXECUTIVE SUMMARY

North America has experienced challenges posed by changing climates and changing patterns of regional development and will continue to do so. Varying impacts on ecosystems and human settlements will exacerbate subregional differences in climate-sensitive resource production and vulnerability to extreme events. Opportunities may arise from a warming climate, and some innovative adaptation strategies are being tested as a response to current challenges (e.g., water banks), but there are few studies on how these strategies could be implemented as regional climates continue to change. Recent experience demonstrates high capability in emergency response to extreme events, but long-term problems remain.

Climate Trends and Scenarios

North America has warmed by about 0.7°C during the past century and precipitation has increased, but both trends are heterogeneous (e.g., seasonal reductions in precipitation in some areas).

For a range of emission scenarios produced for this Third Assessment Report, model results suggest that North America could warm by 1–3°C over the next century for a low-emissions case (B1). Warming could be as much as 3.5–7.5°C for the higher emission A2 case. Published regional impact studies have used climate scenarios with global temperature changes that are similar to these new cases, but regional scenarios may not be directly comparable.

Key Regional Concerns

Water Resources

Changes in precipitation are highly uncertain. There is little agreement across climate scenarios regarding changes in total annual runoff across North America.

The modeled impact of increased temperatures on lake evaporation leads to consistent projections of reduced lake levels and outflows for the Great Lakes–St. Lawrence system under most climate change scenarios (medium confidence). The only exception is the HadCM2 transient scenario incorporating IS92a sulfate aerosol emissions, which suggests slight increases in lake levels and outflows.

Where snowmelt currently is an important part of the hydrological regime (e.g., Columbia basin), seasonal shifts in runoff are likely,

with a larger proportion of runoff occurring in winter, together with possible reductions in summer flows (high confidence).

Adaptive responses to such seasonal runoff changes could include altered management of artificial storage capacity, increased reliance on conjunctive management of ground and surface water supplies, and voluntary water transfers between various water users. It may not be possible, however, to avoid adverse impacts on many aquatic ecosystems or to fully offset the impacts of reduced summer water availability for irrigation and other out-of-stream and instream water uses.

Where lower summer flows and higher water temperatures occur, there may be reduced water quality and increased stress on aquatic ecosystems (medium confidence).

Possible changes in the frequency/intensity/duration of heavy precipitation events may require changes in land-use planning and infrastructure design to avoid increased damages arising from flooding, landslides, sewerage overflows, and releases of contaminants to natural water bodies.

Responses to recurring and emerging water quality and quantity problems will provide opportunities to develop and test adaptive management options.

Natural Resources

Forests

Climate change is expected to increase the areal extent and productivity of forests over the next 50–100 years (medium confidence). Extreme and/or long-term climate change scenarios indicate the possibility of widespread decline (low confidence).

Climate change is likely to cause changes in the nature and extent of several “disturbance factors” (e.g., fire, insect outbreaks) (medium confidence). Of particular interest in North America are changes in fire regimes, including an earlier start to the fire season, and significant increases in the area experiencing high to extreme fire danger. The long-term effects of fire will depend heavily on changes in human fire management activities, which are uncertain, especially in remote boreal forests.

There is a strong need for a long-term comprehensive system to monitor forest “health” and disturbance regimes over regional scales that can function as an early warning system for climate change effects on forests.

Protected Areas

Climate change can lead to loss of specific ecosystem types, such as high alpine areas and specific coastal (e.g., salt marshes) and inland (e.g., prairie “potholes”) wetland types (high confidence). There is moderate potential for adaptation to prevent these losses by planning conservation programs to identify and protect particularly threatened ecosystems.

Food and Fiber

Agriculture

Food production is projected to benefit from a warmer climate, but there probably will be strong regional effects, with some areas in North America suffering significant loss of comparative advantage to other regions (high confidence). There is potential for increased drought in the U.S. Great Plains/Canadian Prairies and opportunities for a limited northward shift in production areas in Canada (high confidence). Crop yield studies for the United States and Canada have indicated a wide range of impacts. Modeled yield results that include direct physiological effects of carbon dioxide (CO_2), with sufficient water and nutrients, are substantially different from those that do not account for such effects. Economic studies that include farm- and agricultural market-level adjustments (e.g., behavioral, economic, and institutional) indicate that the negative effects of climate change on agriculture probably have been overestimated by studies that do not account for these adjustments (medium confidence). However, the ability of farmers to adapt their input and output choices will depend on market and institutional signals, which may be partially influenced by climate change.

Production Forestry

Lands that are managed for timber production are likely to be less susceptible to climate change than unmanaged forests because of the potential for adaptive management. However, when the possibility of replanting with incorrect species is considered, economic impacts could become negative.

Carbon Sequestration—Adaptation Issues

Increased interest in agricultural sinks for carbon sequestration includes proposed use of reduced-tillage practices in North America. Negative consequences may include increased use of pesticides, reduced yields, and increased risk for farmers (medium confidence). Potential benefits include reduced input costs, increased soil moisture, and reduced soil erosion (high confidence).

Marine Fisheries

Climate-related variations in the marine environment—including changes in sea-surface temperatures, nutrient supply,

and circulation dynamics—play an important role in determining the productivity of several North American fisheries (high confidence).

Projected climate changes have the potential to affect coastal and marine ecosystems, with impacts on the abundance and spatial distribution of species that are important to commercial and recreational fisheries. The degree of impact is likely to vary within a wide range, depending on species and community characteristics and region-specific conditions. These impacts are complex and difficult to observe, so climate variability constitutes a significant source of uncertainty for fishery managers. Recent experiences with Pacific salmon and Atlantic cod suggests that sustainable fisheries management will require timely and accurate scientific information on environmental conditions that affect fish stocks, as well as institutional flexibility to respond quickly to such information.

Human Health

Increased frequency and severity of heat waves may lead to an increase in illness and death, particularly among young, elderly, and frail people, especially in large urban centers. The net effect of reduced severity of extreme cold is likely to have a beneficial effect. Acclimatization may be slower than the rate of ambient temperature change.

Increased frequency of convective storms could lead to more cases of thunderstorm-associated asthma. More frequent flood events and other extreme events may result in an increase in deaths, injuries, infectious diseases, and stress-related disorders, as well as other adverse health effects associated with social disruption, environmentally forced migration, and settlement in urban slums.

Vector-borne diseases, including malaria and dengue fever, may expand their ranges in the United States and may develop in Canada. Tick-borne Lyme disease also may also expand its range in Canada. However, socioeconomic factors such as public health measures will play a large role in determining the existence or extent of such infections. Diseases associated with water may increase with warming of air and water temperatures, combined with heavy runoff events from agricultural and urban surfaces.

Respiratory disorders may be exacerbated by warming-induced increases in the frequency of smog (ground-level ozone) events, acidic deposition, and particulate air pollution.

Human Settlements and Infrastructure

Potential impacts of climate change on cities include fewer periods of extreme winter cold; increased frequency of extreme heat; rising sea levels and risk of storm surge; and changes in timing, frequency, and severity of flooding associated with storms and precipitation extremes.

Communities can reduce their vulnerability to potential adverse impacts from climate change through investments in adaptive infrastructure. These adaptations can be expensive. Rural, poor, and indigenous communities may not be able to make such investments. Furthermore, infrastructure investment decisions often are based on a variety of needs beyond climate change, including population growth and aging of existing systems.

Changes in the frequency, severity, and duration of extreme events may be among the most important risks associated with climate change. The rising cost of natural disasters in North America illustrates the vulnerability of current settlement practices. Human alterations of natural systems—such as drainage basins, barrier islands, and coastal margins—fluence the impact of extreme weather hazards. Adaptations such as levees and dams often are successful in managing most variations in the weather, but they can increase vulnerability to the most extreme events.

Tourism

Shifts in temperature and precipitation patterns would lead to shifts in outdoor tourism and recreation opportunities (e.g., winter sports, fishing, parks, beaches). The extent to which ecological changes in parks will affect tourism is uncertain. Future shifts in water management, in response to development pressures as well as climate change, also could affect recreational opportunities and associated property values. Opportunities and challenges for recreational industries and destination areas need to be assessed in a systematic manner before net economic impacts can be reported with sufficient confidence.

Public and Private Insurance and Disaster Relief Systems

Inflation-corrected, weather-driven losses have been increasing in North America over the past 3 decades (high confidence). Both exposure and financial surplus of private insurers (especially property insurers) and reinsurers have been growing, and weather-related profit declines and insolvencies have been observed. Insured weather-related losses in North America (59% of the global total) are increasing with affluence and as populations continue to move into vulnerable areas. Insurer vulnerability to these changes varies considerably by region. Insurers are adversely affected by increased variability or actuarial uncertainty of weather-related events. Governments play a key role as insurers and/or providers of disaster relief, especially in cases in which risks are deemed to be uninsurable by the private sector.

Canada and the United States have different loss profiles (high confidence). In both countries, the nature of weather-related exposures and losses is diverse, ranging from property damages to business interruptions caused by electric power or communication system damage (as in the 1998 ice storm).

U.S. government insurance programs for crops and floods have not been profitable and in some cases have encouraged more human activity in at-risk areas. In the absence of similar programs in Canada, government disaster relief programs have paid roughly 86% of flood losses over the past 2 decades. There remains an important tension between the allocation of such risks between private insurers and the public sector, and the effects of climate changes (e.g., coastal erosion) would increasingly stress government programs.

Recent extreme events have led to several responses by insurers, including increased attention to building codes and disaster preparedness, limiting insurance availability or increasing prices, and establishment of new risk-spreading mechanisms. Insurers can play an important role in climate adaptation and mitigation. However, because their actuarial outlook is based on past climatic experience and forward-looking modeling studies are just now beginning to be used, the potential for surprise is real.

Adaptation Potential and Vulnerability

Case studies for various North American subregions and border regions illustrate how the changing nature of climate-society relationships is influencing the nature of vulnerability, climate-related impacts, and adaptive responses. These cases include observed extreme events and potential responses to climate change scenarios. Increased levels of development may reduce vulnerability in some cases (e.g., agriculture) and increase or change vulnerability in others (e.g., Columbia basin water management).

The nature of observed damages reflects the increasing demands that society is placing on natural resources and systems that are sensitive to extreme events, as climate change is superimposed on complex environmental problems (e.g., coastal eutrophication in the Gulf of Mexico).

Climate-related consequences for water, health, food, energy, insurance, governments, and human settlements are likely to require substantial institutional and infrastructure changes in some cases. The short period of time required to make infrastructure adjustments is likely to require new institutions to cope with rapid and sweeping change. The example of new “water markets” in the western United States illustrates an adaptive measure that also may lead to concerns about accessibility of this essential commodity for lower income people, as well as conflicts about social priorities in its allocation (e.g., farms vs. residential use).

Determining responses to scenarios is a long process that requires dialogue with stakeholders. They understand the goals, objectives, and constraints driving the development, management, and operation of resource production and maintenance systems. This interdisciplinary and intercultural dialogue has the potential for improving sharing of information and enhancing its use in decisionmaking at various scales.

15.1. The North American Region

15.1.1. Previous Work

This chapter offers an assessment for Canada, the United States, and three border regions—the Arctic, U.S.-Mexican, and U.S.-Caribbean borders. More detailed assessments for the Arctic, Mexico, and the Caribbean appear in Chapters 16, 14, and 17, respectively.

The IPCC's *Special Report on Regional Impacts of Climate Change* (IPCC, 1998) provides a review of more than 450 research publications concerned with impacts in North America, generally covering work done during 1975–1997. That review focused on six key sectors:

- Hydrology and water resources
- Nonforest terrestrial and forested ecosystems
- Food and fiber, including agriculture, production forestry, and fisheries
- Coastal systems
- Human settlements and industry
- Human health.

Our update of key regional concerns (see Section 15.2) uses similar categories, with a couple of modifications. First, we consider coastal and marine ecosystems together with terrestrial ecosystems, within the review of natural resources (Section 15.2.2). Second, human settlements are reviewed as a separate category, with extended discussion of infrastructure (Section 15.2.5). Impacts on tourism and insurance are treated separately (Sections 15.2.6 and 15.2.7, respectively). We also include a series of subregional cases that highlight adaptation challenges and opportunities (see Section 15.3).

This categorization of key regional concerns in North America reflects growing interest in higher order impacts. Recent increases in financial losses from extreme weather events (hurricanes, winter storms, floods) have raised new questions about changing frequencies of atmospheric events superimposed on changing development and investment patterns. In the United States, there were 28 such events during the 1980–1997 period with losses exceeding US\$1 billion. The most costly were the droughts and heat waves of 1988 and 1990, Hurricane Andrew in 1992, and the 1993 Mississippi River flood, with combined costs exceeding US\$100 billion. In Canada, the 1996 Saguenay flood and 1998 ice storm in Ontario and Quebec each cost more than US\$0.7 billion (CDN\$ 1 billion) (Etkin, 1998). It is important to understand the extent to which these loss trends hinge on changes in climate or changes in vulnerability that may be independent of any changes in climate.

In recent years, the North American nations have undertaken intensive region-specific assessments of impacts and vulnerability (Canada Country Study, U.S. National Assessment, regional case studies). Although some of these assessments are still in progress at this writing, several themes have emerged. The involvement of stakeholders (commercial entities, local and

regional governments, natural resource managers, and citizens) has brought new perspectives and refocused the definition of research questions. In nearly all regions, stakeholders perceive changes in variability to be far more threatening than decadal-scale gradual change. Many stakeholders see limited problems in adaptation and possible benefits to slow predictable change. However, there may be appreciable changes in ecosystem distributions and water resources, with significant economic impacts, leading to requirements for substantial changes in infrastructure (e.g., in coastal and permafrost regions, major urban centers). There clearly will be winners and losers.

Overall, available information suggests that if projected levels of climate changes occur, North America will become quite a different place.

15.1.2. What is Different about the North American Region?

North America includes economies and resources that might be comparable to those in developed countries and the more developed of the developing countries. Areas within highly urbanized and industrial zones or intensively managed agriculture, forests, and nonrenewable resource extraction all represent large-scale, highly managed resources and human-dominated ecosystems. Within this context, however, there continues to be a great deal of “extensive” land management. Many Canadian and U.S. forests are managed in relatively large tracts compared to other regions and are rather lightly managed aside from harvest schedules. Some are more intensively managed, including post-harvest site preparation for reforestation.

Table 15-1 shows a range of development indicators for Canada and the United States and compares these indicators to Mexico and the rest of the world. Higher levels of resource consumption, urbanization, life expectancy, and gross domestic product (GDP) are obvious, as are the higher rates of CO₂ emissions. At the same time, the two countries also are unusual in preserving extensive rangelands and other landscapes, so a unique feature is the juxtaposition of intensive management with “extensive” management of huge and sparsely populated areas. Some of these areas remain very much a part of the national economy, but other areas are used for subsistence. Areas that are undeveloped or are under aboriginal land claims that support traditional subsistence lifestyles include features that are found in developing country rural economies. These include low levels of built infrastructure, informal barter systems, close ties to the land, and strong historical and cultural attachments to subsistence-based communities, even in the face of opportunities in the modern wage economy.

In wage and nonwage circumstances, climate change scenarios become scenarios of changing opportunities and risks. Given the multi-objective and multi-stakeholder aspects of North American regions, a climate-related change in potential (e.g., longer growing season, higher fire risk, altered hydrological cycle) may not lead to an immediate, linear response by stakeholders (see Section 15.3). An important factor that must be considered

Table 15-1: Human development in North America.^a

Attribute	Canada	USA	Mexico	Rest of World
1995 land area (ha per capita)	31.4	3.4	2.2	2.1
1995 protected areas (ha per capita)	3	0.6	0.1	0.2
1998 internal renewable water (m ³ per capita yr ⁻¹)	94,373	8,983	4,508	6,332

is the extent to which individual rights are valued relative to community interests in the management of landscapes. Changing vulnerabilities may occur as a result of coupling of management to current climatic variability (e.g., watersheds developed for hydroelectric production and flood control must continue to adjust to seasonal and yearly variations in natural streamflow, as well as changing management objectives).

15.1.2.1. High Level of Intensive Water Management

The water resources of North America have been heavily modified and intensively managed to serve a variety of human purposes. Investments in water control and delivery infrastructure range from small, privately constructed impoundments, diversion works, and levees to major multi-purpose projects constructed by federal, state, or provincial governments. The usable human-made reservoir capacity in North America is equal to

approximately 22% of average annual runoff, compared to a worldwide average of 10% (Dynesius and Nilsson, 1994). Development has been most intensive in the United States, where there are approximately 75,000 structures classified as dams, with a combined storage capacity approximating 70% of mean annual runoff, or about 1,300 km³ (1 billion acre-feet) (Graf, 1999). Current water-management infrastructure has allowed the citizens of North America to make productive use of water and to reduce the adverse impacts of extreme high and low flows—but often at the cost of radically altering the natural functioning of aquatic ecosystems. The design of reservoirs and control structures and current operational protocols are based on the past hydrological record. Stationarity in the statistical characteristics of streamflow typically is assumed to apply for the future operational life of the facility. A change in mean flow or in variability could cause the physical infrastructure to be inadequate for the intended purposes or increase the risk of failure of the water resource system under extremes of

drought or flood. In large water systems, such risks are buffered by robustness and resilience in the design of the system (Matalas, 1998); smaller systems may be more vulnerable under climate scenarios beyond those considered in their design.

In addition, North Americans have created laws and institutions that govern allocation of water among competing uses and define the rights and obligations of individuals, government entities, and other organizations with respect to particular water resources. These institutional aspects vary by region and have changed over time, reflecting differences in climatic and historical circumstances and changing societal values. In the western United States and western Canadian provinces, the economic importance of out-of-stream water uses drove the historical development of the prior appropriation system of water law, whereas U.S. states and Canadian provinces east of the 100th meridian generally adhere to riparian or riparian-based permit systems of water law (Chandler, 1913; Hutchins, 1971; Bates *et al.*, 1993; Scott and Coustalin, 1995). Recently, concerns about endangered species, water quality, and other public trust values have led to changes in permitted uses of some water rights in the United States, and environmental legislation is now a powerful force in determining the location, design, and feasibility of new water projects (California Supreme Court, 1983; Wilkinson, 1989; Butler, 1990; Miller *et al.*, 1996). A new development in the United States is that some dams are being removed or considered for removal to alleviate impairment of the aquatic ecosystem and to restore fisheries (WWPRAC, 1998).

Because North America's water management institutions and infrastructure evolved partly as adaptations to current climate variability, we expect these investments to be useful in fostering adaptability to some of the effects of long-term climate change. However, to the extent that water management facilities have impaired the health and diversity of aquatic ecosystems, they may exacerbate the adverse environmental consequences of global climate change by reducing the resilience of natural systems to further climatic stress.

15.1.2.2. Urbanization

Within developed regions of North America, one important feature is the high-value concentrated development center or corridor. Proliferation of these centers and corridors (e.g., U.S. Gulf coast, Boston-New York-Washington corridor) can lead to high damage costs from extreme events associated with weather phenomena (see Sections 15.2.5 and 15.2.7).

A second feature concerns extension of urban land use into previously undeveloped or less-developed areas, including agricultural lands, forested areas, wetlands, barrier islands, and other coastal margins. In the case of urban encroachment on forested areas, climate change effects on human use and value of forest ecosystems are likely to be significant but are very poorly understood (Binkley and Van Kooten, 1994). This is a challenge in considering traditional human uses of forests for wood products, recreational space, or environmental protection. A more recent phenomenon that must be considered, however, is the increase in human populations in many forested areas in the mid-latitude regions of North America. For example, in the Colorado Rocky Mountains in the United States, human population is expected to double in the next 20–40 years (Stohlgren, 1999). These population increases will amplify climate-induced stresses on forest habitat and species assemblages. Moreover, these increases will increase the exposure of human populations to climate-induced catastrophic events (e.g., fire, floods).

15.1.2.3. Continental Free Trade

The North American Free Trade Agreement (NAFTA) between Canada, the United States, and Mexico has contributed to several changes in economic activity. One indicator is the recent increase in the population of Mexican states along the U.S.–Mexican border (see Table 15-2), which is at a faster rate than for Mexico as a whole. Such shifts may alter the relationship

Table 15-2: Population of Mexican states along the U.S.–Mexican border (data from Instituto Nacional de Estadística Geografía e Informática, Mexico, <<http://www.inegi.gob.mx/poblacion/ingles/fipoblacion.html>>).

Population	1990	1992	1997	% change
Baja California	1,660,855	1,908,434	2,241,029	+35
Sonora	1,823,606	1,866,757	2,183,108	+20
Chihuahua	2,441,873	2,503,515	2,895,672	+19
Coahuila	1,972,340	2,040,046	2,227,305	+13
Nuevo Leon	3,098,736	3,336,044	3,684,175	+19
Tamaulipas	2,249,581	2,351,663	2,628,839	+17
Total population in Mexico	81,249,645	85,627,971	93,716,332	+15

between regions and their climate, affecting the nature of future climate-related impacts and adaptation responses (e.g., see Section 15.3.2.9).

15.1.3. Past to Present

Society has long viewed climate as “constant”—that is, we expect year-to-year variations, but we expect that the chances of hurricanes, floods, or heat waves don’t change with time. The probability of a 100-year event (defined by crossing some threshold—say, 5 cm of rain in an hour) should be a constant. As we have developed longer records of climate—from geologic records in ice cores and sediments to longer and longer instrumental records—we have learned that this assumption of constancy simply is not true. As we look back and see constant change, we should look to the future and expect additional changes to climate and to climate variability.

There have been significant changes (i.e., trends) in North America’s climate over the past century. As a whole, North America has warmed by about 0.7°C (Carter *et al.*, 2000), although this warming has been quite heterogeneous. For example, the southeastern United States cooled slightly over that same period, although recent decades have seen some warming. There also have been trends in precipitation. Annual precipitation over North America decreased by about 50 mm in the early years of the century and since then has steadily increased by ~70 mm. These trends, like those of temperature, have been fairly heterogeneous. The largest increases have been in the northern Atlantic and Pacific coastal regions. Some regions have experienced seasonal decreases in precipitation. Accompanying these trends in temperature and precipitation, which are fairly well measured, have been changes in cloud cover and humidity, which affect plant growth as well as people’s perception of temperature. Inferences from atmospheric CO₂ and satellite data suggest that the northern growing season (the period of active plant growth) has lengthened appreciably over the past decades (Myneni *et al.*, 1997), and data from Alaska show an unequivocal warming trend in the western Arctic (Bering Sea Impacts Study, 1999).

Over the course of the 20th century, there have been several extreme periods in the climate. The drought of the 1930s changed all of North American society. The damage to midcontinental agriculture and communities has consequences even today, through changes in land ownership, government policies, and farmer and merchant perceptions of risk. More recently, there have been major consequences of drought, flooding, tropical storms, and tornadoes. There is no clear evidence of trends in the meteorological risks from “heaviest rainfall category” events or that their frequency has changed over the period of instrumental measurements. However, evidence from the paleorecord documents changes over the past thousands of years that lie outside what our contemporary society can remember. For example, there have been several droughts in California, documented in tree-ring and lake-level data, of more than 80 years’ duration (Meko *et al.*, 1991). Evidence from the Rocky

Mountain and Great Plains regions suggests that there have been long periods in the Holocene (the time since the last glaciation) when these regions were much drier than today (Woodhouse and Overpeck, 1998). These historical events did not happen as a result of anthropogenic impacts but are within the range of natural climate variability; they provide a caution against assuming that tomorrow’s climates will necessarily be no less benign than today’s.

15.1.4. Scenarios for the Future

At the large scale, and for a range of emission scenarios produced for the IPCC’s Third Assessment Report (see Section 3.8), climate model results suggest that North America could warm at a rate of 1–3°C over the next century for a low-emissions case (B1). Warming could be as rapid as 3.5–7.5°C for the higher emission A2 case. Even the B1 case suggests substantially more warming over the next century than we have observed over the past 100 years. In addition, we know that the past century saw changes in temperature, precipitation, and other variables. Climate model predictions of precipitation remain highly uncertain. Many models suggest higher rainfall over North America accompanying warming in simulations of the IS92a emission scenario (Schimel *et al.*, 1996). While some models suggest widespread and substantial increases in rainfall over most of North America, other models suggest a weaker increase in rainfall.

Understanding concurrent changes in regional temperature and precipitation is crucial. Warming with increasing precipitation is likely to increase plant growth, which may increase carbon storage (VEMAP Members, 1995) and may increase pest and pathogen invasion and expansion. Warming with a lesser increase or a decrease in precipitation could cause direct vegetation mortality and increase the risk of wildfire. Variability also plays a role. General increases in temperature and precipitation might increase plant growth, but occasional severe droughts would then maximize the chances of wildfire. Preliminary results from modeling of the United States suggest that projected changes in climate will cause very substantial changes to the distribution and productivity of ecosystems and to disturbance regimes (fire and drought probabilities). Subtropical conditions will extend further north into the United States, with accompanying changes to vegetation, hydrology, and the potential for disease. Changes at the Arctic border suggest changes to the forest-tundra transition region, losses of permafrost, and an altered growing season.

Concern about the spatial uncertainty of model-based climate scenarios has led to various attempts at downscaling global scenarios to regional scales. This can influence the results of impact studies, as illustrated by a recent case study of crop yields in the U.S. Great Plains (Mearns *et al.*, 1999). Furthermore, published regional impact studies have used older global climate scenarios similar to the temperatures resulting from the new emissions cases, but these may not be directly comparable.

15.2. Key Regional Characteristics

15.2.1. Water Resources

Available evidence suggests that global warming may lead to substantial changes in mean annual streamflows, seasonal distributions of flows, and the probabilities of extreme high- or low-flow conditions (Leavesley, 1994; Cubasch *et al.*, 1995; Mearns *et al.*, 1995; Trenberth and Shea, 1997). Runoff characteristics may change appreciably over the next several decades, but in the near term, the hydrological effects of global warming are likely to be masked by ongoing year-to-year climatic variability (Rogers, 1994; Miller, 1997; Matalas, 1998). There is some evidence that the intensity of rainfall events may increase under global warming, as a result of increases in the precipitable water content of the atmosphere (IPCC, 1996; Trenberth and Shea, 1997). This may increase flooding risks in some watersheds. Hydrological changes cannot yet be forecast reliably at the watershed scale, although numerous studies have addressed the potential effects of warming scenarios on water availability in North America (e.g., Mortsch and Quinn, 1996; Melack *et al.*, 1997; Moore *et al.*, 1997; Mulholland *et al.*, 1997; Woodhouse and Overpeck, 1998; Wilby *et al.*, 1999; Wolock and McCabe, 2000). Figure 15-1 summarizes some possible regional hydrological and ecological impacts of climate change identified in recent analyses.

In general, there is greater confidence in projections of seasonal shifts in runoff and related hydrological characteristics than there is in projections of changes in annual runoff. Regional patterns of precipitation change are highly uncertain. Runoff changes also will depend on changes in temperatures and other climatic variables. Warmer temperatures may cause runoff to decline even where precipitation increases (e.g., Nash and Gleick, 1993). Changes in vegetation characteristics will have further, complex impacts on streamflows (Callaway and Currie, 1985; Rosenberg *et al.*, 1990; Riley *et al.*, 1996). Wolock and McCabe (2000) computed annual runoff projections for the 18 major water-resource regions of the continental United States for two GCM scenarios used in the U.S. National Assessment. They found very little agreement between the models—the Canadian Centre for Climate Prediction and Analysis (CCC) model and the Hadley Centre for Climate Prediction and Research (HAD) model—regarding the direction of change in average annual runoff. In addition, most of the projected changes for the next century fell within the range of current variability.

Projections of shorter snow accumulation periods appear to be more robust. Many studies of snowmelt-dominated systems show similar seasonal shifts to greater winter runoff and reduced summer flow (e.g., Cooley, 1990; Lettenmaier and Gan, 1990; Rango and Van Katwijk, 1990; Duell, 1992, 1994; Lettenmaier *et al.*, 1992, 1996; Rango, 1995; Melack *et al.*, 1997; Fyfe and Flato, 1999; Wilby *et al.*, 1999). In mountainous areas of western North America, small high-elevation catchments may contribute the bulk of the flow of major river systems (Schaake, 1990; Redmond, 1998). Although some models predict

decreases in snowpack, records from at least one long-term alpine site in the Rocky Mountains show an increase in annual precipitation since 1951 (Williams *et al.*, 1996). Earlier melt-off in combination with either lower or higher snowpack will tend to increase winter or spring flows and reduce summer flows. Warmer temperatures could increase the number of rain-on-snow events in some river basins, increasing the risk of winter and spring floods (Lettenmaier and Gan, 1990; Hughes *et al.*, 1993; Loukas and Quick, 1996). Lower summer flows, warmer summer water temperatures, and increased winter flows are results on which many of the regional ecological impacts identified in Figure 15-1 are based.

Studies based on climate change scenarios from older versions of GCMs that did not include aerosol effects suggest reductions in streamflow and lake levels in many Canadian watersheds, despite scenario increases in annual precipitation (Hofmann *et al.*, 1998). Bruce *et al.* (2000) examined a variety of newer evidence, including temperature and precipitation changes projected by transient runs of seven different atmosphere-ocean GCMs (AOGCMs) with business-as-usual greenhouse gas (GHG) and aerosol increases. They conclude that many areas of Canada, including southwestern Canada and the Great Lakes region, could experience "...reduced total flow, lower minimum flows and lower average annual peak flow" (Bruce *et al.*, 2000).

Open-water evaporation is an important part of the water balance of the North American Great Lakes. Increased evaporation as a result of warmer water temperatures therefore would likely affect future lake levels and outflow into the St. Lawrence River (Mortsch and Quinn, 1996; Mortsch *et al.*, 2000). Most analyses for the Great Lakes suggest declines in lake levels and outflows (Mortsch and Quinn, 1996; Chao, 1999). Chao (1999), for example, examined 10 different transient GCM scenarios (without aerosols) for IPCC decades 2 and 3 and concludes, "In general the decrease in inflows under all the GCM scenarios result in negative impacts to hydropower, navigation and coldwater habitat, and positive ones to shoreline damages." Mortsch *et al.* (2000) compared such early results to results based on transient runs of the CCC model and the HadCM2 model, both of which include aerosol impacts. Whereas the CCC model run suggests declines in lake levels and outflows comparable to the earlier doubled-CO₂ runs (e.g., a 1.01-m decline in the level of Lakes Michigan and Huron by 2050), the HadCM2 model indicates the possibility of a small rise in lake levels and outflows (0.03-m rise in Lakes Michigan and Huron by 2050). Caution is required in interpreting these results because there is substantial uncertainty regarding future sulfate emissions, and projections of aerosol concentrations have declined considerably since these runs were performed (Carter *et al.*, 2000).

Arid environments are characterized by highly nonlinear relationships between precipitation and runoff. Thus, streamflows in the arid and semi-arid western portions of North America will be particularly sensitive to any changes in temperature and precipitation (Schaake, 1990; Arnell *et al.*, 1996; Kaczmarek *et*

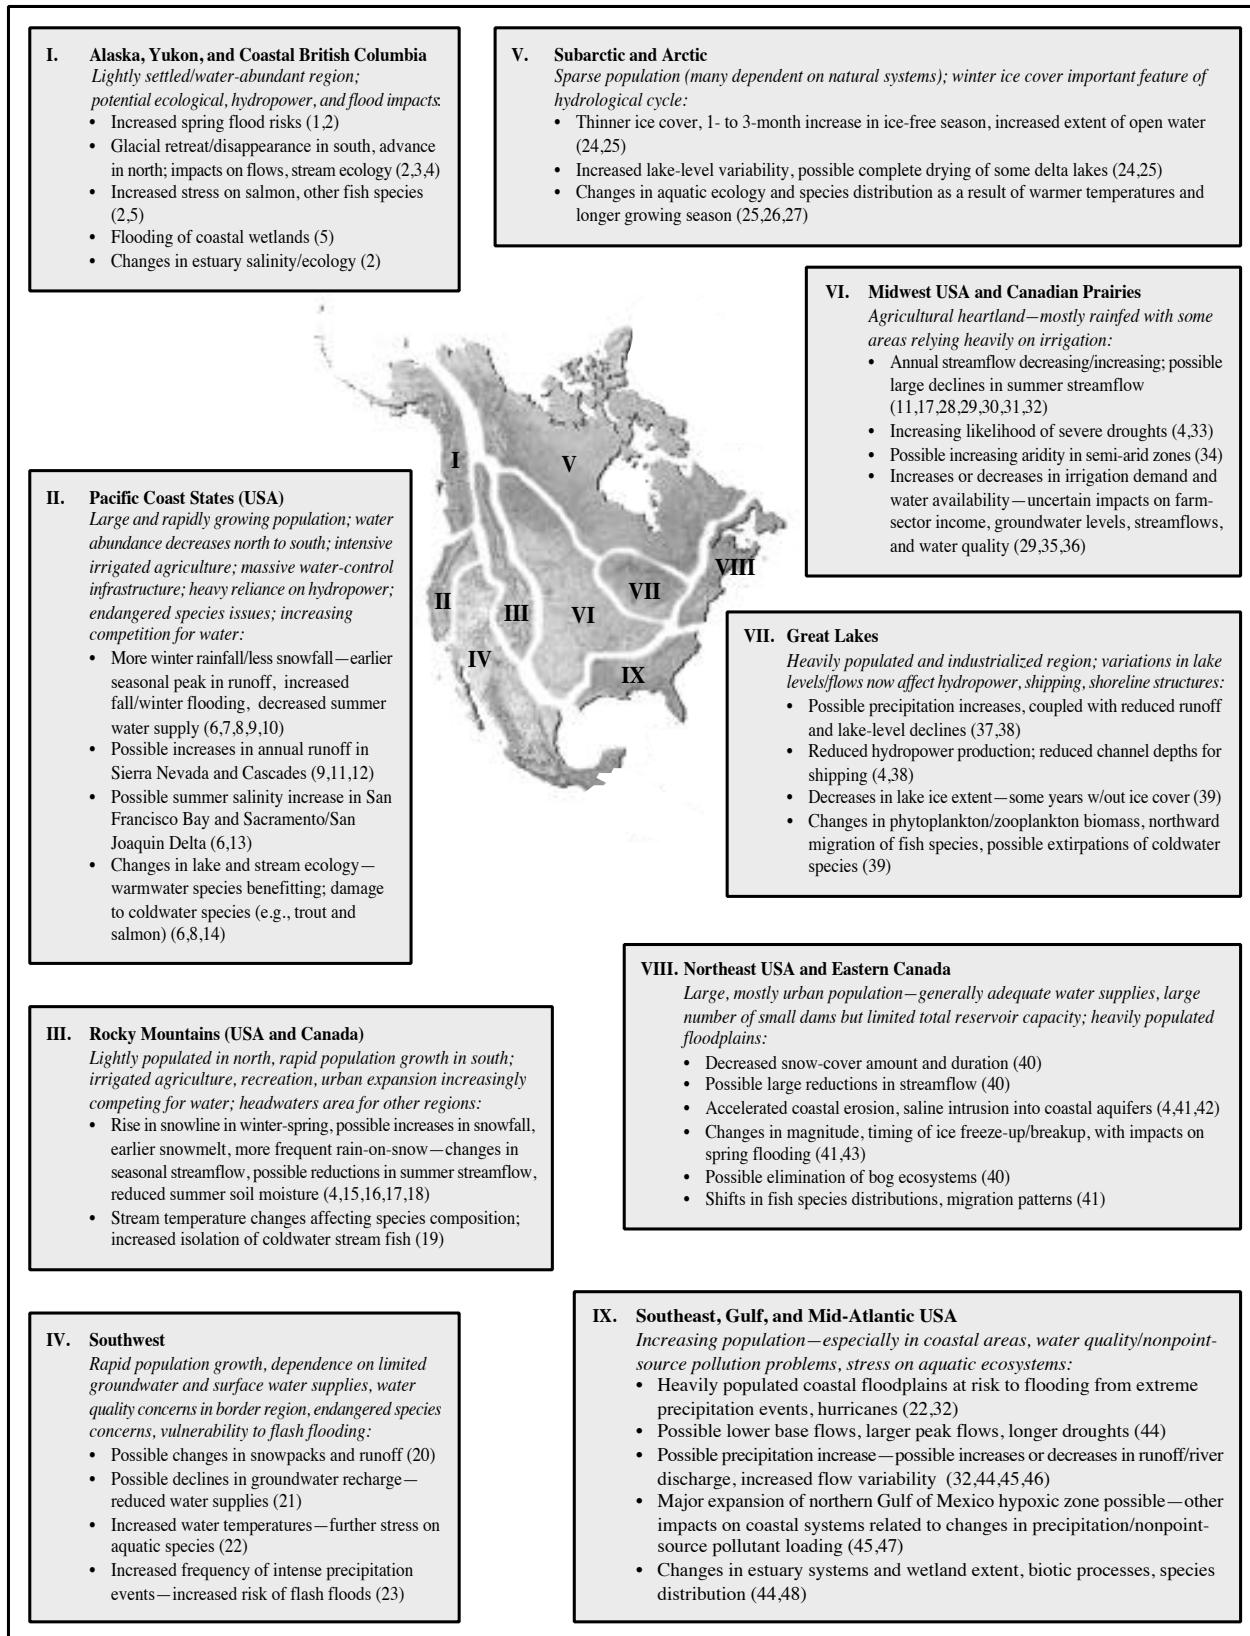

Figure 15-1: Potential water resources impacts.

al., 1996). Rivers that originate in mountainous regions will be particularly sensitive to winter precipitation in the headwaters, regardless of conditions in the downstream semi-arid zone (e.g., Cohen, 1991). In addition, "...severe flood events may be more damaging in drier climates where soils are more erodible..." (Arnell *et al.*, 1996).

Little research attention has been given to the possible impacts of climate change on sediment transport and deposition, which could affect aquatic ecosystems, reservoir storage capacity, potential flood damages, and the need for dredging operations. However, projected increases in the intensity of precipitation events could contribute to increased erosion and sedimentation in some areas (Mount, 1995).

15.2.1.1. Impacts and Adaptation Options

The impacts of hydrological changes and options for effective adaptation will depend on the nature of the hydrological changes, the amount of buffering provided by natural and artificial storage capacity, the nature of demands on the resource, and the effectiveness with which institutions in place balance competing demands. Continued increases in demand are likely for the multiple services provided by North American water resources, encompassing out-of-stream and instream uses. Adaptations to the effects of climate change therefore will occur in conjunction with adjustments to changes in the level and characteristics of water demands.

A major comparative study of six U.S. water resource systems found that although climate change could have significant and often adverse impacts on system performance, adjustments to reservoir operations could be made, allowing those impacts to be smaller than the underlying hydrological changes (Lettenmaier *et al.*, 1999). The authors also found that "The effects of anticipated demand growth and other plausible future operational considerations...would about equal or exceed the effects of climate change over system planning horizons" (Lettenmaier, *et al.*, 1999).

The importance of future changes in demand is echoed by Frederick and Schwarz (1999). They found that even in the absence of climate change, the annual cost of supplying water to meet projected increases in U.S. water demands would be about US\$13.8 billion higher in 2030 than in 1995, based on the current trend of increasingly using conservation to balance growing demands with supplies. This trend has been driven by

"...the high costs of developing new supplies, environmental concerns, a growing appreciation for the values of instream flows and efforts to improve water quality" (Frederick and Schwarz, 1999). Using projected runoff changes calculated by Wolock and McCabe (2000) for 18 water resource regions, the study found that runoff increases projected by the HadCM2 model tended to reduce the cost of balancing future water supplies and demands, whereas the reduced flows projected by the CCC model resulted in large cost increases. With the CCC model projections, the study found that under an "efficient management" scenario, annual water costs could increase "...by nearly US\$105 billion, about US\$308 per person. Much higher cost increases would result from policies to maintain relatively high streamflow levels under such dry conditions" (Frederick and Schwarz, 1999).

This finding—that institutions can have significant impacts on the costs arising from reduced water availability—is supported by a study that assessed the possible consequences of a severe sustained drought on the Colorado River system (Lord *et al.*, 1995). The study authors found that the "Law of the River," as currently interpreted and implemented, would leave sensitive biological resources, hydropower generation, recreational values, and Upper Colorado basin water users vulnerable to damages despite extraordinary engineering attempts to drought-proof the river. The study also found that certain proposed institutional and system operating changes could considerably alter the level and incidence of the damages (Booker, 1995; Kenney, 1995; Lord *et al.*, 1995; Sangoyomi and Harding, 1995). For example, reallocation from low- to high-valued uses (e.g., through intrastate or interstate water marketing) and changes in reservoir storage policies to hold water in the Upper Colorado basin to reduce evaporative losses could reduce consumptive use damages by more than 90% (Booker, 1995).

Such "what if" analyses can foster creative thinking about adaptation options. Future adaptation strategies also are likely to build on current creative solutions to meeting water supply challenges. For example, when increases in agricultural and sewerage runoff in the Catskill/Delaware watershed region threatened the quality of New York City's water supplies, the city was faced with a choice of either building an artificial filtration plant or taking action to protect and restore the natural purification capacity of the watershed's ecosystem. The capital cost of the filtration plant would have been US\$6–8 billion, plus annual operating costs of US\$300 million. The city found that for a fraction of that cost it could enter into agreements with landowners in the watershed to adopt land-use practices

Eheart *et al.*, 1999; 36. Hurd *et al.*, 1998; 37. Mortsch and Quinn, 1996; 38. Chao, 1999; 39. Magnuson *et al.*, 1997; 40. Moore *et al.*, 1997; 41. Abraham *et al.*, 1997; 42. Frederick and Gleick, 1999; 43. Hare *et al.*, 1997; 44. Mulholland *et al.*, 1997; 45. Justic *et al.*, 1996; 46. Arnell, 1999; 47. Cruise *et al.*, 1999; 48. Porter *et al.*, 1996.

that would adequately protect water quality, making the filtration plant unnecessary (PCAST, 1998; Platt *et al.*, 2000).

Adjustments to the effects of climate change as well as to evolving demands for out-of-stream and instream water uses may entail impacts on the distribution of water-use benefits. The question of who will bear the costs of any reduction in water availability depends on the nature and ownership of existing water rights, how those rights are measured, and how they may be modified by other policies. In the United States, federal legislation—including the Endangered Species Act and the Clean Water Act—has regulated or constrained development of many new water projects and could be applied to modify existing water diversions (WWPRAC, 1998). Native American (aboriginal) communities often possess reserved water rights that, despite their high priority, have never been developed or clearly quantified. Substantial litigation and negotiation efforts have focused on clarifying these rights. Any significant change in water availability may heighten tensions between these communities and neighboring water users (Echohawk and Chambers, 1991). Under riparian water law and permit systems, governmental authorities may have substantial discretion in regulating water uses under drought conditions (Abrams, 1990; Flood, 1990; Sherk, 1990; Dellapenna, 1991; Scott and Coustalin, 1995). Under the prior appropriation system of water law, which is followed in western Canada and most states in the western portion of the United States, the risk of a shortfall generally is inversely proportional to the seniority of the right. Many junior rightholders, however, have access to water stored in reservoirs, which improves their security of supply.

Several studies have argued that improving the functioning of water markets could help to create the kind of flexibility needed to respond to uncertain changes in future water availability (e.g., Trelease, 1977; Tarlock, 1991; OTA, 1993; Miller *et al.*, 1997). If water supplies decline in particular locations or seasons, water markets could soften the impacts by moving water from lower to higher valued uses. In the western United States, where irrigation now accounts for more than 80% of consumptive water use, water market activity is likely to continue the current trend of movement of water out of irrigated agriculture to accommodate other water uses (WWPRAC, 1998). However, water markets are not likely to adequately protect instream flows and sensitive biological resources unless public agencies are given budgets to buy or rent water to protect those values (Wilkinson, 1989; NRC, 1992). In addition, water rights have to be clearly defined for water markets to function properly. Even in the western United States, where water markets have developed rapidly in recent years (Saliba and Bush, 1987; NRC, 1992; Colby, 1996; Yoskowitz, 1999), market development has been hampered by the fact that water rights often are not well documented (e.g., Costello and Kole, 1985; Gould, 1988; Colby, 1998). To avoid adverse impacts on other water users, water authorities typically review each transfer proposal. The entire process often entails substantial transaction costs, and these costs differ significantly across jurisdictions (Saliba and Bush, 1987; MacDonnell, 1990; NRC, 1992). This suggests that administrative practices and other institutional factors

affect the efficiency of the water transfer process and that administrative reforms to reduce transaction costs could improve adaptability to the effects of climate change.

Finally, permanent water transfers are not particularly effective in promoting flexible adaptation to climatic variability or uncertain climate changes. Small, temporary transfers through water banks such as California's Emergency Drought Water Banks would provide greater flexibility (see Section 15.3.2.3).

Although well-functioning water markets may ameliorate the socioeconomic impacts of reduced water availability, they cannot completely eliminate the adverse impacts of a drying scenario. Using models that assume optimal allocation of water across all sectors (which implicitly assumes perfect, cost-free water markets), Hurd *et al.* (1998) estimated the water resources-related costs of climate change scenarios for four major river basins in the United States. They found that losses from moderate and severe drying scenarios tended to be greater in the semi-arid western United States than in the eastern states. From this analysis, they project that national water-related welfare losses arising from a temperature increase of 2.5°C coupled with a 7% increase in precipitation would be on the order of US\$9.5 billion. A scenario with a temperature increase of 5°C coupled with no change in precipitation would result in losses of US\$43 billion. Overall, they found that the economic costs probably would be dominated by impacts on water quality and instream nonconsumptive water uses, especially hydroelectricity generation. This result hinges on their assumption that irrigators—who currently dominate ownership of water in the western United States—would benefit by selling some of their water to other sectors. More realistic assumptions regarding the costs of transferring water through water markets would have produced larger estimated losses and a different distribution of losses across sectors.

Water rights are not always defined in terms that would permit the transfer of a specific amount of water from one use to another, particularly in eastern U.S. and Canadian jurisdictions that still follow a traditional riparian system of water law (Tarlock, 1989; Flood, 1990; Scott and Coustalin, 1995). In such areas, accommodation of competing demands and changing supplies will require local and regional planning and coordination. For example, if the levels and outflows of the Great Lakes-St. Lawrence system decline, as most available scenarios suggest, adaptation options are likely to raise sensitive interjurisdictional allocation issues and may require infrastructure investments that will increase the need for cooperative planning and management of the basin's water resources (Bruce *et al.*, 2000).

15.2.1.2. Water Quality

Water quality changes may be driven by changes in hydrological flowpaths in a watershed that are associated with changes in patterns of precipitation and evapotranspiration and changes in total flow in streams and rivers or in water level or duration of ice cover in temperate lakes. In regions such as the Precambrian

shield, where watersheds are predicted to become drier in spring and summer, concentrations of dissolved organic material reaching lakes and streams from their catchments will decrease, increasing water clarity and changing physical and thermal regimes by increasing average thermocline depths in small, stratified lakes, for example (Snucins and Gunn, 1995; Schindler *et al.*, 1996; Perez-Fuentetaja *et al.*, 1999). In contrast, in the Great Lakes and other large lakes where dissolved organic carbon (DOC) concentrations are low, thermocline depths are determined by area or wind fetch and are not affected by DOC (Fee *et al.*, 1996). Models for the Great Lakes indicate that rapid spring warming may cause shallower and steeper thermoclines (reviewed by Magnuson *et al.*, 1997). For lakes and streams receiving flow from deep and shallow groundwater sources, drier watersheds could cause the major ion chemistry to be dominated more by the deep baseflow water sources (Webster *et al.*, 1996).

In several regions where warmer temperatures and longer growing seasons are expected, changes in water quality will be driven by increases in primary production, organic matter decomposition, and nutrient cycling within lake or stream ecosystems (e.g., Mulholland *et al.*, 1997). In the Great Lakes region, warming over the past 60 years already has moved forward by an average of 3 weeks the time of ice-cover breakup (ice-out), which has moved ahead the spring bloom of algal growth and changed the seasonal dynamics of nutrient utilization and production and decomposition of organic matter (Magnuson *et al.*, 1997).

Where streamflows and lake levels decline, water quality deterioration is likely as concentrations of nutrients and contaminants from wastewater treatment, agricultural and urban runoff, and direct industrial discharge increase in reduced volumes of carrying waters. The extent of water quality deterioration will depend on adaptations in land use, population, and water use under changing climate. Warmer water temperatures may have further direct impacts on water quality—for example, by reducing dissolved oxygen concentrations. In the southeast, intensification of the summer temperature-dissolved oxygen squeeze (simultaneous high water temperatures and low dissolved oxygen concentrations) in many rivers and reservoirs is likely to cause a loss in habitat for coolwater fish species (Mulholland *et al.*, 1997).

Changes in the characteristics of precipitation events also may affect water quality, in complex ways. For example, increased incidence of heavy precipitation events as predicted for the southeast may result in increased leaching and sediment transport, causing greater sediment and nonpoint-source pollutant loadings to watercourses (Mulholland *et al.*, 1997). Because these high-flow events are episodic, the associated increase in nutrient and contaminant dilution during the event is not likely to offset the deleterious effects on water quality from low summer flows.

Warmer temperatures will increase the salinity of surface waters, especially lakes and reservoirs with high residence

times, by increasing evaporative water losses. Higher initial salinities in reservoir water will then exacerbate salinity problems in irrigation return flow and degrade water quality in downstream habitats.

15.2.1.3. Flood Risks

Flooding poses risks to human life and property. Vulnerability to flood damages is highly location-specific, and there is considerable variability across watersheds in the value of developed property and population located within 500-year floodplains as defined by current understanding of current climate (Hurd *et al.*, 1999). Flood events also can have significant impacts on ecosystems. For example, heavy precipitation events may leach nitrogen and other nonpoint-source pollutants from agricultural lands, and the resulting nutrient pulse may severely stress coastal and estuarine ecosystems (Justic *et al.*, 1996; Rabalais *et al.*, 1996). In addition, the influx of freshwater during floods may affect estuary-dependent species. For example, oyster populations suffer severe declines when floods reduce the salinity of Galveston Bay (Hofmann and Powell, 1998).

Coupling of natural disasters, such as extreme storm events, with large-scale human disturbance of the landscape can cause extreme disturbance to freshwater and marine resources that would not be predicted by considering these effects independently. The consequences of Hurricanes Dennis and Floyd in eastern North Carolina in September 1999 provide a recent example of the importance of this coupling (see Section 15.3.2.7). Rainfall of almost 1 m generated highly polluted, organic-rich floodwaters as containment ponds for poultry and hog waste were breached and raw sewage, fertilizers, decaying vegetation, and other organic sources were entrained by the flood. One serious effect was contamination of shallow groundwater sources with fecal coliforms and organic pollutants, which may jeopardize local water supplies long after the floodwaters subsided. Of even greater economic impact for this region, the surge of floodwater caused the waters of the biologically rich estuary between the Carolina mainland and the Outer Banks to be the color of weak coffee and deposited large amounts of organic material in coastal sediments, especially in the estuaries and westernmost Pamlico Sound. The Albemarle-Pamlico Estuarine System provides fully half of the area used as nursery grounds for commercially important fish from Maine to Florida. These waters are a vitally important feeding area for small sport fish and menhaden and an important nursery for flounder, weakfish, shrimp, and crabs. At the time, there was considerable concern that the release of nutrients and consumption of oxygen as deposited organic material decomposed would cause physical stresses, disrupting the coastal food web and commercial fisheries for a significant period (Paerl *et al.*, 2000). As it turned out, the mesohaline estuaries west of the Pamlico Sound sustained the greatest damage from pollution that was washed in and deposited to the bottom muds (Burkholder *et al.*, 2000). Pamlico Sound was protected from high impacts because much of the pollution settled out in the estuaries and because of its

high flushing exchange with the ocean relative to the estuaries. The high dilution provided by the extreme runoff associated with Hurricane Floyd was a “saving grace” that appeared to buffer the pollution effects, so no fish kills were reported throughout the system (Burkholder *et al.*, 2000). However, concerns remain about chronic, more long-term impacts from the pollution that remained behind in the estuaries.

Possible changes in runoff patterns, coupled with apparent recent trends in societal vulnerability to floods in parts of North America, suggest that flood risks may increase as a result of anthropogenic climate change (see Section 15.2.5). Changes in snowpack accumulation and the timing of melt-off are likely to affect the seasonal distribution and characteristics of flood events in some areas. For example, in mountainous western watersheds, winter and early spring flood events may become more frequent (Melack *et al.*, 1997; Lettenmaier *et al.*, 1999). In southeastern Canadian and northeastern U.S. watersheds, reductions in winter snowpacks and river ice will tend to reduce winter and spring flood risks (Bruce *et al.*, 2000), where at present “rain-on-snow and snowmelt floods can be the largest and most destructive stormflow events in the region” (Platt *et al.*, 2000). However, Canadian rivers in northern areas may begin to experience winter ice break-ups and associated flooding (Bruce *et al.*, 2000).

In inflation-adjusted terms, average annual flood damage has increased in the United States over the past few decades. This increasing trend in damages appears to be related to increases in population and the value of developed property in floodplains, as well as changes in precipitation characteristics, with perhaps as much as 80% of the trend attributable to population and wealth changes (Pielke and Downton, 2000). Measured as a proportion of real tangible wealth, average annual flood damages have been roughly constant over time (Pielke and Downton, 2000). This ongoing vulnerability comes despite the fact that various federal, state, and local governments and private entities have built approximately 40,000 km of levees along the rivers and streams of the United States—a combined total distance that is long enough to encircle the Earth at the equator (Pielke, 1999).

Recent severe flood events—particularly the 1993 Mississippi River floods, the 1996 Saguenay flood, the 1997 Red River flood, and winter flooding in California in 1997—have led to reexaminations of traditional approaches to flood management. For example, a U.S. federal interagency task force was formed in the wake of the 1993 floods, and its recommendations have contributed to altered federal practices (IFMRC, 1994). In an assessment of the 1993 floods, which caused on the order of US\$18 billion in damages, Changnon (1996) notes that the extreme and prolonged flooding had significant and unexpected impacts that defied previous experience and design extremes. Changnon further concludes that many systems for monitoring and predicting flood conditions were inadequate; that incomplete or incorrect information was released during the flood; and that many previous approaches to mitigate flood losses failed. He also identifies benefits, including benefits to the natural ecosystem of the Mississippi floodplain.

It has been demonstrated that the efforts of one community to protect itself from floods (for example, through levee construction) may affect the likelihood of flood damages in other communities (Mount, 1995). Therefore, coordinated regional planning and management may allow more efficient adaptation to changing flood risks than uncoordinated efforts by individual communities. However, there are many things that individual communities can do to rationally adapt to flood risks and reduce the likelihood of serious damages (City of Tulsa, 1994). Many entities that are responsible for floodplain management are rethinking the design of levee systems and other flood management policies (City of Tulsa, 1994; IFMRC, 1994; Mount, 1995; Tobin, 1995; Pielke, 1996; Wright, 1996). These developments may improve resilience to future flooding events, but it is not yet clear if recent policy discussions will lead to substantial and effective changes in floodplain management or flood response practices.

15.2.2. Natural Resources

In this section, impacts studies on forests, grasslands, and protected areas are reviewed. Protected areas include mountains, wetlands, and coastal/marine areas.

15.2.2.1. Forests

We must consider two types of climate change effects on forests:

- Changes in the functions of existing forests relating to productivity, nutrient cycling, water quality, ecosystem carbon storage, trace gas fluxes, and biodiversity.
- Changes in composition as forests regenerate under altered conditions. Fundamental changes in forest ecosystem structure can lead to very dramatic changes in functions. Climate change effects on catastrophic events (e.g., fire, insect outbreaks, pathogens, storms) that have marked effects on ecosystem structure are particularly important to consider.

A general discussion of forest response to climate change appears in Chapter 5.

North America contains about 17% of the world’s forests (Brooks, 1993), and these forests contain about 14–17% of the world’s terrestrial biospheric carbon (Heath *et al.*, 1993). Key climate change issues related to forests in North America include:

- Changes in the geographic range of different forest types
- Increases in the frequency of fire and insect outbreaks
- Changes in the carbon storage function of forests (i.e., from sinks to sources)
- Evaluation of the importance of multiple stresses (ozone, nitrogen deposition, land-use change) that work in concert with climate change

- Changes in human interactions with forests (e.g., risk to settlements, recreational use)
- Concern for the boreal forests of Canada because of their large extent, carbon reserves, and commercial value, combined with the fact that climate change is expected to be most severe at high latitudes.

15.2.2.1.1. Changes in function of existing forests

There is strong evidence that there has been significant warming at high latitudes (Jacoby *et al.*, 1996) and that this warming has increased boreal forest productivity (Ciais *et al.*, 1995; Myneni *et al.*, 1997). However, carbon balance is not necessarily changed by increases in productivity. Net ecosystem carbon flux (or carbon storage) is a product of changes in ecosystem production and decomposition. Keyser *et al.* (2000) used long-term meteorological records to drive the BIOME-BGC model to evaluate changes in the carbon balance of North American high-latitude forests. They conclude that increases in net primary production and decomposition were roughly balanced and that net ecosystem production (i.e., total carbon storage) was not likely to shift significantly with climate change. In contrast, Goulden *et al.* (1998) and Lindroth *et al.* (1998) found that boreal forests could become net CO₂ sources. The key uncertainties in this area are the effects of permafrost melting on release of previously frozen carbon, the ability of more productive ecosystem types (aspen, white spruce) to expand in extent, and the importance of soil moisture. Evaluating changes in carbon balance in northern forests should be a priority topic for research.

There is consensus emerging that at mid-latitudes, site-specific conditions as well as history, human management, air pollution, and biotic effects (e.g., herbivory) are much stronger controllers of forest productivity, decomposition, and carbon balance than climate change or CO₂ enrichment (Eamus and Jarvis, 1989; Aber and Driscoll, 1997; Ollinger *et al.*, 1997; Goodale *et al.*, 1998; Stohlgren *et al.*, 1998).

There is general agreement that excess nitrogen deposition, which is most pronounced in the mid-latitudes, has increased carbon storage in mid-latitude forests by facilitating increases in production in response to elevated CO₂ (Townsend *et al.*, 1996). The ability of forests to continue to absorb excess nitrogen and CO₂ is not at all certain, however (Norby, 1998).

Evidence for climate change effects on forest ecosystem "services" (i.e., functions that are important to productivity, environmental quality, and other human concerns) are beginning to emerge in North America. Murdoch *et al.* (1998) suggest that climate warming increases soil acidification and stream nitrate (NO₃⁻) concentrations, especially in forests with a history of high nitrogen deposition. Extreme climate events (e.g., soil freezing, which may increase as a result of warming-induced decreases in snow cover) also appear to lead to increases in soil and stream acidification and NO₃⁻ levels (Mitchell *et al.*, 1996; Groffman *et al.*, 1999). Evaluations of climate change effects

on fluxes of trace gases other than CO₂ [methane (CH₄), nitrous oxide (N₂O)] have been inconclusive (Prather *et al.*, 1995).

Climate change effects on biogeochemical processes are likely to be small relative to site characteristics, land-use history, and atmospheric chemistry, especially in mid-latitudes (Aber and Driscoll, 1997).

15.2.2.1.2. Wholesale changes in forest structure and function

If climate change results in wholesale replacement of one forest community with another, effects on ecosystem functions ranging from carbon storage to wildlife habitat could be dramatic (Tilman, 1998). Possible wholesale changes in forest structure have been a great source of uncertainty and concern. The North America assessment in the IPCC's *Special Report on Regional Impacts of Climate Change* concluded that there were equal probabilities of considerable forest dieback and enhanced forest growth, given state-of-the-art models and GCM predictions (Shriner and Street, 1998).

Many types of models (biogeographic individual-based forest growth, gap, dynamic global vegetation, regression tree analysis, response surface, richness, and rare and endangered species) have been used with numerous climate scenarios to examine broad-scale climate change-induced changes in vegetation (VEMAP Members, 1995; Shugart and Smith, 1996; Aber *et al.*, 2001). There is great uncertainty about the precision and accuracy of each of these models and the assumptions that underlie them (Loehle and LeBlanc, 1996; Repo *et al.*, 1996; Beuker *et al.*, 1998). Many studies suggest that all major forest types in North America will expand northward and most will increase in extent in the next 50–100 years. The increase in forests is predicted to be driven by slight warming coupled with increases in water-use efficiency (WUE) associated with increased atmospheric CO₂ (Saxe *et al.*, 1998). However, with continued warming, increased water use associated with higher temperatures overwhelms the CO₂ effect, resulting in potentially important decreases in forest area (Aber *et al.*, 2001).

Wholesale changes in forest ecosystem structure over time are likely to be mediated by changes in disturbance regimes and/or catastrophic events that provide opportunities for forest regeneration over large areas (Suffling, 1995; Loehle and LeBlanc, 1996). Of particular interest in North America are changes in fire and insect outbreaks.

15.2.2.1.3. Fire

Stocks *et al.* (1998) used outputs from four GCMs to project forest fire danger levels in Canada under a warmer climate. Their analysis shows an earlier start to the fire season and significant increases in the area experiencing high to extreme fire danger. Increased lightning frequency associated with global warming also may increase fire frequency (Goldammer and Price, 1998). Changes in fire frequency have a wide range of

effects, from production of tropospheric aerosols that influence climate (Clark *et al.*, 1996) to changes in ecosystem carbon storage and trace gas fluxes. The long-term effects of fire will depend heavily on changes in human fire management activities, which are uncertain—especially in remote boreal forests, where fire is a critical issue (e.g., see Section 15.3.2.8). In mid-latitudes, climate effects on fire frequency are much less important than human management factors (Veblen *et al.*, 2000).

15.2.2.1.4. Insects

Insects represent dominating disturbance factors (Hall and Moody, 1994) in North America's forests; during outbreaks, trees often are killed over vast areas (Hardy *et al.*, 1986; Candau *et al.*, 1998). Because the potential for wildfire often increases in stands after insect attack (Stocks, 1987; Wein, 1990), uncertainties in future insect damage patterns also lead to uncertainties in fire regimes. Insect outbreaks also lead to changes in ecosystem carbon and nutrient cycling, biomass decomposition, energy flow (Mattson and Addy, 1975; Schowalter *et al.*, 1986; Szujecki, 1987; Haukioja *et al.*, 1988; Chapin, 1993; Haack and Byler, 1993), and competitive relationships between plants (Morris, 1963; Holling, 1992)—hence successional pathways, species composition, and forest distribution.

Climate change already appears to be accelerating the seasonal development of some insects (Fleming and Tatchell, 1994). Forecasts based on historical relationships between outbreak patterns and climate in specific areas are likely to predict change as the climate in those areas changes. Such analyses suggest more frequent [mountain pine beetle (Thomson and Shrimpton, 1984), spruce budworm (Mattson and Haack, 1987), eastern hemlock looper (Carroll *et al.*, 1995), jack pine budworm (Volney and McCullough, 1994), western spruce budworm (Thomson *et al.*, 1984)] or longer [forest tent caterpillar (Roland *et al.*, 1998), spruce budworm (Cerezke and Volney, 1995)] outbreaks or range shifts northward and to higher elevations [spruce budworm (Williams and Liebhold, 1997)] as climate change progresses.

15.2.2.1.5. Vegetation In human settlements

Vegetation in human settlements plays two potentially important roles that are relevant to climate change: modification of local climate and sequestration of carbon.

Trees reduce demands for seasonal heating and cooling of the interiors of buildings and absorb air pollutants (Heisler, 1986; Nowak *et al.*, 1994). In the city of Chicago, calculations suggest that increasing tree cover by 10% could reduce building energy use by 5–10% (Nowak *et al.*, 1994). Thus, urban tree planting represents an adaptive strategy that can reduce energy use and associated CO₂ emissions and counteract temperature increases in urban areas, which are predicted to be extreme in some cases.

Carbon density in residential areas can be significant, amenable to management, and often overlooked in evaluation of landscape, regional, and national carbon budgets. Freedman *et al.* (1996) found that aboveground tree biomass of an old residential neighborhood in Halifax, Nova Scotia, was only slightly smaller than that of a natural forest in a nearby reserve. Nowak *et al.* (1994) estimated that carbon storage by urban forests in the United States was 440–990 Mt. There is a strong need for better estimates of “natural” carbon fluxes in human-dominated environments.

15.2.2.2. Protected Areas

15.2.2.2.1. Mountains

In the 20th century, there has been increasing human pressure on mountainous regions, initially through trapping, forestry, and reservoir construction and now through development of ski areas and other resorts and construction of residences, as well as forestry and continuing reservoir construction in northern Canada. At the same time, however, the national park systems in the United States and Canada and wilderness preserves have expanded to include many mountainous areas that are essentially pristine with respect to human development, especially in the Rocky Mountains. It is now recognized that these protected mountain ecosystems are still vulnerable to anthropogenic change through transport of atmospheric contaminants, such as nitrate and sulfate in acid rain, and through climate change. Warming of the climate eventually will cause two major changes—retreat of mountain glaciers and upward movement of treeline—and the response times for reaching new equilibrium conditions are on the order of 100 years or more, so these responses will lag continuing climate change.

Retreat of glaciers is driven by the rate of ablation, which includes melt, exceeding the rate of advance driven by snow accumulation over the glacier, and corresponds to a change in the shape of the glacier to a new equilibrium. Retreat of mountain glaciers already has begun in North America (Brugman *et al.*, 1997) and in other regions of the world, and this retreat will contribute to sea-level rise in an amount comparable in magnitude to expansion of ocean waters as a result of warming. On a regional scale, the retreat of glaciers will affect water resources by changing (probably decreasing) water supply from glacial melt during summer or changing the spatial location of the melt source [summer flows initially may increase but eventually will decline as glacier reservoir capacity declines (Pelto, 1993)]. Furthermore, glacial retreat will expose terrain that gradually will evolve with soil development and revegetation, and new lakes will form in exposed basins. These changes eventually will influence the water quality of drainage from these lakes. These sequences of glacial advance and retreat have occurred through the quaternary; the effect of climate change is to induce these changes. In terms of human vulnerability to climate change, retreat of mountain glaciers also is significant because it is an observable change that can be directly comprehended by the public as an indicator of warming—more so than warming

of the open ocean or an increase in extreme hydrological events. For example, a recent article in a travel magazine (*Conde Nast*) outlined vacations to view retreating glaciers in North America, Europe, and Africa while they were still there.

From paleolimnological studies of alpine and subalpine lakes, the rise in treeline in response to past warming of climate is well-documented. The boundary between alpine tundra and subalpine forest is controlled by extremes of temperature, moisture, and wind. Vegetation in both ecosystems is long-lived, and changes will proceed slowly and in a manner that depends on whether total annual snowpack decreases or increases and whether melt occurs earlier; both factors control the growth of alpine and subalpine species. Movement of treeline could have a minor feedback on climate change by sequestering more carbon in subalpine forests. The eventual effect of upward movement of the treeline will be to shrink the extent of alpine tundra in North America, possibly causing species loss and ecosystem degradation through greater fragmentation (see Section 15.2.6. and Chapter 5).

15.2.2.2.2. Wetlands

Wetlands represent a variety of shallow water and upland water environments that are characterized by hydric soils and plant and animal species that are adapted to life in saturated conditions (NRC, 1995). These ecosystems are considered to be of great importance in a variety of functional contexts, including waterfowl habitat, carbon sequestration, CH₄ production, flood regulation, pollutant removal, and fish and shellfish propagation (Mitsch and Gosselink, 1993). About 14% of Canada's surface area is covered by wetlands, which is 24% of the global total (NWWG, 1988). Approximately 6% of the United States is wetland (Kusler *et al.*, 1999).

Mid-latitude wetlands have been greatly affected by a variety of human activities over the past 200 years. More than 50% of the original wetlands in the United States have been destroyed for agriculture, impoundment, road building, and other activities (Dahl, 1990). Most of the remaining wetlands have been altered by harvest, grazing, pollution, hydrological changes, and invasion by exotic species (Kusler *et al.*, 1999). High-latitude wetlands have experienced much lower levels of human disturbance (Schindler, 1998).

Climate change can have significant impacts on wetland structure and function, primarily through alterations in hydrology, especially water-table level (Clair *et al.*, 1998; Clair and Ehrman, 1998). Wetland flora and fauna respond very dynamically to small changes in water-table levels (Poiani *et al.*, 1996; Schindler, 1998). Moreover, climate change can exacerbate other stresses (e.g., pollution), especially in fragmented landscapes where wetlands have been cut off from other wetlands by a variety of landscape-level alterations (Mortsch, 1998; Kusler *et al.*, 1999). With rising sea levels, shoreline development and efforts to protect private property from coastal erosion could lead to loss of public tidelands and coastal marshes, particularly

along bayshores where preservation of natural shorelines has received less policy attention than is the case for most ocean beaches (Titus, 1998).

Specific changes predicted to occur in North American wetlands are wide ranging. Sea-level rise will result in loss of coastal wetlands in many areas, with potentially important effects on ocean fisheries (Michener *et al.*, 1997; Turner, 1997). Increased drought conditions in the Prairie Pothole Region of the northern Great Plains, which are forecast to occur under nearly all GCM scenarios, will significantly reduce U.S. breeding duck populations (Sorenson *et al.*, 1998). Tourism may benefit from extended seasons but will suffer if key processes (e.g., hunting, birding) are disrupted (Wall, 1998a). Alteration of water-table levels could affect the carbon sequestration function of the vast northern wetlands of Canada, but there is great uncertainty about the nature and extent of this effect (Moore *et al.*, 1998; Waddington *et al.*, 1998).

Wetlands have been the target of numerous protection and restoration efforts (NRC, 1995), which suggests that there is high potential for adaptive management in response to climate change, at least in mid-latitudes. Kusler *et al.* (1999) recommend a series of strategies for reducing the impacts of climate change on wetlands. These strategies include better control of filling and draining of wetlands, prevention of additional stresses, prevention of additional fragmentation, creation of upland buffers, control of exotic species, protection of low flows and residual water, enhanced efforts to restore and create wetlands, and aggressive efforts in stocking and captive breeding of critical wetland species. Five states in the United States have adopted rolling easement policies, which ensure that wetlands and/or beaches can migrate inland as sea level rises, instead of being squeezed between coastal development and the advancing sea (Titus, 1998). These efforts would be greatly enhanced by creation of regional inventories and management plans for wetlands at greatest risk from climate change.

15.2.2.2.3. Coastal/Marine

With the concentration of population on the coasts, various development constraints and environmental regulations have been enacted to protect areas of coast as wildlife preserves and for harvesting of shellfish. Coastal ecosystems clearly are vulnerable to change associated with eventual sea-level rise (see Section 15.2.2.3.4). Coastal and marine biota also are vulnerable to changes in upwelling, current dynamics, freshwater inflow, salinity, water temperatures, and other processes that affect food webs and nursery areas (Boesch *et al.*, 2000). Moreover, long-term studies of estuaries such as San Francisco Bay have indicated that natural cycles of ecosystem processes, such as phytoplankton blooms, are being altered on a global scale by human activities. This includes manipulation of river flows, input of toxic contaminants and nutrients, and invasion of exotic species (Cloern, 1996). Thus, in the nearer term, estuaries and coastal ecosystems may be most vulnerable to hydrological changes in rivers and groundwater flows from

shifts in inland precipitation, evapotranspiration, and river ecosystem dynamics.

The increased frequency and geographical range of incidents of hazardous blooms in estuaries on the Gulf, Atlantic, and Pacific coasts has caused serious economic impacts for numerous fisheries and poses a great public health challenge in closing beaches to shellfish. Consumption of toxic algae by shellfish causes the shellfish to contain concentrations of toxins that are high enough to cause paralysis and death of humans who consume the shellfish. This situation has raised concerns that increased nitrogen loading to watersheds has led not only to general coastal eutrophication but also to a greater probability of circumstances that are conducive to these blooms. Factors that appear to contribute to harmful algal bloom occurrence are warmer temperatures and high runoff from watersheds that feed the estuaries, although much remains to be learned and predictive capability has yet to be achieved. Thus, indirect effects of climate change, which exacerbate the hazardous algal bloom problem, could be significant and difficult to identify until better understanding is gained (Anderson, 1997; see Chapter 6).

15.2.2.4. Wildlife

The Endangered Species Act in the United States and other regulatory efforts preserve and manage wildlife populations in many regions of North America. These efforts have begun to involve habitat protection and ecosystem management rather than taking a strict population focus. Changes in habitats driven by climate change could further restrict wildlife populations. One process would be causing habitats to be less interconnected, restricting migration of individuals among different populations and causing loss of genetic diversity within more isolated populations. This process is a concern for aquatic and terrestrial wildlife.

Fish populations and other aquatic resources are likely to be affected by warmer water temperatures, changes in seasonal flow regimes, total flows, lake levels, and water quality. These changes will affect the health of aquatic ecosystems, with impacts on productivity, species diversity, and species distribution (Arnell *et al.*, 1996). For example, warming of lakes and deepening of thermoclines will cause a loss of habitat for coldwater fish in areas such as Wisconsin and Minnesota, and decreases in summer flow and increased temperatures will cause loss and fractionation of riverine habitat for coolwater fish species in the Rocky Mountain region (Rahel *et al.*, 1996; Cushing, 1997).

Wetlands and dependent wildlife resources may be adversely affected by general increases in evapotranspiration and reduced summer soil moisture, which may reduce the extent of semi-permanent and seasonal wetlands, particularly in the prairie regions of North America (Poiani *et al.*, 1995).

The state of terrestrial wildlife in North America varies geographically, by taxa, and by habitat association. In general, biodiversity increases from north to south, and species that are

associated with rare habitats are most likely to be at high risk of extinction (Dobson *et al.*, 1997; Ricketts *et al.*, 1999). Many factors can cause a species to be at risk of extinction, but the most common causes include loss of habitat, pressures from introduced species or hunting, and reduced fitness as a result of chemical contaminants (Wilson, 1992; Meffe and Carroll, 1994). A minimum estimate of the number of species at risk comes from data for the United States, for which a recent summary suggests that 42 mammal species, 56 bird species, 28 reptile species, and 25 amphibian species are considered at least vulnerable to extinction (UNEP, 2000). Key additional pressures on wildlife associated with global climate change include changes in temperature and precipitation, changes in sea level, and changes in the frequency of extreme weather events (Peters, 1992; Parmesan *et al.*, 2000).

Climate-related pressures can act directly on wildlife through physiological effects (i.e., changes in growth rates, food demands, abilities to reproduce and survive) or indirectly through effects on other plant and animal species (e.g., Payette, 1987; Lewis, 1993; Post and Stenseth, 1999). These physiological effects can lead to changes in the range and abundance of North American species; recent studies suggest that we already are seeing climate-linked changes in butterflies (Parmesan, 1996) and desert-associated species (Brown *et al.*, 1997b; Smith *et al.*, 1998a). A key potential indirect effect of climate change on wildlife is loss of total habitat available as a result of changes in the distribution of a particular habitat type. An obvious example is loss of coastal habitat as a result of sea-level rise; in many places, coastal habitats will not be able to shift inland because adjacent lands already are developed (Harris and Cropper Jr., 1992; Daniels *et al.*, 1993). Similarly, potential shifts in the ranges of species in northern habitats are bounded by the Arctic Ocean (Kerr and Packer, 1998). A second key impact of climate-change related pressures on wildlife relate to how species interact with other species on which they depend. Because temperature and precipitation can be triggers for many wildlife behaviors, changes in these factors may differentially impact species in the same location. We already have evidence that the timing of bird migrations (Bradley *et al.*, 1999; Inouye *et al.*, 1999), bird breeding (Brown and Li, 1996; Brown *et al.*, 1999; Dunn and Winkler, 1999), and emergence of hibernating mammals (Inouye *et al.*, 1999) is becoming earlier. Depending on how food sources and other related species respond to changes, wildlife may become decoupled from the many ecological relationships of which they are a part.

15.2.3. Food and Fiber

This section includes a review of impacts on agriculture, production forestry, and marine fisheries.

15.2.3.1. Agriculture

Most global climate change scenarios indicate that higher latitudes in North America would undergo warming that would

affect the growing season in this region. For example, estimates of increases in the frost-free season under climatic change range from a minimum of 1 week to a maximum of 9 weeks (Brklacich *et al.*, 1997a). For the Prairies, Ontario, and Quebec, most estimates suggest an extension of 3–5 weeks. Estimated temperature increases for the frost-free season in Ontario and Quebec are mostly between 1.5 and 5.0°C, and agricultural moisture regimes show an even broader range of estimates, indicating precipitation changes for the Prairies and Peace River regions ranging from decreases of 30% to increases of 80% (Brklacich *et al.*, 1997a).

Although warmer spring and summer temperatures might be beneficial to crop production in northern latitudes, they may adversely affect crop maturity in regions where summer temperature and water stress limit production (Rosenzweig and Tubiello, 1997). Predicted shifts in thermal regimes indicate a significant increase in potential evapotranspiration, implying increased seasonal moisture deficits. Modeling studies addressing the southeast United States have shown that changes in thermal regimes under conditions of doubled CO₂ would induce greater demand for irrigation water and lower energy efficiency of production (Peart *et al.*, 1995).

15.2.3.1.1. Change in land use

Drought may increase in the southern Prairies, and production areas may shift northward in Canada. In assessing the potential for expansion to areas in northern Canada (i.e., north of 55°N and west of 110°W) and Alaska, Mills (1994) identified 57 Mha of potentially arable land (class 1–5, based on Canada Land Inventory criteria) with agricultural potential for use in either annual cropping or perennial forage systems. This estimate drops to 39 Mha when climatic limitations are imposed but under a scenario of doubled atmospheric CO₂, increases to 55 Mha with an accompanying improvement of land class to class 3. Similar outcomes—expansion of agricultural land, especially expansion of the zone suitable for corn and soybean production—are expected for northern areas of eastern Canada (Brklacich *et al.*, 1997a). Other case studies conducted in the southern portion of the Mackenzie basin in northwestern Canada show that two different climate-change scenarios would relax the constraints imposed by a short and cool frost-free season but that drier conditions and accelerated crop development would offset the potential gains of a warmer climate (Brklacich *et al.*, 1996, 1997b).

Southern regions growing heat-tolerant crops such as citrus fruit and cotton might benefit from reduced incidence of killing frosts resulting from a change in climate (Miller and Downton, 1993; Mearns *et al.*, 2000). Results of simulations without CO₂-induced yield improvement indicate that production of citrus fruit would shift northward in the southern United States, but yields may decline in southern Florida and Texas because of excessive heat during the winter (Rosenzweig *et al.*, 1996).

Mexican agriculture appears to be particularly vulnerable to climate-induced changes in precipitation because most (about

85%) of its agricultural land is classified as arid or semi-arid. Recent national assessments of the impacts of climate change indicate that the northern and central regions of Mexico are most vulnerable in the agricultural sector (Conde, 1999) and that in these regions, the area of land that is unsuitable for rainfed maize production would expand under climate change (Conde *et al.*, 1997). On average, more than 90% of losses in Mexican agriculture are caused by drought (Appendini and Liverman, 1995). Using five GCM-based scenarios, it was estimated that potential evaporation may increase by 7–16% and the annual soil moisture deficit could increase by 18–45% in important maize-growing regions in eastern Mexico (Liverman and O'Brien, 1991). Rising levels of CO₂ can have the greatest relative beneficial impacts when water is limited. Therefore, rising CO₂ may be expected to have a significant positive impact because so much of Mexican crops are water-limited and rising CO₂ enhances water-use efficiency (see Chapter 14).

15.2.3.1.2. Crop yields and adaptation

Depending on existing conditions, global warming and CO₂ enrichment can have positive or negative effects on crop yields. It is believed that yield increases in mid- and high latitudes are caused by positive physiological effects of CO₂, longer growing season, and amelioration of the effects of cold temperature on growth. Decreases in yield could result from shortening of the growing period, reduced water availability, and/or poor vernalization.

Estimates of the impacts of climate change on crops across North America vary widely (see Table 15-3). In some studies, the impacts range from nearly total crop failure for wheat and soybeans at one U.S. site to wheat yield increases of 180–230% for other sites in the United States and Canada (Brklacich *et al.*, 1994; Rosenzweig *et al.*, 1994). Recent modeling efforts indicate that the impacts on yields for many crops grown under dryland conditions, even without adaptation, is positive (Reilly *et al.*, 2000). Threshold limits associated with temperature increases may be important. Rosenzweig *et al.* (1995) report generally positive crop yield responses to temperature increases of 2°C, but yield reductions occurred at increases of more than 4°C. Modeled yield results that include the direct physiological effects of CO₂ are substantially different from those that do not account for such effects (Fischer *et al.*, 1996).

Although it is known that the distribution and proliferation of weeds, crop diseases, and insects are determined to a large extent by climate, most crop modeling efforts have not thoroughly accounted for potential impacts of climate change and variability on pest populations and ranges. Interactions between crops and pests under changing climate conditions will be very complex and are difficult to predict because elevated CO₂, warmer temperatures, and increased climate variability would alter the relationships between crops, weeds, and insects significantly. Higher temperatures and warmer winters could reduce winterkill of insects as well as broaden the range of other temperature-sensitive pathogens (Rosenzweig *et al.*, 2000). Increases in the

Table 15-3: Range of climate change scenario impacts on agriculture.

Crop Yield (% change from current)	Cropped Area	Change in Soil Carbon/Soil Quality	Pesticide Expenditures ⁶ (% change)	Irrigated Acreage	Livestock Production
Canada ¹					
– Smallgrains	-24 to +14 ^a -35 to +66 ^b -75 to +73 ^c -17 to 0 ^d +21 to +124 ^e	Increase ³ and decrease ⁴	Increase ⁵	Corn +10 to +20	Increase ⁷
US ²				Wheat -15 to +15	Decrease ⁸
– Spring Wheat	+17 to +23			Potato + 5 to +15	
– Winter Wheat	-9 to +24				
– Corn	+11 to +20				
– Soybean	+7 to +49			Soybean and Cotton +2 to +5	
– Sorghum	+32 to +43				
– Potato	+7 to +8				
– Citrus (oranges/grapefruit)	+13 to +40				

¹ Data pertain to (a) Peace River/agricultural margin; (b) Alberta, Saskatchewan, Manitoba; (c) Ontario, Quebec; and (d) Atlantic region [adapted from Brklacich *et al.*, 1997a; based on scenarios from pre-1995 versions of four GCMs (CCC, GFDL, GISS, and UKMO) with different crop models (FAO and CERES), assuming no adaptation and no CO₂ fertilizer effects]. Data for note (e) represents yields of corn, spring and winter wheat, and canola [from McGinn *et al.*, 1999; based on CCC model (results also show growing degree days increase by 50%)].

² Weighted average yield impact for crops grown under dryland conditions with adaptation, percentage change from base conditions (Reilly *et al.*, 2000). Results based on simulations at 46 sites of current major production representing changes in climate predicted by the CCC, Hadley Centre, and Pacific Northwest National Laboratory models, and calculated using 20-yr averages centered around the year 2030, with an atmospheric CO₂ concentration of 445 ppm; crop yields were simulated by the DSSAT models (Tsuiji *et al.*, 1994).

³ For Alaska and northwestern Canada (Mills, 1994), and Peace River region, northern Ontario, and Quebec in northern Canada (Brklacich *et al.*, 1997b).

⁴ For example, in citrus production in the southeastern United States, if risk of freeze damage increases with climate change (Miller and Downtown, 1993), area in cropland decreased 5–10% (Reilly *et al.*, 2000).

⁵ If soil conservation practices (e.g., no tillage, increased forage production, higher cropping frequency) implemented as mitigation strategies (TAR WGIII).

⁶ Reilly *et al.* (2000) results based on simulations at 45 sites of current major production representing changes in climate predicted by the CCCM and Hadley Centre models, and calculated using 20-yr averages centered around 2090, with an atmospheric CO₂ concentration of 660 ppm.

⁷ Irrigated acreage estimated to increase by 0.8–7.3Mha in the United States (Adams *et al.*, 1990).

⁸ Direct effects include warmer temperatures, which are estimated to suppress livestock appetite. If quality or supply of forage/feed grains is altered, production may be more affected by changes in pasture and grain prices (Adams *et al.*, 1999).

incidence of extreme weather events could reduce the efficacy of pesticide applications and result in more injury to nontarget organisms (Patterson *et al.*, 1999).

Modeling studies of changes in crop production show strong regional effects, with some areas suffering significant losses compared to other regions—suggesting that climate change may affect the comparative advantage of agricultural production regions within North America. For example, in scenarios investigated for the U.S. National Assessment (Reilly *et al.*, 2000), the lake states, mountain states, and Pacific region showed gains in production, whereas the southeast, delta, southern Plains, and Appalachia generally lost. The economic impact of these changes in crop production as a result of climate change is considered to be mostly beneficial to society as a whole. The effects are largely detrimental to producers because the overall positive effect on production leads to decreasing prices. Thus, climate change is beneficial for foreign trade surplus and for consumers. Analyses of the economic effects of

various climate change scenarios on the welfare of consumers and producers in the United States show that agricultural welfare strictly increases with 1.5 °C warming, but further warming reduces the benefit at an increasing rate (Mendelsohn *et al.*, 1999). Additional precipitation is strictly beneficial (Adams *et al.*, 1999).

The costs and benefits of climate change must be evaluated concurrently with behavioral, economic, and institutional adjustments brought about by climate change. These adjustments occur at different levels. For example, farm-level adaptations can be made in plant and harvest dates, crop rotations, selections of crops and crop varieties for cultivation, water consumption for irrigation, use of fertilizers, and tillage practices. At the market level, prices are a strong signal to adapt as farmers make decisions about land use and which crops to grow.

Current economic studies of climate change that include farm- and/or market-level adjustments suggest that the negative

effects of climate change on agriculture probably have been overestimated by studies that do not account for adjustments that will be made. This may be caused by the ability of the agricultural production community to respond with great flexibility to a gradually changing climate. Typically, extreme weather poses a significant challenge to individual farming operations that may lack the spatial diversity and financial resources of large, integrated, corporate enterprises with production capabilities in one or more areas.

Simulation modeling using four GCM-based scenarios showed that U.S. cereal production decreases by 21–38% when farmers continue to do what they are now doing (i.e., no adaptation) (see Table 15-4). When scenarios that involve adaptation by farmers are used, decreases in cereal production are not as large and the adaptations are shown to offset the initial climate-induced reduction by 35–60% (Schimmelpfennig *et al.*, 1996; Segerson and Dixon, 1999).

15.2.3.1.3. Response to climate variability and extreme events

The effects of changes in the variability of temperatures and precipitation on crop yields have been evaluated through simulation modeling. Changes in diurnal and interannual variability of temperature and moisture can result in substantial changes in the mean and variability of wheat yields. In Kansas, doubling of temperature variability resulted in greatly reduced average yield and increased variability of yield, primarily as a result of crop failure by winterkill (Mearns *et al.*, 1996). The main risk of climate change to some regions may be primarily from the potential for increased variability. Increased variability of temperature and precipitation results in substantially lower mean simulated yields, whereas decreased variability produces only small increases in yield that were insignificant (Reilly *et al.*, 2000). This asymmetric response to temperature variability underscores a major reason that the corn belt region of the United States is so productive: There generally is low variability in temperature across the region. It should be noted, therefore, that if minimum temperatures increase more than maximums, two outcomes could be suggested: Temperature variability may decline, and winterkill should be reduced.

These effects of diurnal and interannual climate variation may have important implications for farm values. Economic analysis has shown that greater interannual variation is harmful to farm values, and the marginal effect of temperature variation is relatively larger than the effect of variations in precipitation (Mendelsohn *et al.*, 1999).

15.2.3.1.4. Vulnerability of livestock

The effects of climate change on livestock can be direct (e.g., effects of higher temperature on livestock appetite) or indirect (e.g., effects of changes in quantity and quality of forage from grasslands and supplies of feed). In areas where livestock rely on surface water availability, water quality could have an impact

Table 15-4: Percentage change in U.S. supply of cereals under various constraints, by climate change scenario (Schimmelpfennig *et al.*, 1996).

Scenario	No adaptation	With adaptation
GISS	-21.5	-8.7
GFDL	-37.8	-22.3
UKMO	-34.1	-19.4
OSU	-31.9	-20.9

on weight gain. This would be particularly important where fewer water sources become used by greater numbers of cattle.

Estimates of livestock production efficiency suggest that the negative effects of hotter weather in summer outweigh the positive effects of warmer winters (Adams *et al.*, 1999). The largest change occurred under a 5°C increase in temperature, when livestock yields fell by 10% in cow-calf and dairy operations in the Appalachia, southeast, Delta, and southern Plains regions of the United States. The smallest change was 1% under 1.5°C warming in the same regions. Livestock production also is affected by changes in temperature and extreme events. For example, an ice storm in eastern Canada and the northeast United States in the winter of 1998 had severe effects on livestock in the region (see Section 15.3.2.6).

15.2.3.1.5. Role of changing water resources

Although several studies have examined the potential implications of climate change for streamflows and water delivery reliability from reservoir systems in regions where irrigated agriculture is now important (see Section 15.2.1), there have been few direct analyses of the economic impacts on irrigated agriculture of changes in water availability. Some assessments of the impacts of climate change on agriculture in North America have relied on optimistic assumptions regarding the availability of irrigation water to offset precipitation deficiencies (Mendelsohn *et al.*, 1994). Other studies have attempted to estimate the impacts of projected climate change on the potential use of irrigation water. A study of potential climate change impacts on irrigation water use in the United States concluded, “The greatest impact of a warmer climate on the agricultural economy will be in the West where irrigators will be hard put to maintain even present levels of irrigation” (Peterson and Keller, 1990). That conclusion is based on first-order impacts of reduced water availability and does not consider possible earnings from sale or lease of water rights.

Studies of the impacts of drought events may provide useful insights into the impacts of substantial changes in seasonal streamflows that may result from climate warming—particularly in western North America, where mountain snowpacks now sustain streamflows into the summer months (see Section 15.2.1). However, the impacts of short-term droughts are an imperfect analog to long-term impacts of a drier climate because farmers

are likely to adjust crop choices and farming practices as they acquire experience with any new climate regime.

Under some scenarios, demand for irrigation water declines (e.g., as a result of more rapid crop maturation and/or increased growing-season precipitation). Scenarios investigated for the U.S. National Assessment (Reilly *et al.*, 2000) suggest that demand for water resources by agriculture would decline nationwide on the order of 5–10% by 2030 and 30–40% by 2090. Land under irrigation showed similar magnitudes of decline. Crop yield studies generally favor rainfed over irrigated production and show declines in water demand on irrigated land. Such adaptations could help to relieve some of the stress

on regional water resources by freeing water for other uses (Hurd *et al.*, 1999). However, the interplay between changes in irrigation demand and changes in water supplies has not been fully assessed.

15.2.3.1.6. Carbon sequestration

North American soils have lost large quantities of carbon since they first were converted to agricultural systems, leaving carbon levels in agricultural soils at about 75% of those in native soils (Bruce *et al.*, 1999c). Because carbon in agricultural soils is a manageable pool, it has been proposed that these soils be managed to sequester carbon from atmospheric CO₂.

15-1. Carbon Sequestration: Adaptation Issues

The Kyoto Protocol commits industrialized nations to take on binding targets for GHG emissions for the period 2008–2012. The Protocol mentions human-induced land-use changes and forestry activities (afforestation, reforestation, deforestation) as sinks of GHGs for which sequestration credits can be claimed; it also mentions that agricultural sinks may be considered in the future. As a result, a significant market is emerging in North America for ways to enhance carbon sequestration in these sectors. Although it is not within the purview of this section to deal with mitigation strategies, land management decisions impact a wide range of factors. There may be several consequent issues that result or are derived from implementation and adoption of these strategies. Negative consequences of reduced tillage implemented to enhance soil carbon sequestration may include (medium confidence):

- Increased use of pesticides for disease, insect, and weed management. This increased pesticide load may affect adjacent ecosystems and the quality of water within and outside agroecosystems.
- Capture of carbon in labile forms that are vulnerable to rapid oxidation if the system is changed. This may require that reduced-till systems be maintained for an extended period (which also would lengthen the beneficial aspects of reduced tillage).
- Reduced yields and cropping management options and increased risk for farmers (Would yield reductions and increased risk be compensated?).

Beneficial consequences of reduced tillage (especially no-till) may include (high confidence):

- Reduced input costs (e.g., fuel) for farmers, thereby increasing the economic profit margin
- Increased soil moisture and hence reductions in crop water stress in dry areas
- Reduction in soil erosion, which inhibits loss of carbon from erosional forces and preserves the natural land base
- The overall combination of these effects improves soil quality and the ability of soils to physically and chemically support plant growth, as well as conserving the continent's natural resources.

The extent to which carbon will be sequestered in agricultural and forest systems will be related to practical economics and land-use policies. For example:

- Expansion of agricultural lands for carbon sequestration may increase competition with use of agricultural lands for traditional food and fiber production. The effect may be decreased food and fiber production, with subsequent increases in prices and decreases in exports for agricultural commodities.
- Land prices may change (e.g., increase) as a consequence of competition between crops for food and crops for mitigation strategies.
- Reduction of agricultural lands by transferring these lands to forestry to enhance carbon sequestration also may increase competition for food and fiber production, but the influx of land into forestry subsequently may decrease forestry prices.

Thus, a focus on carbon sequestration in ecosystems may result in the transfer of large quantities of land between agriculture and forestry and change the management of existing agricultural and forest ecosystems. These changes may provide opportunities for landowners, but they also may have implications for food and fiber production and ecosystem functions.

The rate at which carbon is lost has subsided for most agricultural soils, and carbon levels in some soils have been maintained or even begun to increase as conservation farming practices have been adopted in the past 15–20 years. On cultivated land, these practices include conservation tillage (i.e., reduction or elimination of tillage) and residue management, use of winter cover crops, elimination of summer fallow, and methods to alleviate plant-nutrient and water deficiencies and increase primary production (Lal *et al.*, 1998). Revegetation of marginal lands and modified grazing practices on pastures can be used to increase soil carbon levels. On degraded soils, preventing and controlling erosion and reducing salinization help to maintain or increase soil carbon. Greater adoption of these measures in the United States and Canada could result in agricultural soils more effectively capturing carbon from atmospheric CO₂.

However, these agricultural practices that are effective in building soil carbon also may result in greater emissions of other GHGs (e.g., N₂O). Therefore, research is needed to weigh the positive and negative effects of building up soil carbon with respect to the overall goals of reducing GHG emissions. Moreover, implementation of such mitigation strategies and their effects on adaptation need further evaluation from the perspective of practical economics and land management decisions (see Box 15-1).

Some scenario studies suggest that interactions between soil and atmosphere will occur under a positive feedback system as temperatures increase: Higher temperatures will cause greater decomposition of soil carbon, in turn causing greater emissions from soil of CO₂, which will enhance the greenhouse effect and cause even higher temperatures. However, there is evidence that negative feedback mechanisms also exist. Some experiments indicate that more primary production is allocated to roots as atmospheric CO₂ rises (Schapendonk *et al.*, 1997), and these roots decompose more slowly than those grown at ambient CO₂ levels (Van Ginkel *et al.*, 1997). Recent comprehensive analyses of field data of forest soils suggests that increased temperature alone will not stimulate decomposition of forest-derived carbon in mineral soil (Giardina and Ryan, 2000).

Analysis of yield trends for 11 major crops over the period 1939–1994 indicates that the rate at which yield increased ranged from 1% on average to more than 3% yr⁻¹ (Reilly and Fuglie, 1998). Conservative extrapolation of yields implies that the average annual increase in yield for the 11 crops between 1994 and 2020 would range from 0.7 to 1.3% yr⁻¹. More optimistic estimates of growth rates indicate that yield increases could be as high as 3% yr⁻¹. These yield increases could lead to substantial increases in soil carbon if crop residues are retained.

15.2.3.2. Production Forestry

Evaluation of effects of climate change on production forestry are constrained by uncertainties discussed in Section 15.2.2.1 (i.e., state-of-the-art forest models and GCM predictions produce equal probabilities of “considerable forest dieback”

and “enhanced forest growth”). Moreover, in many cases, site-specific conditions as well as history, human management, air pollution, and biotic effects (e.g., herbivory) are much stronger controllers of forest productivity than climate change or CO₂ enrichment (Eamus and Jarvis, 1989; Aber and Driscoll, 1997; Ollinger *et al.*, 1997; Goodale *et al.*, 1998), especially in mid-latitudes. Finally, lands managed for timber production are likely to be less susceptible to climate change than unmanaged forests because of the potential for adaptive management (Binkley and Van Kooten, 1994).

In a broader assessment for the United States, Sohngen and Mendelsohn (1999) used several GCMs, a variety of ecological models, and a dynamic economic model (with adaptation) to assess climate change impacts on the U.S. timber market. Under a broad range of climate and ecosystem model predictions, economic changes were positive, as a result of generally positive impacts of climate change on U.S. forest production and the ability of producers to adapt. Disturbances from insects and fire were assumed to increase, but the study also assumed that there would be salvage logging followed by planting of the right species for a new climatic regime. In a sensitivity analysis, in which the possibility of replanting with incorrect species was considered, economic impacts became negative as a result of reductions in available stocks and increased regeneration costs.

The foregoing uncertainty raises questions about evaluating impacts and developing adaptation strategies. For example, Woodbury *et al.* (1998) used a climate change scenario derived from four GCMs, results from experimental studies, and a probabilistic regional modeling approach and estimate that there is a high likelihood that loblolly pine (a major timber production species) growth is likely to decrease slightly over a 12-state region of the southern United States. However, they also estimate that there is a substantial chance of either a large decrease or a large increase in growth. How can this information be used by the timber industry? Should managers assume that there would be no problems with loblolly pine plantations? Should they increase the area of these plantations? Should they convert plantations to a more mixed plantation community? Should plantations be converted to “natural succession”? Crippling uncertainty of this type may lead this production industry (as well as others) to disregard climate change as a factor in planning.

Similar questions have been raised in northwest Canada (see Section 15.3.2.8). Within the Mackenzie Basin Impact Study (MBIS), debate about forest management concerned the scenario of reduced spruce yield and increased risk of losses from fire and insect damage (Hartley and Marshall, 1997; Rothman and Herbert, 1997). In the short term, a large number of pressing issues divert attention from long-term climate change (e.g., land-use planning, British Columbia’s Forest Practices Code, treaty negotiations with aboriginal people, trade with the United States, protected area strategy). Adaptation to climate change requires information that is relevant to the context of the industry, particularly if there are implications for harvesting (Barrett, 1997; Fletcher, 1997).

15.2.3.3. Marine Fisheries

Climate-related variations in marine/coastal environments are now recognized as playing an important role in determining the productivity of several North American fisheries. For example, large changes in species abundance and ecosystem dynamics off the coast of California have been associated with changes in sea-surface temperatures (SSTs), nutrient supply, and circulation dynamics (Ebbesmeyer *et al.*, 1991; Roemmich and McGowan, 1995; Bakun, 1996). Similar relationships have been observed in the Bering Sea, the northeastern Pacific, and the Gulf of Alaska (Polovina *et al.*, 1995; Ware, 1995; Shuntov *et al.*, 1996; Beamish *et al.*, 1997; Downton and Miller, 1998; Francis *et al.*, 1998; Beamish *et al.*, 1999a, 2000) and in the North Atlantic (Atkinson *et al.*, 1997; Sinclair *et al.*, 1997; Hofmann and Powell, 1998). In the Gulf of Mexico, variations in freshwater discharge affect harvests of some commercially important species (Hofmann and Powell, 1998). Projected climate changes have the potential to affect coastal and marine ecosystems through changes in coastal habitats, upwelling, temperature, salinity, and current regimes. Such changes may affect the abundance and spatial distribution of species that are important to commercial and recreational fisheries (Boesch *et al.*, 2000).

Fishery management involves the difficult task of maintaining viable fish populations in the presence of difficult-to-predict shifts in resource availability, while regulating competition among harvesters for access to publicly managed, common-property fishery resources (McKay, 1995; Fujita *et al.*, 1998; Myers and Mertz, 1998; Roughgarden, 1998). Attainment of management objectives may be confounded by the fact that some fish stocks tend to fluctuate widely from year to year. These fluctuations may arise from natural causes that are unrelated to fishing pressure or be exacerbated by harvesting. The exact cause of a sudden shift in abundance often is poorly understood. Climate variations often play a role in natural fluctuations, although their role may be complex and indirect. For example, a climatic variation may affect phytoplankton and zooplankton abundance in some part of the ocean, with cascading effects through a chain of predator-prey relationships (Bakun, 1996). These processes may result in multiple and lagged impacts on the abundance of a harvested species. Because it is difficult to identify and predict such effects, climate variability constitutes a significant source of uncertainty for fishery managers.

The potential impacts of climate change on fish populations are equally difficult to predict. Some work has focused on the direct impacts of warmer temperatures on marine species (e.g., Wood and McDonald, 1997; Welch *et al.*, 1998a,b). However, Bakun (1996) notes that climate variables that are important on land (e.g., temperature and precipitation) may be relatively unimportant for organisms that live in the ocean. He identifies three basic processes (enrichment, concentration, and transport/retention) that influence the productivity and spatial distribution of marine fish populations but notes that very little is known regarding how these will change with global climate change.

Efforts to assess the impacts of climate change on the U.S. fishery sector are severely hampered by our current lack of understanding of possible changes in fish populations. Markowski *et al.* (1999) performed a sensitivity analysis that examined the potential economic impacts of hypothetical changes in the abundance of selected fish populations, but the analysis is too hypothetical for use here.

Uncertainty regarding the magnitude and sources of variations in fish stocks also creates political stumbling blocks to effective fisheries management. Within single jurisdictions, competing harvesters and gear groups vie for shares of a "pie" whose dimensions are imperfectly known. In the case of international fisheries, cooperative harvesting agreements often have degenerated into mutually destructive fish wars when expectations have been upset by unforeseen changes in abundance or the spatial pattern of availability (McKelvey, 1997). For example, the Pacific Salmon Treaty foundered for several years because declining runs of southern coho and chinook salmon and increasing salmon abundance in Alaskan waters frustrated efforts to achieve a mutually acceptable balance of U.S. and Canadian interceptions of one another's salmon stocks (Munro *et al.*, 1998; Miller, 2000a).

Accounts of the collapse of cod stocks off Newfoundland on Canada's east coast have cited the inability of governments to effectively control fishing pressure and a natural shift to less favorable environmental conditions (Hutchings and Myers, 1994; Sinclair *et al.*, 1997; Hofmann and Powell, 1998). This case suggests that sustainable fisheries management will require timely and accurate scientific information on the environmental conditions that affect fish stocks and institutional flexibility to respond quickly to such information.

The western U.S.-Mexican border region is located between subtropical and mid-latitude ocean regions. Variations in temperature in this transition zone result in major fluctuations in fisheries productivity (Lluch *et al.*, 1991). In recent decades, this region of the Pacific has shown a trend toward warming and changes in regional productivity, independent of overexploitation. In a global warming scenario, the sardine population may decrease along the U.S.-Mexican Pacific Ocean border region, whereas the shrimp population may increase. Interdecadal natural climate variability, however, appears to be the most important sardine population modulator (Lluch-Cota *et al.*, 1997).

Available evidence suggests that there are likely to be impacts on fisheries arising, for example, from changes in current dynamics, temperature-dependent distribution, and food web dynamics. These impacts will be variable across species and locations and are difficult to forecast with any precision. Because the effects of exploitation and environmental change can be synergistic, it will be increasingly important to consider changing environmental conditions in future fisheries management (Boesch *et al.*, 2000; see Chapter 6 for further discussion).

15.2.4. Human Health

Global climate change would disturb the Earth's physical systems (e.g., weather patterns) and ecosystems (e.g., disease vector habitats); these disturbances, in turn, would pose direct and indirect risks to human health. Direct risks involve climatic factors that impinge directly on human biology. Indirect risks do not entail direct causal connections between climatic factors and human biology (McMichael, 1996; McMichael *et al.*, 1996). Health care will significantly help people to adapt to climate change. Unfortunately, not everyone has adequate health care; for example, in 1996, nearly 18% of Americans did not have access to a doctor's office, clinic, health center, or other source of health advice or treatment (Miller *et al.*, 2000).

15.2.4.1. Potential Direct Health Impacts of Climate Change

15.2.4.1.1. Health impacts of thermal extremes

In a warmer world, heat waves are expected to become more frequent and severe, with cold waves becoming less frequent (Kattenberg *et al.*, 1996). Increased frequency and severity of heat waves may lead to an increase in illness and death, particularly among the young (CDC, 1993), the elderly (Ramlow and Kuller, 1990; CDC, 1993; Semenza, 1999; Patz *et al.*, 2000), the poor (Schuman, 1972; Applegate *et al.*, 1981), the frail and the ill, and those who live in the top floors of apartment buildings and lack access to air conditioning (Patz *et al.*, 2000), especially in large urban areas (CDC, 1989; Grant, 1991; Canadian Public Health Association, 1992; Kalkstein, 1993, 1995; Kalkstein and Smoyer, 1993a,b; Canadian Global Change Program, 1995; Environment Canada, 1995; Guidotti, 1996; Kalkstein *et al.*, 1996a,b; Tavares, 1996; Last *et al.*, 1998). Other vulnerable people are those who take medications that affect the body's thermoregulatory ability (Marzuk *et al.*, 1998; Patz *et al.*, 2000).

Heat waves affect existing medical problems, not just those related to problems of the respiratory or cardiovascular systems (Canadian Global Change Program, 1995). Morbidity—such as heat exhaustion, heat cramps, heat syncope or fainting, and heat rash—also results from heat waves (Shriner and Street, 1998; Patz *et al.*, 2000).

In the United States, populations in northeastern and midwestern cities may experience the greatest number of heat-related illnesses and deaths in response to increased summer temperatures (Patz *et al.*, 2000). Recent episodes include the heat-related deaths of 118 persons in Philadelphia in 1993 (CDC, 1993), 91 persons in Milwaukee in 1995, and 726 persons in Chicago in 1995 (CDC, 1995; Phelps, 1996; Semenza *et al.*, 1996, 1999). This follows several episodes in the 1980s, particularly in 1980, 1983, and 1988 (CDC, 1995).

In Canada, urbanized areas in southeastern Ontario and southern Quebec could be “impacted very negatively” by warmer temperatures. An “average” summer in 2050 could result in 240–1,140 additional heat-related deaths yr^{-1} in Montreal,

230–1,220 in Toronto, and 80–500 in Ottawa, assuming no acclimatization (Kalkstein and Smoyer, 1993b). The significance of these estimates is demonstrated by the fact that a total of only 183 Canadians died as a result of excessive heat for the years 1965–1992 (Duncan *et al.*, 1998). Heat-related illness and death are largely preventable through behavioral adaptations, such as use of air conditioners and increased intake of fluids. In the United States, use of air conditioning is expected to become nearly universal by the year 2050 (U.S. Census Bureau, 1997a,b). Other adaptive measures include development of community-wide heat emergency plans, improved heat warning systems, and better heat-related illness management plans (Patz *et al.*, 2000).

Finally, it is important to note that in a warmer world, cold waves are expected to become less frequent. For example, in Saskatoon, Canada, the number of January days with temperature below -35°C could decrease from the current average of 3 days yr^{-1} to 1 day every 4 years (Hengeveld, 1995). Currently, more people die of cold exposure than heat waves. Therefore, an expected decrease in cold waves is likely to have a beneficial effect—a decrease in weather-related mortality.

15.2.4.1.2. Health impacts of extreme weather events

It has been postulated that there will be increases in the frequency and severity of extreme events, which may result in an increase in deaths, injuries, toxic contamination or ingestion, infectious diseases, and stress-related disorders, as well as other adverse health effects associated with social disruption, environmentally forced migration, and settlement in poorer urban areas (McMichael *et al.*, 1996). Adaptive measures to counter the health impacts of extreme events include improved building codes, disaster policies, warning systems, evacuation plans, and disaster relief (Noji, 1997).

15.2.4.1.2.1. Convective storms

There is some evidence of increases in the intensity or frequency of some extreme events at regional scales throughout the 20th century. Frequencies of heavy precipitation events have been increasing in the United States and southern Canada (Easterling *et al.*, 2000). Unfortunately, it is difficult to predict where these storms will occur and to identify vulnerable populations. In 1997, severe storms caused 600 deaths and 3,799 reported injuries in the United States.

Patients with specific allergies to grass pollen are at risk of thunderstorm-related asthma (Venables *et al.*, 1994; Celenza *et al.*, 1996; Hajat *et al.*, 1997; Knox *et al.*, 1997; Suphioglu, 1998). Thunderstorm-associated asthma epidemics in Melbourne, Australia (1987/1989), and London, England (1994), placed considerable demands on the health system. Several London health departments ran out of drugs, equipment, and doctors (Davidson *et al.*, 1996). It is unclear if this situation could arise in North America.

15.2.4.1.2.2. Floods

Floods also may become more frequent (see Section 15.2.1.3). All rivers are susceptible to flooding, and nearby populations are potentially vulnerable. In the United States, floods are the most frequent natural disaster, as well as the leading cause of death from natural disasters. The mean annual loss of life is estimated to be 146 deaths yr^{-1} (National Weather Service, 1992; Patz *et al.*, 2000). In 1997, the Canadian Red River flood displaced more than 25,000 people (Francis and Hengeveld, 1998; Manitoba Water Commission, 1998).

During a flood, disaster relief workers may be at risk of injury. For example, 119 injuries were identified from medical claims of people engaged in sandbagging activities in the 1993 Midwest floods. Heat-related injury or illness (HRI), which occurs when the body can no longer maintain a healthy core temperature, was the most frequently reported injury diagnosis; a total of 23 HRI (19.3% of the 119 total injuries) were reported (Dellinger *et al.*, 1996). HRI therefore is a potential problem in disaster relief situations, particularly if high ambient temperature and high humidity exist. Following a flood, flood victims may be at risk of post-traumatic stress disorder (PTSD) and depression, which are risk factors for suicide. Krug *et al.* (1998) showed that suicide rates increased from 12.1 to 13.8 per 100,000 population in the 4 years after floods. Inundations of sites that contain toxic wastes, sewage, animal wastes, or agrochemical products may result in immediate human exposure to wastes from floodwaters, contamination of edible fish, and long-term contamination of flooded living structures (see Sections 15.2.1.3 and 15.2.4.2.2).

15.2.4.1.2.3. Hurricanes

Climate models currently are unable to project accurately how hurricanes will change in the future. Today, an average of two hurricanes make landfall each year along the coastline of the continental United States (Hebert *et al.*, 1993). There has been considerable interdecadal variability in the number of landfalling hurricanes in the United States (Pielke and Pielke, 1997). The Federal Emergency Management Agency (FEMA) declared fewer than 20 natural disasters annually in the 1950s and 1960s but more than 40 yr^{-1} in the 1990s (Miller *et al.*, 2000). Hurricanes' strong winds and heavy rains cause injury, death, and psychological disorders (Logue *et al.*, 1979; Patz *et al.*, 2000). A total of 20–30% of adults who lived through Hurricane Andrew showed evidence of PTSD at 6 months and 2 years after the event (Norris *et al.*, 1999).

15.2.4.1.2.4. Ice Storms

Milder winter temperatures will decrease heavy snowstorms but could cause an increase in freezing rain if average daily temperatures fluctuate about the freezing point. It is difficult to predict where ice storms will occur and identify vulnerable populations. The ice storm of January 1998 (see Section 15.3.2.6)

left 45 people dead and nearly 5 million people without heat or electricity in Ontario, Quebec, and New York (CDC, 1998; Francis and Hengeveld, 1998; Kerry *et al.*, 1999). The storm had a huge impact on medical services and human health. Doctors' offices were forced to close, and a large number of surgeries were cancelled (Blair, 1998; Hamilton, 1998). One urban emergency department reported 327 injuries resulting from falls in a group of 257 patients (Smith *et al.*, 1998b).

15.2.4.1.2.5. Tornadoes

Although some evidence is available regarding increases in the intensity and frequency of some extreme weather events, it is not yet clear how tornadoes will be affected. The tornado of July 31, 1987, in Edmonton, Alberta, killed 27 people and injured 253 (Etkin *et al.*, 1998). Trends in the United States appear to show a decreasing number of deaths since the 1950s, although data on the number of events causing deaths do not show a trend (Kunkel *et al.*, 1999). Godleski (1997) reports that persons who endure tornadoes often experience a variety of stress responses, including depression, acute and post-traumatic stress disorders, substance abuse, anxiety, and somatization.

15.2.4.2. Potential Indirect Health Impacts of Climate Change

15.2.4.2.1. Vector-borne diseases

15.2.4.2.1.1. Encephalitis

In the midwestern United States, outbreaks of St. Louis encephalitis (SLE) appear to be associated with a sequence of warm, wet winters; cold springs; and hot, dry summers (Monath, 1980). In the western United States, a 3–5°C increase in mean temperature may cause a northern shift in the distribution of western equine encephalitis (WEE) and SLE outbreaks and a decrease in the range of WEE in southern California (Reeves *et al.*, 1994). In Canada, the ranges of eastern equine encephalitis (EEE), snowshoe hare virus (SHV), and WEE probably would expand with global warming. All three already have been reported in Canada or adjacent U.S. states, albeit sporadically (McLean *et al.*, 1985; Artsob, 1986; Tourangeau *et al.*, 1986; Keane and Little, 1987; Heath *et al.*, 1989; Carman *et al.*, 1995; Duncan *et al.*, 1998).

15.2.4.2.1.2. Malaria

In the United States, sporadic autochthonous malaria transmission was observed in New York and New Jersey during the 1990s (Layton *et al.*, 1995; Zucker, 1996). Malaria is imported into Canada, however.

According to studies by Martens *et al.* (1995), Martin and Lefebvre (1995), and Duncan (1996), with global warming, malaria may extend northward into temperate countries. These studies note, however, that many of these countries had regular

epidemics of malaria in the 19th century and the first half of the 20th century and that continued and increased application of control measures—such as water management, disease surveillance and prompt treatment of cases—probably would counteract any increase in vectorial capacity.

Malaria once prevailed throughout the United States and southern Canada (Bruce-Chwatt, 1988). As recently as 1890, the census recorded more than 7,000 malaria deaths per 100,000 people across the American South and more than 1,000 malaria deaths per 100,000 people in states such as Michigan and Illinois. It is important to note that diagnoses and reporting did not meet today's standards. By 1930, malaria had been controlled in the northern and western United States and generally caused fewer than 25 deaths per 100,000 people in the South. In 1970, the World Health Organization (WHO) Expert Advisory Panel on Malaria recommended that the United States be included in the WHO official register of areas where malaria had been eradicated.

In Canada, vivax malaria became widespread at the end of the 18th century, when refugees from the southern United States settled in large numbers as far north as “the Huron” in the aftermath of the American War of Independence. Malaria was further spread with the building of the Rideau Canal (1826–1832) (Duncan, 1996). By the middle of the 19th century, malaria extended as far north as 50°N. In 1873, the great malarious district of western Ontario was only a fraction of a large endemic area, extending between Ontario and the state of Michigan. In Canada, the disease disappeared at the end of the 19th century (Bruce-Chwatt, 1988; Haworth, 1988; Duncan, 1996).

The history of malaria in North America underscores the fact that increased temperatures may lead to conditions that are suitable for the reintroduction of malaria to North America. Socioeconomic factors such as public health measures will continue to play a large role in determining the existence or extent of such infections (Shriner and Street, 1998).

15.2.4.2.1.3. Dengue and Yellow Fever

Although the *Aedes aegypti* mosquito already is found in the southern United States, socioeconomic factors play a large role in determining the actual risk of climate-sensitive diseases (see Chapter 9). For example, socioeconomic differences between Texas and bordering Mexico determine disease incidence: A total of 43 cases of dengue were recorded in Texas during 1980–1996, compared to 50,333 in the three contiguous border states in Mexico (Reiter, 1999).

15.2.4.2.1.4. Lyme Disease and Rocky Mountain Spotted Fever

Lyme disease—the most common vector-borne disease in the United States—currently circulates among white-footed mice in woodland areas of the Mid-Atlantic, Northeast, upper Midwest, and West Coast of the United States (Gubler, 1998). In 1994, more than 10,000 cases of the disease were reported

(Shriner and Street, 1998). Although possible tick vectors have been reported in various parts of Canada, self-reproducing populations of infected ticks are believed to occur only in Long Point, Ontario (Barker *et al.*, 1992; Duncan *et al.*, 1998). Lyme disease has been predicted to spread within Canada with increased temperatures (Grant, 1991; Canadian Global Change Program, 1995; Environment Canada, 1995; Guidotti, 1996; Hancock and Davies, 1997). However, in assessing climate-induced risks for Lyme disease, the ecology of two mammalian species along with projections for land use make predictions very difficult (see Chapter 9). Finally, Grant (1991) has suggested that, with warming, Rocky Mountain Spotted Fever might increase in some localities in Canada.

15.2.4.2.2. Rodent-borne diseases

15.2.4.2.2.1. Hantavirus

In 1993, Sin Nombre virus, which causes hantavirus pulmonary syndrome (HPS), emerged in the Four Corners region of the southwestern United States. Unusually prolonged rainfall associated with the 1991–1992 El Niño was implicated as a causal factor in the outbreak (Engelthaler *et al.*, 1999; Glass *et al.*, 2000). As of 1999, 231 cases had been confirmed in the United States, with a mortality rate of 42% (Patz *et al.*, 2000). A total of 16 cases of HPS have been identified in Canada. These cases occurred in British Columbia, Alberta, and Saskatchewan (Stephen *et al.*, 1994; Werker *et al.*, 1995; Duncan *et al.*, 1998).

HPS could undergo changes in occurrence related to increased contacts between rodents and people. Because the virus is present in rodents in the United States and Canada and changes in climate and ecology are known to affect rodent behavior, it is assumed that changes in the incidence of HPS would result with global warming (Duncan *et al.*, 1998), but they will be difficult to predict because of local rainfall variability.

Adaptive measures to reduce the risks of contracting vector- and rodent-borne diseases include providing information, vaccination, and drug prophylaxis for travellers, as well as use of repellants, surveillance, and monitoring (Patz *et al.*, 2000).

15.2.4.2.2.2. Diseases associated with water

More than 200 million people in the United States have direct access to treated public water supply systems. Nevertheless, 9 million cases of water-borne diseases are estimated to occur each year (Bennett *et al.*, 1987). Although most of the water-borne disease involves mild gastrointestinal illness, some disease causes severe outcomes, such as myocarditis (Patz *et al.*, 2000).

Giardia occurs in American and Canadian watersheds, resulting in widespread human exposure (Schantz, 1991; Chow, 1993; Moore *et al.*, 1993; Wallis *et al.*, 1996; Olson *et al.*, 1997;

Duncan *et al.*, 1998). A study of 1,760 water samples from 72 municipalities across Canada showed that giardia cysts were found in 73% of the raw sewage samples, 21% of the raw water samples, and 18.2% of the treated water samples (Wallis *et al.*, 1996). Cryptosporidium—considered to be one of the most common enteric pathogens worldwide (Meinhardt *et al.*, 1996)—is less common in Canada than giardia cysts, however. Cryptosporidium was found in only 6.1% of raw sewage samples, 4.5% of raw water samples, and 3.5% of treated water samples (Wallis *et al.*, 1996).

Increases in ambient temperatures, a prolonged summer season, increased heavy rainfall and/or runoff events, and many watersheds with mixes of intensive agriculture and urbanization led to recent large outbreaks of cryptosporidium in the United States (MacKenzie *et al.*, 1994; Goldstein *et al.*, 1996; Osewe *et al.*, 1996) and the UK (Bridgeman *et al.*, 1995) and may be indicative of the future. In 1993, more than 400,000 cases (including 54 deaths) resulted from a cryptosporidium outbreak in the Milwaukee, Wisconsin, water supply (MacKenzie *et al.*, 1994). A positive correlation between rainfall, cryptosporidium oocyst and giardia cyst concentrations in river water, and human disease outbreaks has been noted (Weniger *et al.*, 1983).

The largest ever reported outbreak of toxoplasmosis was traced to the municipal water supply of the greater Victoria area of British Columbia (British Columbia Toxoplasmosis Team, 1995; Den Hollander and Noteboom, 1996; Mullens, 1996; Bowie *et al.*, 1997; Duncan *et al.*, 1998). There already is evidence that exposure to the causative parasite in Canada is widespread (Tizard *et al.*, 1977, 1978). Given the increasing number of feral cats in Canada and the persistence of sporulated oocysts in a variety of environments (Dubey and Beattie, 1988), areas in Canada that are hospitable to oocyst survival are likely to expand as a result of climate change.

Warm marine water may favor growth of toxic organisms such as red tides, which cause three varieties of shellfish poisoning: paralytic, diarrheic, and amnesic. Domoic acid—a toxin produced by the *Nitzchia pungens* diatom that causes amnesic shellfish poisoning—appeared on Prince Edward Island for the first time in 1987. A total of 107 patients were identified, of whom 19 were hospitalized. Of those requiring hospitalization, 12 people required intensive care because of coma, profuse respiratory secretions, or unstable blood pressure. A total of four people died as a result of eating contaminated mussels (Perl *et al.*, 1990). The outbreak coincided with an El Niño year, when warm eddies of the Gulf Stream neared the shore and heavy rains increased nutrient-rich runoff (Glavin *et al.*, 1990; Perl *et al.*, 1990; Teitelbaum *et al.*, 1990; Hatfield *et al.*, 1994; Shriner and Street, 1998). In the United States, marine-related illness increased during El Niño events over the past 25 years. During the strong El Niño event of 1997–1998, precipitation and runoff greatly increased counts of fecal bacteria and viruses in local coastal waters in Florida (Harvell *et al.*, 1999). Contamination of water bodies by animal and human wastes can stimulate harmful algae such as *Pfiesteria* that have been

demonstrated to cause illness in humans and death in some species of fish (Burkholder *et al.*, 2000).

Potential adaptive measures to reduce water-borne disease include improved water safety criteria, monitoring, treatment of surface water, and sewage/sanitation systems (Patz *et al.*, 2000). Land-use management should include consideration of water supply and quality.

15.2.4.2.3. Respiratory disorders

In 1997, approximately 107 million people in the United States lived in counties that did not meet air quality standards for at least one regulated pollutant (Patz *et al.*, 2000). Climate change increases smog (NRC, 1991; Sillman and Samson, 1995; USEPA, 1998a; Patz *et al.*, 2000) and acidic deposition. Climate change is likely to have a positive (worsening) effect on suspended particulates (Maarouf and Smith, 1997). These changes would have an impact on human health. However, at this time there are too few studies on the effect climate change will have on all pollutants to project human health impacts. Studies (Bates and Sitko, 1987, 1989; Tseng *et al.*, 1992; Burnett *et al.*, 1994; Delfino *et al.*, 1994, 1997; Schwartz, 1994; Thurston *et al.*, 1994) have demonstrated that hospital admissions for respiratory illnesses are increased during contemporary air pollution episodes, when levels of ozone, acid aerosols, or particulates are elevated (Campbell *et al.*, 1995).

Adaptive measures to changing pollution levels include federal legislation and warnings for the general population and susceptible individuals (Patz *et al.*, 2000).

15.2.4.2.3.1. Smog

More than half of all Canadians live in areas in which ground-level ozone may reach unacceptable levels during the summer months (Duncan *et al.*, 1998). Peak 1-hour concentrations during typical pollution episodes in the Windsor-Quebec City corridor often reach 150 ppb. Windsor exceeds standards for ozone air quality (82 ppb) 30 days yr⁻¹ on average. In the Lower Fraser Valley, ozone concentrations typically are in the 90–110 ppb range during pollution episodes. In the Southern Atlantic region, peak hourly ozone concentrations are in the 90–150 ppb range (Duncan *et al.*, 1998).

Two expert panels from the Canadian Smog Advisory Program have listed a wide range of health effects of ground-level ozone at levels that plausibly may occur in Canada. These effects include pulmonary inflammation, pulmonary function decrements, airway hyper-reactivity, respiratory symptoms, possible increased medication use and physician/emergency room visits among individuals with heart or lung disease, reduced exercise capacity, increased hospital admissions, and possible increased mortality (Stieb *et al.*, 1995). The panels conceptualized potential health effects of air pollution as occurring in a logical “cascade” or

"pyramid," ranging from severe, uncommon events (e.g., death) to mild, common effects (e.g., eye, nose, and throat irritation) and asymptomatic changes of unclear clinical significance (e.g., small pulmonary function decrements and pulmonary inflammation) (American Thoracic Society, 1985; Bates, 1992).

Healthy persons can demonstrate effects from ozone exposure when they have an increased respiratory rate (e.g., when they are involved in strenuous activities outdoors) (Brauer *et al.*, 1996). Ozone may pose a particular health threat, however, to those who already suffer from respiratory problems such as asthma, emphysema, or chronic bronchitis (Stieb *et al.*, 1996). These three conditions affect about 7.5% of the Canadian population (Ontario Lung Association, 1991). Ozone also may pose a health threat to young, elderly, and cardiovascular patients (Duncan *et al.*, 1998). An increase in smog also would pose a greater risk to African Americans, who have consistently higher rates of deaths and emergency room visits than caucasians (Mannino *et al.*, 1998).

15.2.4.2.3.2. Acidic deposition

Acidic aerosols—such as sulfur dioxide (SO_2), sulfates, and nitrogen dioxide (NO_2)—have a colloidal affinity to fine particulates, which provide the vector needed to penetrate deeply into the distal lung and airspaces. In general, NO_2 and SO_2 have acute negative impacts on the respiratory system (Campbell *et al.*, 1995).

Several studies (Bates and Sitzo, 1987, 1989; Tseng *et al.*, 1992; Burnett *et al.*, 1994; Delfino *et al.*, 1994; Schwartz, 1994; Thurston *et al.*, 1994) have demonstrated that hospital admissions for respiratory illnesses increase during contemporary air pollution episodes when levels of ozone, acid aerosols, or particulates are elevated (Campbell *et al.*, 1995). A study by Raizenne *et al.* (1996) that examined the health effects of acid aerosols on children living in 24 communities in the United States and Canada found that long-term exposure had a deleterious effect on lung growth, development, and function. Dockery *et al.* (1996) found that children living in communities with the highest levels of strong particle acidity were significantly more likely to report at least one episode of bronchitis in the past year compared to children living in the least polluted communities.

15.2.4.2.3.3. Suspended particulates

Fine particulates are associated with respiratory symptoms, airway hyperreactivity, impaired lung function, reduced exercise capacity, pulmonary inflammation, pulmonary function decrements, increased number of emergency room visits for asthma, increased hospitalizations, increased absence from school or work, and increased mortality from cardiopulmonary disease and lung cancer. Children, the elderly, smokers, asthmatics, and others with respiratory disorders are especially vulnerable to particulate air pollution (Stieb *et al.*, 1995; Seaton, 1996; Choudry *et al.*, 1997; Duncan *et al.*, 1998; USEPA, 1998a).

15.2.4.2.4. Nutritional health

In the United States, food-borne diseases are estimated to cause 76 million cases of illness annually, with 325,000 hospitalizations and 5,000 deaths (Mead *et al.*, 1999). Future food importations are likely to be associated with increases in outbreaks of some viral, parasitic, and bacterial diseases, such as hepatitis A (Duncan *et al.*, 1998).

Many aboriginal communities undertake hunting, fishing, and other resource-based activities for subsistence. Climate change is likely to dramatically alter the abundance and distribution of wildlife, fish, and vegetation. As a result, food supplies and economic livelihoods of many First Nations peoples would be in jeopardy (Last *et al.*, 1998; Weller and Lange, 1999). Disappearance of traditional medicinal plants from areas populated by Native American and other indigenous peoples may likewise affect physical, mental, and spiritual well-being.

15.2.5. Human Settlements and Infrastructure

Large metropolitan centers and industrial areas are particularly vulnerable to global environmental change (Schmandt and Clarkson, 1992). Large cities are considered to be areas of high risk because warming could lead to problems such as heat stress, water scarcity, and intense rainfall. Other potential impacts vary with location. In Canada and the northern United States, for example, people in larger cities are expected to experience fewer periods of extreme winter cold (Born, 1996). Many coastal communities will be affected by rising sea levels and increased risk of storm surge, but the impacts will differ because of variations in local and regional factors (Nicholls and Mimura, 1998). Most people in North America live in land that now is considered coastal and subject to coastal weather extremes. This sector of the urban population is growing faster than the population as a whole—a trend that is expected to continue (Boesch *et al.*, 2000). Indeed, "25 percent of the buildings within 500 feet of U.S. coastlines are predicted to fall victim to erosion in the next six decades" (Associated Press, 2000). Cities that are vulnerable to regular flooding may experience changes in the timing, frequency, and severity of this hazard (Weijers and Vellinga, 1995). In addition, the risk of increased periods of drought will be a challenge, particularly for communities that already are struggling to cope with water management issues. Overall, climate change should reduce vulnerability to some hazards such as cold waves but increase it with respect to others such as sustained periods of extreme heat.

15.2.5.1. Demographic Pressures

The number of people in North America increased from 83 million in 1901 to 301 million in 1998 (Statistics Canada, 1999a; U.S. Census Bureau, 1999b). The number living in large urban communities of more than 750,000 people increased over this period from 6 million to more than 140 million. A higher share of the population in North America lives in large urban centers

(45% in 1995) than in any other region of the world (UNDP, 1999). These large population centers may be vulnerable to climate change.

Aging of the population is another important demographic trend in North America. Europe and Japan currently are adapting to an aging of the population that is just emerging in North America. These demographic trends also appear in native communities with individuals living to older ages: Elderly people who have lived away from reservations may return home for retirement. An older population typically is more vulnerable to climate extremes (McMichael, 1997).

15.2.5.2. Infrastructure Investments in Adaptation

Many systems have the potential to be impacted negatively by climate change, including drainage and water systems, roads and bridges, and mass transit (Miller, 1989). Communities can reduce their vulnerability and increase their resilience to adverse impacts from climate change through investments in adaptive infrastructure (Bruce *et al.*, 1999a).

Across North America, however, government spending on public infrastructure has been declining for some time, measured as a share of economic activity. Almost 3.5% of GDP was spent on a broad range of infrastructure projects in the early 1960s, compared to less than 2% in the 1990s (Statistics Canada, 1999b; USBEA, 1999).

Sustained lower spending has increased society's vulnerability to some hazards. The American Society of Civil Engineers, for example, has warned that many dams in the United States have exceeded their intended lifespan (Plate and Duckstein, 1998). More than 9,000 regulated dams have been identified as being at high risk of failing, and there may be significant loss of life and property from future failures.

Highways, bridges, culverts, residences, commercial structures, schools, hospitals, airports, coastal ports, drainage systems, communications cables, transmission lines, and other infrastructure have been built on the basis of historical climate experience (Bruce *et al.*, 1999a). Similarly, land-use practices and building codes have been developed to provide effective protection from the existing climate. Emerging knowledge about future climate pressures was not available when most investment decisions were made. This includes, for example, recent research into actions that can be taken to protect underground transit systems from the increased risk of intense rainfall and subsequent flooding (Liebig, 1997). Furthermore, building codes have been modified frequently over the years to reflect emerging information about safer construction techniques, but these changes have not been applied to existing structures.

Coastal communities have developed a variety of systems to manage exposure to erosion, flooding, and other hazards affected by rising sea levels, but some of these systems have not been maintained—increasing the difficulty of putting in place

enhancements to address future risk. Similarly, consideration of investments in larger diameter storm sewers in communities that expect more periods of intense rainfall may be affected by the age of existing systems (Fowler and Hennessey, 1995; Trenberth, 1998). Urban expansion and population growth further complicate decisionmaking with respect to infrastructure investments.

15.2.5.3. Coastal Regions Particularly Vulnerable

The prospect of rising sea level is one of the most widely recognized potential impacts of climate change. Some parts of North America have been experiencing sea-level rise for thousands of years (Hendry, 1993; Lavoie and Asselin, 1998). Most climate models, however, project that the pace will accelerate in many regions. This acceleration would increase the difficulty of adaptation for human settlements and natural systems. The greatest vulnerability is expected in areas that recently have become much more developed, such as Florida and much of the U.S. Gulf and Atlantic coasts. Insured property value in Florida alone exceeds US\$1 trillion (Nutter, 1999).

Titus and Richman (2001) have developed a data set of coastal land elevations by using digital-elevation models and printed topographic maps to determine areas that are vulnerable to sea-level rise along the U.S. Atlantic and Gulf coasts. Louisiana, Florida, Texas, and North Carolina account for more than 80% of the 58,000 km² that are vulnerable to sea-level rise.

Rising sea levels, in turn, can cause increased erosion to shores and habitat and may contaminate some freshwater bodies with salt (Mason, 1999). Climate extremes, such as hurricanes, can add to the adverse impact (Michener *et al.*, 1997). Sea-level rise and climate and weather extremes cause problems associated with beach erosion, siltation of waterways, and flood risk in coastal communities (Hanson and Lindh, 1996; Leatherman, 1996).

More than 65% of people in North America live in coastal communities (Changnon, 1992; see also Figure 15-2). This includes those who live near the Atlantic or Pacific oceans as well as those near the Great Lakes, where the impact of climate change is very different (see Sections 15.2.1 and 15.3.2.5). Accordingly, there is vulnerability across most of the region. Particular concern arises with regard to the combination of sea-level rise with other risks, such as storm surge. Salt intrusion and frequent flooding may adversely impact farming and manufacturing activity in low-lying areas (Gough and Grace, 1998).

Tourism frequently is the major industry in many coastal communities. The risk of beach erosion, siltation, and flooding may become an important challenge for some existing tourism sites, yet these same changes may open new opportunities for some other communities. Tourism has been and will continue to be affected by beach closures resulting from coliform from septic systems and sewage outflows during and following

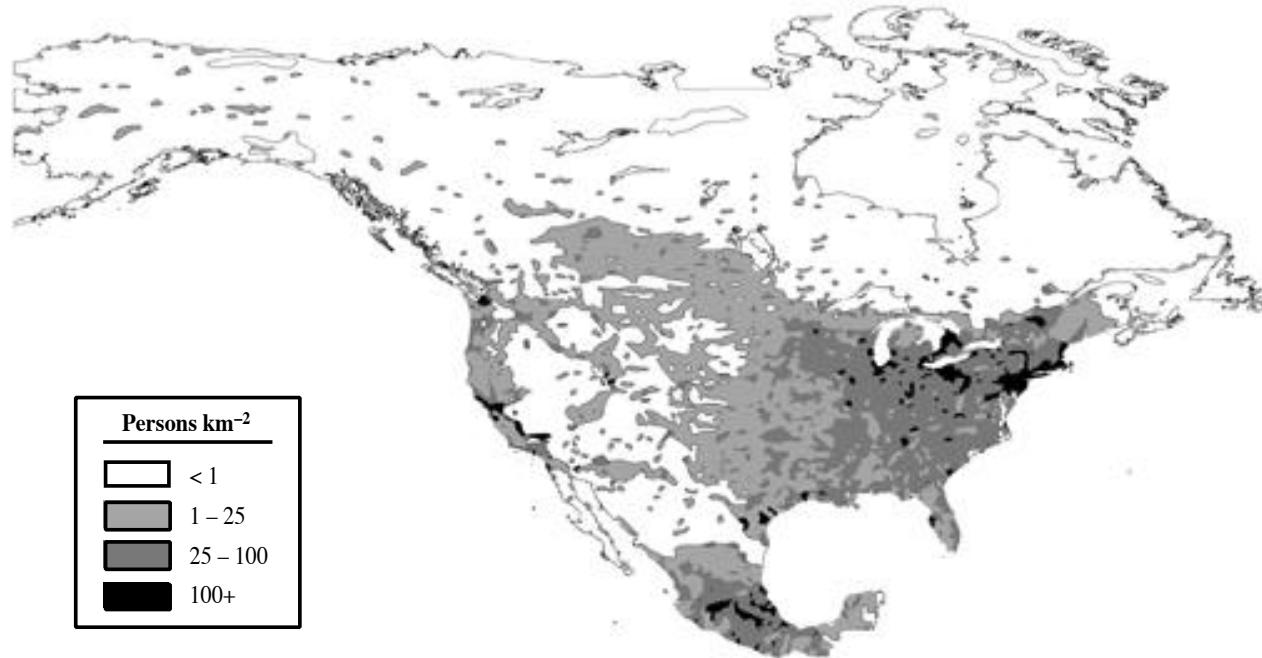

Figure 15-2: North American population density (ESRI, 1998).

storms and extreme events (see also Section 15.2.6). Sea-level rise also will be an important challenge for major ports in many parts of North America.

A study of the impact on the United States of the increase of sea levels through 2065 found losses of US\$370 million for dryland, US\$893 million for wetlands, and US\$57–524 million in transient cost (Yohe *et al.*, 1999). This estimate is much lower than those of earlier U.S. studies because of assumed adaptation responses, including decisions not to protect certain areas. No comparable information is available for Canada, although several vulnerable areas have been identified—particularly the Fraser River delta, Nova Scotia, and the Beaufort Sea region (Shaw *et al.*, 1998).

15.2.5.4. Vulnerability to System Failure

Investments in summer cooling, winter heating, and shelter from the elements are common for most people and businesses in North America. Similar investments are evident around the world, but the scope and scale often is greater in North America. For example, the percentage of homes with air conditioning units in the United States increased from 35% in 1970 (U.S. Census Bureau, 1975) to 76% in 1997 (U.S. Census Bureau, 1999a). Similarly, more vehicles, schools, hospitals, and businesses now have climate control mechanisms. Even traditional tasks have changed, such as air-conditioned cabs on farm vehicles.

The trend of warming across North America should reduce the cost of heating and the cost of investing in heating systems. At

the same time, demand for summer cooling is expected to rise. In turn, changes in the weather affect demand for power: Peak demand for electricity is strongly correlated to swings in summer temperature (Colombo *et al.*, 1999).

Investments to manage normal fluctuations in the weather presumably have been effective in increasing the comfort of people in North America. These investments, however, also have increased vulnerability to systems failure. This could become most evident for most people in North America during a summer heat wave or a winter storm, when a failure in major support systems could place many people at risk. For example, in January 1998, a severe ice storm caused a power failure in Quebec and eastern Ontario (see Section 15.3.2.6).

A similar investment is in human alteration of hydrological drainage systems, including building of dikes, which may be an important factor in determining the severity of flooding (Changnon and Demissie, 1996). These interventions appear to be successful in managing most variations in the weather, but they can increase vulnerability to extreme events as new investments are made in regions that were thought to be sheltered from severe weather.

15.2.5.5. Development and Vulnerability to Extreme Events

The cost of natural disasters in North America has increased dramatically since the mid-1980s, in spite of the goal of the International Decade for Natural Disaster Reduction (the 1990s) to reduce the costs of natural disasters by 50% by the year 2000. Although an increase in the number of storms may

play a role in these disasters, there is no question that the increasing costs are largely the result of increased vulnerability (Pielke and Downton, 2000).

Natural disasters occur when social vulnerability is triggered by a natural event (see Figure 15-3). Society responds to a disaster through three overlapping activities: response and recovery, mitigation, and preparedness. These activities alter future vulnerability (and therefore the construct of future disasters)—reducing risk if they are done wisely, or not if they are done otherwise. Often, however, mitigation that is designed to protect against natural hazards increases long-term vulnerability (Burton *et al.*, 1993). An example is the levee system planned for the Grand Forks region, as part of the post-1997 Red River flood mitigation scheme. NHC/DRI (1999) notes, “If the levee system is constructed as planned...[it will] have the potential to greatly increase damage and losses if the levee is breached or overtapped in a future flood.”

Superimposed on the changing development landscape is the possibility that climate warming will reduce the risk of some extreme events and increase the risk of others (Karl *et al.*, 1996; White and Etkin, 1997). Changes in the frequency, severity, and duration of extreme events may be among the most important

risks associated with climate change. In some parts of North America, this includes fewer periods of extreme cold, fewer snowstorms (although there may be an increase in the number of intense storms), increased spring flooding, more frequent summer droughts, and more wildfires. Studies also suggest that there will be a more thermodynamically unstable atmosphere in the future, which probably will result in more frequent heavy rainfalls and possibly increased hail risk and more tornadoes and downbursts (Etkin, 1996).

Studies suggest that El Niño and La Niña events may become more frequent in the future, although there is still much uncertainty regarding predictions of tropical phenomena (Henderson-Sellers *et al.*, 1998; Timmermann and Oberhuber, 1999). Any changes would affect the number of extreme events, including the occurrence of Atlantic hurricanes because during El Niños (La Niña), Atlantic hurricanes are less (more) frequent. Landsea *et al.* (1999) point out that recent intensification of urban development along the U.S. Atlantic coast parallels a reduction of hurricane activity from 1966 to the early 1990s; they ask whether the United States is prepared for a recurrence of higher frequencies.

North American measures of property damage from severe storms are consistently higher and the loss of life lower, compared to less-developed countries. Investments in warning systems and disaster preparedness save lives. When these systems are overwhelmed by extreme events, however, the damage can be catastrophic. It is interesting that housing losses from extreme events generally are on the same scale in North America as those in developing countries, particularly when disaster strikes large urban centers (Comerio, 1997).

Older buildings often experience the greatest damage during extreme events. New buildings, however, also are at risk if insufficient effort is made to ensure compliance with building codes. Studies show that compliance with building codes may have eliminated up to 25% of insured losses resulting from major hurricanes (IBHS, 1999).

Damage from flooding in North America has increased in the past few decades (Mileti, 1999). Land-use planning remains a powerful tool to help reduce the loss of life and property. One study that indirectly illustrates this concept is Brown *et al.* (1997a). They found that nonagricultural flood damage from a set of storms moving through Michigan exceeded that of southwestern Ontario by a factor of about 900, even though the flood yields in Ontario were greater than those in Michigan. Their analysis ascribes the cause as greater development in flood-prone areas. In Michigan, the storms generally exceeded land-use design thresholds, whereas in Ontario they did not.

Munich Re (1997) found that “the extent of loss has not infrequently been increased through a false assessment of the risk circumstances or in the pursuit of profit.” If the amount of development arising from the perception of reduced short-term risk tends to be disproportionate to the real increased risk from rare events, long-term vulnerability is increased. Mileti (1999)

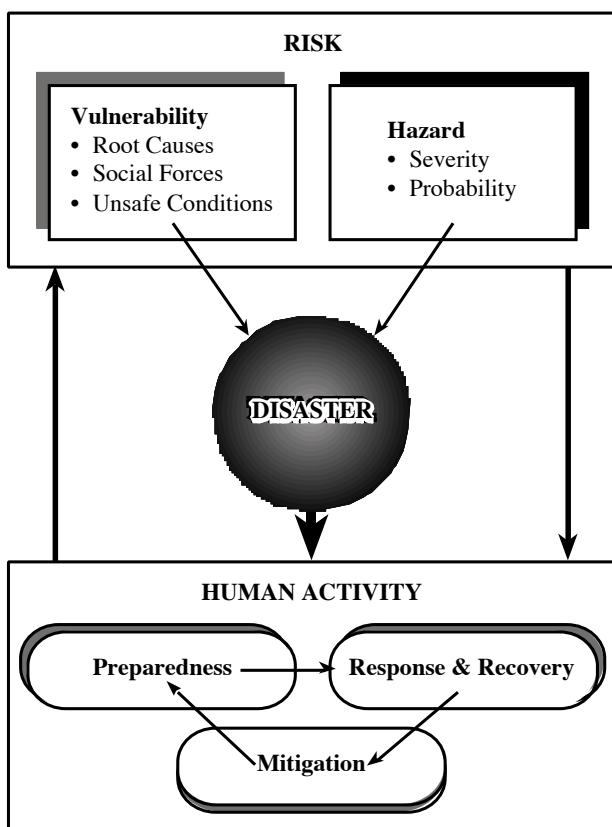

Figure 15-3: Cycle of human response to natural hazards, including response and recovery, mitigation, and preparedness. This response can alter vulnerability and thereby influence future disasters (Etkin, 1999).

argues that "...our national [U.S.] path also is leading us toward natural and related technological catastrophes in the next millennium that are larger than any we have ever experienced ...that is the future we have designed for ourselves.... [We] have done more to postpone losses into the future than to eliminate them." Social and economic trends suggest overall increases in vulnerability; if natural triggers of disasters are exacerbated as a result of climate change, it seems likely that more frequent and severe natural disasters are going to occur in the future (see Section 15.2.7).

15.2.6. Tourism and Recreation

Tourism is a major sector of the global economy, with global receipts from international tourism of US\$439 billion in 1998. With a projected annual growth rate of 6.7%, annual international tourism expenditures are expected to surpass US\$2 trillion by 2020 (WTO, 1998). The United States and Canada were among the top 10 tourism destinations in terms of international tourist arrivals, with related 1998 receipts of US\$71 billion and US\$9 billion, respectively (WTO, 1999). Domestic tourism is many times more important in terms of participation and economic activity. The magnitude of the implications of climate change for the tourism and recreation sector will depend on the distribution and importance of tourism and recreation phenomena and the characteristics of climate change and variability. In the United States, the Pacific and south Atlantic regions are major providers of tourism and recreation opportunities. However, if population distribution is taken into consideration, less populated areas often have high economic dependence on tourism and recreation.

One critically important dimension of the tourism and recreation sector that will be sensitive to climate change is the length of the operating season. Any changes in season length would have considerable implications for the short- and long-term viability of tourism and recreation enterprises. In Canada, where 43% of domestic and 62% of international tourism expenditures take place in July through September, an extended warm-weather recreation season is likely to be economically beneficial (Wilton and Wirjanto, 1998). The limited regional studies of golfing, camping, and boating that are available reinforce this conclusion (Wall, 1998a,b). This positive outlook must be tempered with the possibility that economic benefits may occur at the expense of increased environmental deterioration, as destinations host more visitors for longer periods of time. These concerns will be particularly relevant for national parks and other natural areas, which may need to establish "no-go" zones or visitation limits.

Conversely, winter recreations—such as downhill skiing, cross-country skiing, snowmobiling, ice fishing, and other activities that are dependent on snow or ice—as well as the businesses and destination areas associated with them are likely to be impacted negatively. Case studies from the Great Lakes (McBoyle and Wall, 1992) and New England (Bloomfield and Hamburg, 1997) regions indicate that the vulnerability of ski resorts will differ considerably, depending on location (latitude

and altitude) and adaptations (snowmaking) to offset or compensate for the effects of less reliable snow conditions. Another potential adaptive strategy is diversification of activities to ensure that investments in property and infrastructure generate income and employment for much of the year. Without analysis of the impacts of altered snow conditions for major ski areas in the mountain ranges of western Canada and the United States and the large snowmobile industry in both nations, the economic impact to the winter recreation sector in North America remains uncertain.

Perhaps as important as changes to season length will be the impact of climate change on the availability and quality of the resource base on which recreational activities depend. Below-average Great Lakes water levels in 1999 again revealed the sensitivity of marinas and the substantial recreational boating industry to climate variability. Similarly, the impact of the 1988 drought on Prairie wetlands and waterfowl breeding success is illustrative of the potential impact of climate change for this sport-hunting resource. Global warming is anticipated to modify many other ecosystems on which outdoor recreations depend. Parks and other natural areas are important tourism and recreation resources whose attractions are based to a considerable extent on the species they conserve and the ecological processes they sustain. A climate change assessment of Canada's National Park system (Scott and Suffling, 2000) indicates that 75–80% of the parks would experience a shift in dominant vegetation under 2xCO₂ scenarios. Analysis of vegetation response in the Yellowstone National Park region in the United States revealed regional extinctions and the emergence of communities with no current analog (Bartlein *et al.*, 1997). Moreover, a global analysis of habitat change resulting from climate change found that more than 50% of the territory of seven Canadian provinces and greater than 33% of the territory in 11 U.S. states are at risk (Malcolm and Markham, 2000). Although this will pose an unprecedented challenge to the conservation mandate of protected areas, the impact of ecological changes on tourism remains uncertain.

Changes in the magnitude and frequency of extreme events such as hurricanes, avalanches, fires, and floods have considerable implications for tourism and recreation. One likely consequence of global climate change is sea-level rise. This may have considerable consequences for the provision of recreational opportunities in coastal communities, particularly if it is associated with increased storm frequency.

Coastal zones are among the most highly valued recreational areas and are primary tourist destinations. Houston (1996) estimates that 85% of all tourist revenues in the United States are earned by coastal states, and there are as many as 180 million recreational visitors to U.S. coasts every year (Boesch *et al.*, 2000). Sea-level rise in beach areas backed by seawalls or other development that precludes landward migration would lead to loss of beach area through inundation or erosion and pose an increased threat to the recreation infrastructure concentrated along the coast (sea-front resorts, marinas, piers, etc.). Beach nourishment is widely used to protect highly valued recreational

beaches. One study estimates that this adaptation strategy would cost US\$14–21 billion to preserve major U.S. recreational beaches from a 50-cm sea-level rise (Wall, 1998c). Furthermore, impacts to ecologically important wetlands and coral reefs also could have major implications for sport fishing and diving-related tourism activities in coastal regions. The risk to coastal recreation is most prominent in warm-weather destinations in the southern United States and small island nations in the Caribbean (see Chapter 17 and Section 15.3.2.10), where tourism is a leading sector of the economy.

Intersectoral resource competition also may become more pronounced, particularly with respect to water resources. Climate change scenarios for the Trent-Severn Waterway (Walker, 1996) indicate that regulation of flows for adequate downstream municipal demand would diminish the recreational boating industry, with attendant impacts for riparian recreational home property values. Increased municipal and agricultural water demand in arid regions may outweigh development of new golf courses and, in severe cases, diminish the capacity to irrigate existing facilities economically. Like declining resource availability and quality, increased resource competition may constrain the opportunities afforded by a longer recreational season.

Two main groups can be considered with respect to the potential to adapt to climate change: participants themselves and businesses and communities that cater to them. The former may be able to adapt to climate change much more readily than the latter, which are more likely to have large amounts of capital invested in fixed locations. The effect of and potential for substitution as an adaptive strategy, including locations (beach, ski resort), preferred species (coldwater vs. warmwater fish), and recreational activities broadly (skiing to mountain hiking, snowmobile to all-terrain vehicle use, golf to sailing) require more detailed investigation.

Tourism and recreation are not regarded as major net generators of greenhouse gases (except, perhaps, in the travel phase), but GHG reduction policies (e.g., carbon taxes) may increase the cost of travel, with substantial implications for destination areas (particularly isolated destinations with little domestic tourism demand).

Improvement in climate change projections, although helpful, will be insufficient to improve understanding of the implications of climate change for tourism and recreation. Even if climate change could be reliably forecast now, it is doubtful if the industry has sufficient understanding of its sensitivity to climatic variability to plan rationally for future conditions. Furthermore, the salience of climate change versus other long-term influencing variables in this sector (globalization and economic fluctuations, fuel prices, aging populations in industrialized countries, increasing travel safety and health concerns, increased environmental and cultural awareness, advances in information and transportation technology, environmental limitations—water supply and pollution) remains a critical source of uncertainty.

Global climate change will present challenges and opportunities for recreational industries and destination areas. The net economic impact of altered competitive relationships within the tourism and recreation sector is highly uncertain. Studies by Mendelsohn and Markowski (1999) and Loomis and Crespi (1999) attempt to put an economic value on climate change impacts in the United States. Although these were pioneering efforts, the assumptions and methods employed limit the confidence that can be placed in the findings. Until systematic national-level analyses of economically important recreation industries and integrated sectoral assessments for major tourism regions have been completed, there will be insufficient confidence in the magnitude of potential economic impacts to report a range (based on disparate climate, social, technical, and economic assumptions) of possible implications for this sector.

15.2.7 Public and Private Insurance Systems

The North American economy is widely affected by weather conditions. The Chicago Mercantile Exchange stated recently that weather affects US\$2 trillion of the US\$9 trillion gross national product (GNP). Insurance is a critical part of the vulnerability/adaptation equation because many of the economic risks and impacts of weather-related events are diversified and ultimately paid through insurance.

The discussion in the following subsections embraces public and private insurance systems, as well as disaster relief. Within the private insurance sector are many actors, including property/casualty (P/C) insurers, life/health insurers, reinsurers, self-insurers, and various trade allies (risk managers, brokers, agents, etc.). Within the public sector are direct insurance programs, as well as disaster preparedness and recovery activities. Other segments of the financial services sector appear to be less vulnerable and are treated in Chapter 8.

15.2.7.1 Private-Sector Insurance Systems

Private insurance is among the largest economic sectors in North America, with about 40% (US\$780 billion) of global premium revenues in 1998 (Swiss Re, 1999). North American premiums represent 9% of GDP, or about US\$2,600 per capita. Despite its size, the industry is hardly a monolith; there are numerous types of insurance companies and market segments (Mills *et al.*, 2001).

Weather-related loss data presented here are based on diverse sources, and the particular costs included can vary somewhat among countries and over time. In some cases, definitions set minimum thresholds for inclusion; for example, because of the minimum cost threshold of US\$25 million in the U.S. (formerly US\$5 million), no winter storms were included in the statistics from 1949–1974, and few were included thereafter (Kunkel *et al.*, 1999). Although large in aggregate, highly diffuse losses from structural damages as a result of land subsidence also

would be captured rarely in these statistics. Data-gathering conventions can result in omission of certain types of costs (e.g., weather-related vehicle losses). Thus, the totals presented here are inherently underestimates of actual losses.

Although North America experienced 59% of global weather-related insurance losses and 36% of total economic losses during the 1985–1999 period, it experienced only 20% of the events and 1% of associated mortalities (see Figure 15-4). Total economic losses (insured and uninsured) from weather-related events represented US\$253 billion (current dollars) during this period. Of that total, 38% (US\$96 billion) were privately insured, with considerable year-to-year fluctuations in the ratio.

During this period, weather-related natural disasters represented 82% of total natural disaster losses in the United States and virtually the entire total in Canada (where significant earthquake losses have not occurred). Although considerable attention is given to catastrophic losses, half of all insured weather-related losses are from relatively small events (see Chapter 8).

Inflation-adjusted catastrophe losses have been growing in North America over the past 3 decades (see Figure 15-5). Corresponding exposures, measured as the inverse of the ratio of premium income to losses, have been growing (i.e., if the ratio goes down, exposure goes up); the ratio has varied by a factor of six in the United States between 1974 and 1999, and by a factor of four in Canada between 1987 and 1999 (see Figure 15-6).

Although many of the upward trends in weather-related losses are consistent with what would be expected under climate change (see Chapter 8), efforts to disentangle socioeconomic and demographic effects from climatic factors have had mixed results in the United States (Changnon *et al.*, 1997, 2000; Karl and Knight, 1998; Pielke and Landsea, 1998; Changnon, 1999). In Canada, there is a stronger sense that both factors are at work (White and Etkin, 1997; Hengeveld, 1999).

Irrespective of climate changes, it is clear that human exposure is increasing with affluence and as populations continue to move into harm's way. The estimated value of insured coastal property exposure for the first tier of counties along the Atlantic and Gulf Coasts as of 1993 was US\$3.15 trillion (IPLR and IRC, 1995).

Most types of weather-related events—rain, hail, ice storms, tidal surges, mudslides, avalanche, windstorm, drought, land subsidence, lightning, and wildfire—are of concern to insurers (Ross, 2000). Corresponding losses can range from property damage to business interruptions and temporary housing costs as a result of loss of electric power. Coastal erosion is an important consequence of sea-level rise and already is responsible for a considerable and growing rate of losses (Heinz Center, 2000). Insurance in North America originally focused on fire peril; only since the late 1930s have insurers provided broad-based coverage for weather-related events (Mills *et al.*, 2001).

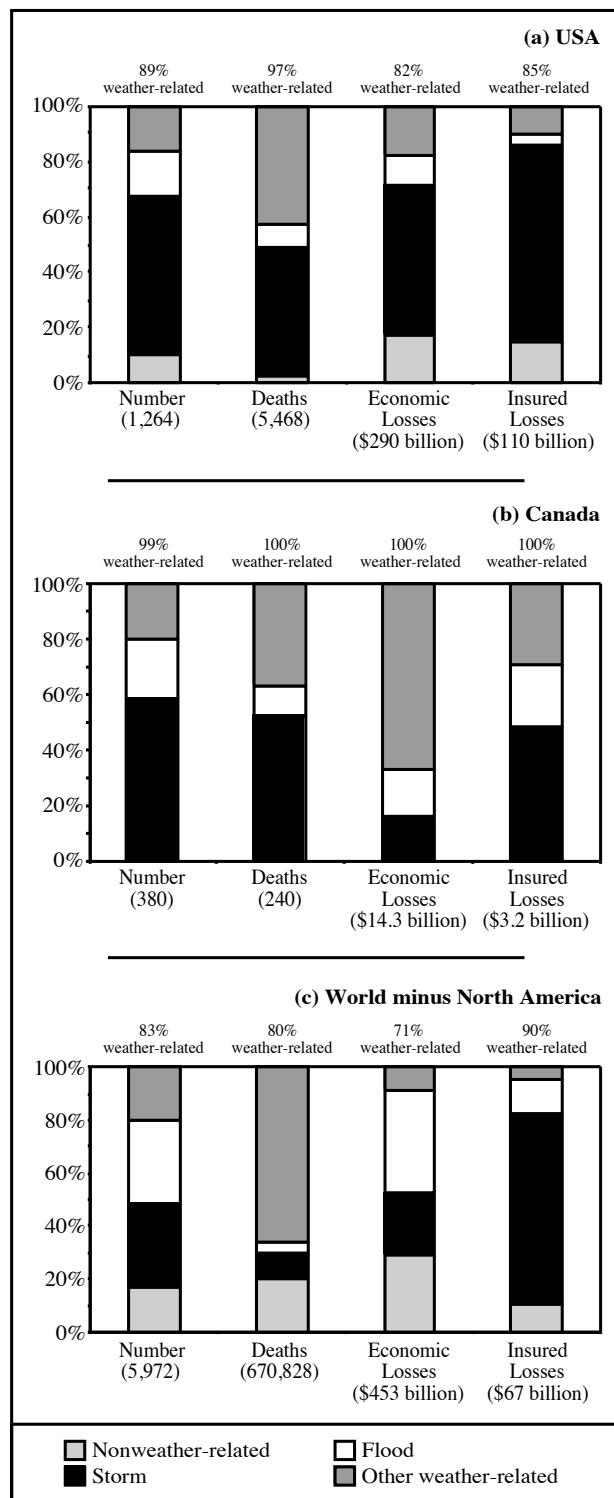

Figure 15-4: Distribution of natural-disaster losses in (a) Canada, (b) the United States, and (c) globally: 1985–1999 (Munich Re, 2000). “Storm” includes hurricanes, tornadoes, and high winds. “Other” includes weather-related events such as wildfire, landslides, avalanches, extreme temperature events, droughts, lightning, frost, and ice/snow damages.

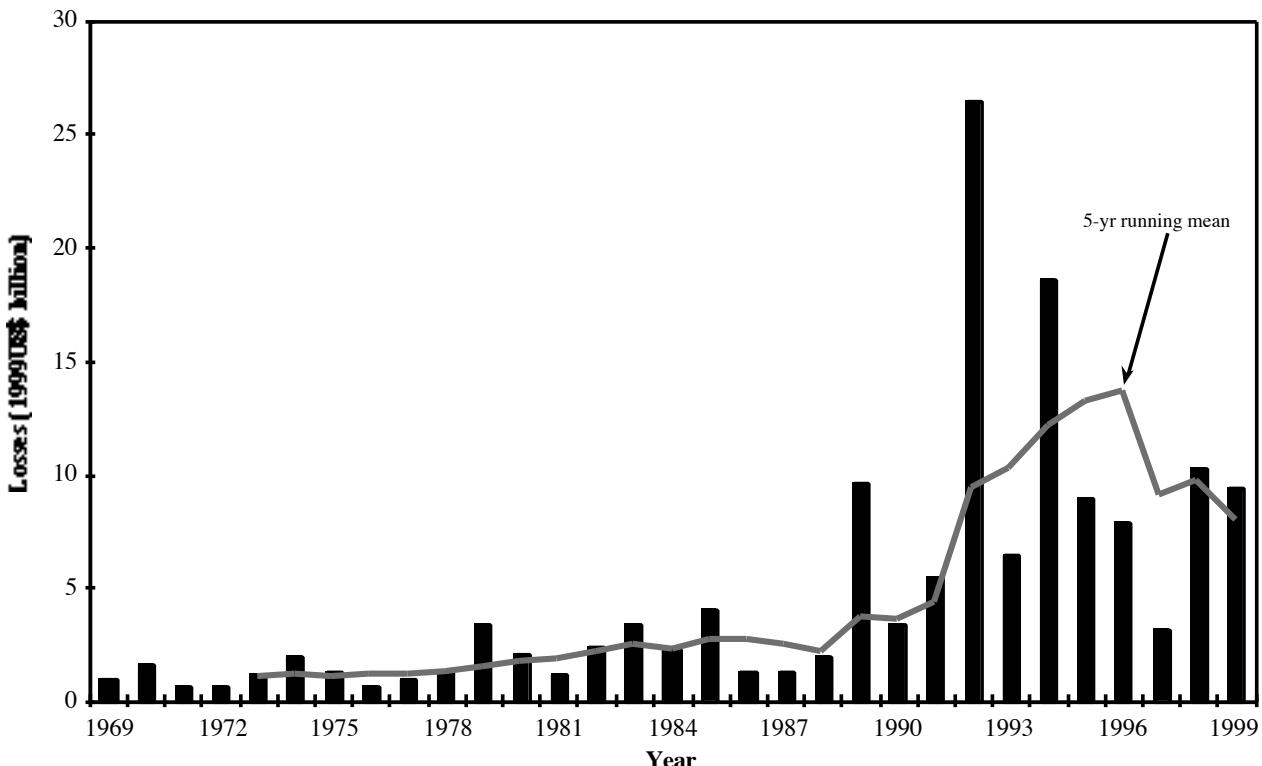

Figure 15-5: Insured natural disaster losses have increased 10-fold in North America between 1969 and 1999 (based on 5-year running mean). Data include nonweather-related losses (~15% of total). Sources: Emergency Preparedness Canada, 2000; Kunreuther and Roth, 1998 (United States).

The types of weather-related losses vary considerably between the United States and Canada. As shown in Figure 15-4, storm-related losses, including hurricanes, represent a larger share of

losses in the United States, whereas flood and other weather-related events represent a far higher share in Canada. Large hurricane losses are substantial in the United States but have been virtually absent in Canada since Hurricane Hazel in 1954. Flood and storm events (other than hurricanes) have accounted for 95% of Canada's recent weather-related losses.

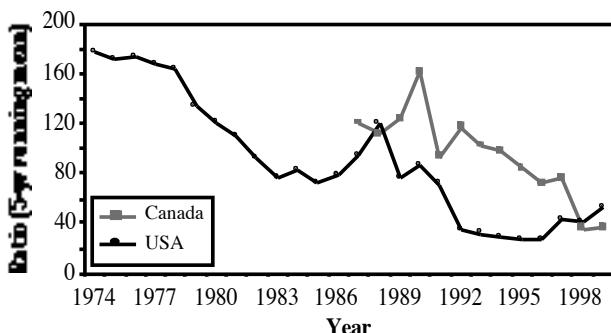

Figure 15-6: Ratio of property/casualty insurance premiums to catastrophe losses. This measure of exposure ranges from 180:1 in 1974 to 52:1 in 1999, with a minimum value of 27:1 in 1992 (the year of Hurricane Andrew). For Canada, the high value is 161:1 in 1990, and the low value is 37:1 in 1999. U.S. premiums are from AM Best and insured natural catastrophe loss figures are from Property Claims Service (Kunreuther and Roth, 1998). Canadian premiums are from Insurance Bureau of Canada (2000) and losses are from Emergency Preparedness Canada (2000). Note that premiums include revenues from nonweather-related business segments.

North American insurers have demonstrated sensitivity to the extremes and uncertainties of weather-related events. The trend in recent decades is toward increasing adverse impacts such as rising losses, upward pressure on prices, availability problems, company insolvencies, depressed stock prices, and increased reliance on government-provided insurance and disaster preparedness/recovery resources (see Chapter 8). P/C industries in the United States (see Chapter 8) and Canada (Emergency Preparedness Canada, 2000) have observed reduced and even negative operating results in years with large natural disaster losses.

A U.S.-based insurance trade association estimates that in 1997, 17% of U.S. insurance P/C premiums were associated with "significant" exposure to weather-related loss, 2% with "moderate" exposure, 66% with "minor" exposure, 10% with "minor to no" exposure, and 4% with "no" exposure (American Insurance Association, 1999). In these estimates, "exposure" is measured in terms of insurer premiums as opposed to the value of exposed property. Most flood and crop risks are not included

because government insurance programs assume them. The “minor exposure” segment is mostly vehicle insurance. However, in the United States, 16% of automobile accidents are attributed to adverse weather conditions (NHTSA, 1998), as are one-third of the accidents in Canada (White and Etkin, 1997). Vehicles also sustain privately insured losses from floods and hailstorms.

In practice, insurer surplus is not poolable. Even at an industry-wide level, insurance pricing can be inadequate to cover future losses. This was evident in the case of the Northridge earthquake in California, where the US\$3.4 billion in earthquake premiums collected during 25 years prior to the event fell far short of the US\$15.3 billion loss (Gastel, 1999). Individual firms can come under stress long before the industry does as a whole. U.S. P/C insurers experienced approximately 650 insolvencies (bankruptcies) between 1969 and 1998, 8% of which were caused primarily by natural disasters (Matthews *et al.*, 1999). These disaster-related insolvencies include small as well as very large firms (see Chapter 8). Meanwhile, no recorded Canadian insurance insolvencies have been attributed to extreme events.

Insurers’ ability to withstand weather-related losses is based on a combination of event magnitude and resources (often referred to as assets or surplus) with which they can pay claims.

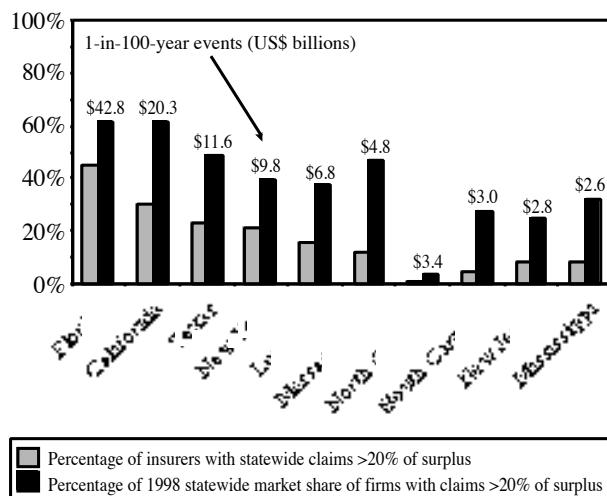

Figure 15-7: Vulnerability of U.S. insurers to 100-year events, represented as combined effect of loss magnitude and insurance company capacity (GAO, 2000). This analysis assumes that all insurers place and price policies identically. It excludes reinsurance, as well as local government-supported insurance or reinsurance programs in California and Florida. It also excludes effects of catastrophes striking more than one state (e.g., estimated 1-in-100-year loss for the entire United States is \$155 billion). Capacity implied may include some surplus amounts that are not available for paying natural catastrophe claims. Losses that result in claims of more than 20% of surplus trigger initial stage of formal solvency review by National Association of Insurance Commissioners. Puerto Rico (not shown) has a 1-in-100-year loss of US\$27.1 billion.

Probable maximum losses (PMLs) and vulnerability vary by locality and have been on the rise (Davidson, 1996; Cummins, 1999; GAO, 2000). As illustrated for the United States, natural disasters that are limited to the boundaries of a given state have widely varying potential impacts on insurers, depending on the capacity for paying losses (see Figure 15-7). Insurers have not performed quantitative analyses of the potential effects of climate change on PMLs.

Surplus—a measure of adaptive capacity—tends to be unstable over time, sometimes changing abruptly in response to perturbations in stock and bond market valuations or interest rates (Mooney, 1999; GAO, 2000; Swiss Re, 2000). Although U.S. insurer capacity increased considerably through the 1990s, as illustrated in Figure 15-8, large events still can result in a substantial volume of unpaid claims. Adaptive capacity can be depleted by multiple sequential events (AIRAC, 1986), as well as by past nonweather-related losses [e.g., from environmental liability (Superfund)]. There also are potential losses stemming from issues such as tobacco liability or the combination of increasing reliance on information technology and emerging questions regarding the reliability of the electricity grid. The finding that U.S. electric cooling demand would increase under global warming (Morrison and Mendelsohn, 1999) would be a compounding factor in the latter example, and adaptation (e.g., increased use of air conditioning) would result in increased GHG emissions. The trend toward increased competition is an additional stress on insurers, although consolidation also can—under the proper circumstances—increase resilience of firms.

An insurer’s vulnerability often extends beyond the borders of the country in which it resides. For example, U.S. insurers collected US\$35 billion in premiums for overseas insurance sales in 1997, and such insurance has been growing faster than overall premiums in recent years (III, 1999). Canadian insurers also write policies outside the country, including vulnerable parts of the United States (White and Etkin, 1997). Reinsurers (many of which are based in North America) have a high degree of vulnerability given the geographical diversity of their risk portfolios.

15.2.7.2 Government-Based Insurance and Disaster-Relief Systems

Government entities are vulnerable to climate change as providers of insurance and/or disaster relief; providers of domestic and international disaster preparedness/services; and managers of property and weather-sensitive activities.

Private insurers find certain weather-related risks to be technically uninsurable as a result of their spatial concentration, actuarial uncertainty, and associated difficulties in pricing. In the United States, this problem arises mostly with respect to crop and flood risks, although government flood insurance is limited to residential and very small commercial customers. There is ongoing tension between government and private-sector players

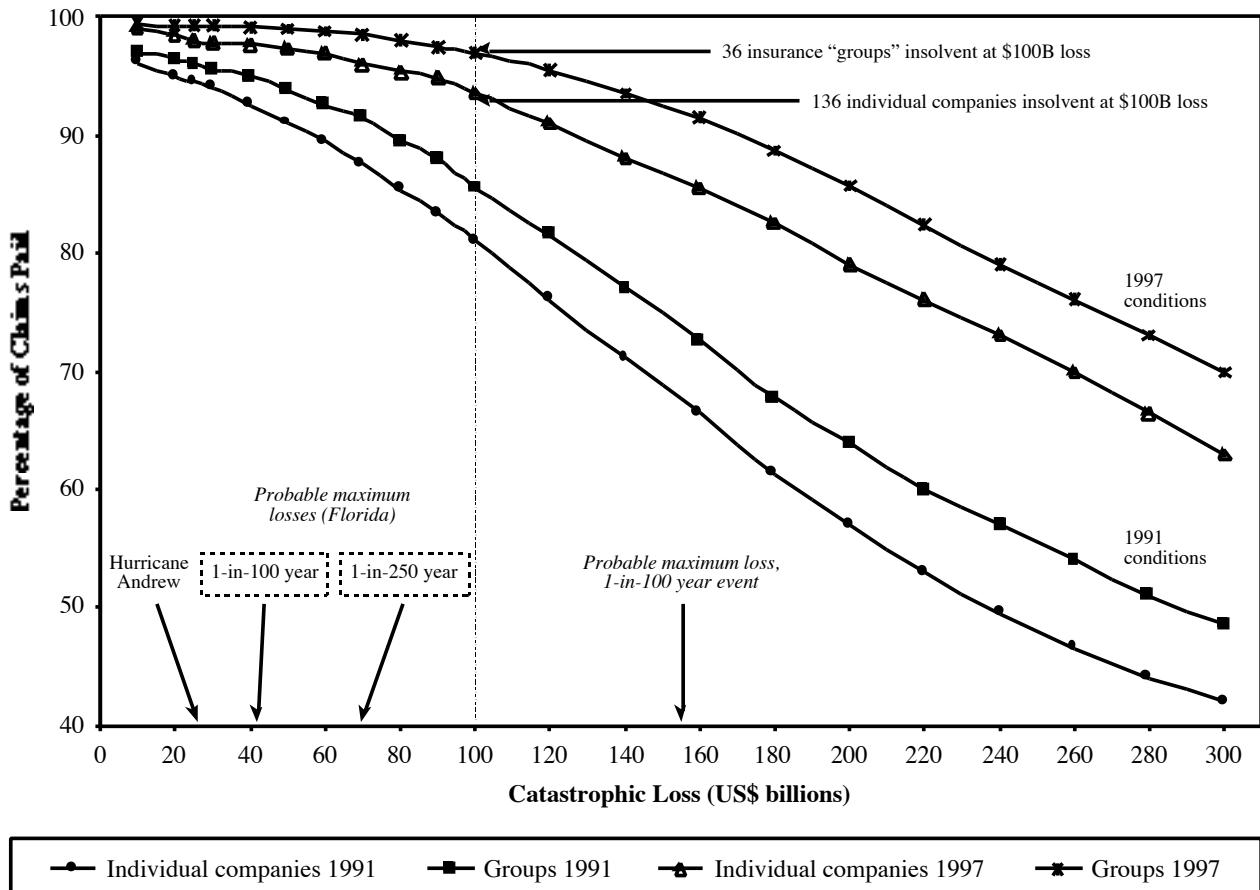

Figure 15-8: Reductions in claims payable, by size of loss. Ability of U.S. property-casualty insurance sector, as a whole, to pay claims over a wide range of losses. The chart shows four views, encompassing changes in capacity between 1991 and 1997 and whether companies have access to resources of groups that own them. Groups are not obligated to pay losses experienced by individual member firms but retain the option to do so. Together, these four scenarios represent a range of ability to pay losses. For example, for a US\$155 billion loss year—a recent estimate of probable maximum loss (PML) (GAO, 2000) could be several events combined, including weather- and nonweather-related ones—65 to 90% of claims would be paid (adapted from Cummins *et al.*, 1999). PML benchmarks are from GAO (2000).

in the natural disaster arena, with each looking to the other to clarify the somewhat ambiguous division of responsibility.

In Canada, government (federal, provincial, and municipal) has paid most of the natural disaster payments, amounting to US\$15 billion (CDN\$22 billion) in disaster relief between 1982 and 1999, including 86% of flood-related losses (Emergency Preparedness Canada, 2000). Consolidated data for U.S. government payments for natural disasters are not readily available. One source reports US\$119 billion (1993US\$) in government outlays between 1977 and 1993 (Anderson, 2000).

Government insurance programs can have difficulty achieving solvency, as exemplified by the US\$810 million deficit in the U.S. flood insurance program in the mid-1990s (Anderson, 2000). U.S. crop and flood insurance programs have never been profitable, and growing coastal erosion risks will require doubling of rates in the United States (GAO, 2000; Heinz

Center, 2000). Government insurance programs also have resulted in cases of maladaptation (e.g., inducing people to settle in vulnerable areas) (Heinz Center, 2000).

15.2.7.3 Creating and Maintaining Adaptive Capacity

Private and public insurers alike have at their disposal a variety of tools to increase adaptive capacity. These tools can be divided into the broad categories of risk spreading and risk reduction (see Chapter 8). Some of these strategies involve shifting of risk between the public and private spheres, or even back to the consumer, and in that regard have considerable public policy ramifications that are beyond the scope of this chapter.

Given their sensitivity and potential vulnerability to weather-related losses, North American insurers and their regulators have designed a variety of adaptation mechanisms. These

strategies include economic measures—raising premiums or deductibles, withdrawing coverage, creating systems for pooling risks among multiple insurers (e.g., U.S. government-mandated FAIR Plans or beach/windstorm plans and state-mandated “guaranty funds” based on mandatory contributions of insurers, to pay the claims of insolvent insurers)—and the use of capital market alternatives to finance risk (see Chapter 8). Responses also include more engineering-oriented risk-reduction strategies, such as land-use planning, flood control, cloud seeding (see Section 15.3.2.4), and early warning systems.

Hurricane Andrew in 1992 and the 1998 ice storm (see Section 15.3.2.6) were wake-up calls for the North American insurance industry. Among the numerous responses have been increased utilization of catastrophe modeling, a more proactive stance toward disaster preparedness/recovery, new efforts in land-use planning, increased attention to building codes, and increased use of incentives to implement loss-prevention measures (Bruce *et al.*, 1999b).

One embedded vulnerability facing insurers and government risk managers alike is that, by design, their actuarial outlook and disaster reserving conventions are based on past experience. There is an emerging and encouraging trend to forward-looking catastrophe modeling, although it has yet to integrate knowledge from climate change modeling. Thus, under climate change, the potential for surprise is real. Vulnerability is compounded by the potential for changes in the frequency, variability, and/or spatial distribution of extreme weather events. Increased uncertainties of this nature can complicate and confound insurer methods for preparing for future events (Chichilnisky and Heal, 1998).

15.2.7.4 Equity and Sustainability Issues in Relation to Insurance

Although North America is a wealthy region, significant equity considerations arise from its cultural and economic diversity (Hooke, 2000). This raises important issues concerning the design and deployment of effective natural disaster preparedness programs (Solis *et al.*, 1997). Lower income groups tend to live in more vulnerable housing and are least able to afford potential increases in insurance costs by insurers or cross-subsidies utilized to spread risks (Miller *et al.*, 2000). Poorer individuals also tend to carry little if any life and health insurance and thus may be uninsured against public health risks such as urban heat catastrophes or urban air quality risks posed by climate change (see Chapter 9).

In some cases, sustainable development and environmental protection complement insurance loss reduction objectives. Examples include protection or restoration of wetland areas that increases tidal flooding defense, sustainable forest practices that reduce risk of inland flooding and mudslides, or agricultural practices that increase drought resistance or reduce soil erosion (see Chapters 5 and 8; Scott and Coustalin, 1995; Hamilton, 2000). Similarly on the end-user side, a variety of energy

conservation and renewable energy measures have been found to offer insurance loss-control co-benefits (Mills, 1996, 1999; Nutter, 1996; Mills and Knoepfel, 1997; American Insurance Association, 1999; Vine *et al.*, 1999). The insurance sector itself has begun to examine its activities within the broader framework of sustainability (Mileti, 1997; Kunreuther and Roth, 1998).

15.3. Adaptation Potential and Vulnerability

15.3.1. Generic Issues

Subregions within North America can be affected by global climate change through direct first-order effects on land and water resources and through indirect impacts that are related to reactive and proactive responses by actors within and outside the subregion. Direct effects include incremental processes and extreme weather events with long-term impact on the region’s environmental, social, or economic systems. Indirect effects would include societal changes that could be set in motion, primarily by policies generated outside the region, to mitigate greenhouse warming or adapt to perceived threats.

Calculations of climate-related impacts within subregions must consider both direct and indirect effects. Actual impacts will depend on the effectiveness of adaptation. For example, changes in growing season, natural streamflow, or climate-related demand for heating and cooling energy can be calculated directly from changes in climatic parameters. However, changes in potential may not necessarily lead to a response by stakeholders. Other factors may intervene to prevent a subregion from adapting to a new climate-related opportunity or risk, including changes in market conditions, institutional arrangements, and management objectives.

Because North America includes areas of intensive urban and landscape management, as well as areas of “extensive” management, adaptation capabilities and vulnerabilities are likely to vary between subregions. There is potential for maladaptation, in part as a result of the availability of insurance and disaster relief measures (MacIver, 1998). Vulnerabilities also exist in highly developed regions with well-maintained infrastructure (e.g., dams designed for flood control) because of the growing need to manage resources to achieve multiple objectives. Would climate change ameliorate or exacerbate these risks? Analysis of case studies can provide guidance.

15.3.2. Subregional and Extra-Regional Cases

15.3.2.1. Introduction

The discussion that follows offers a sample of subregional and extra-regional cases that reflect the unique and changing nature of the relationship between climate and places in the North American context. Six subregions have been defined: Pacific, Rocky Mountains–Southwest United States, Prairies–Great Plains,

Great Lakes–St. Lawrence, North Atlantic, and Southeast United States (see Figure 15-9). These subregions represent unique landscapes that have experienced development paths that reflect natural potential for resource development as well as region-specific histories of evolving economies and communities. Some of these cases describe responses to recent extreme events. Others focus on scenarios of future climatic changes. Canada and the United States have a long history of cooperating on resource management concerns in transboundary areas, including the Boundary Waters Treaty of 1909 and more recent agreements on transboundary air pollution, watershed development, and the environmental agreement associated with NAFTA. There also have been binational and subregional conflicts over a wide range of issues that are climate-sensitive, including water resources, wetland protection, trading of forest and agricultural commodities, and harvesting of transboundary fish stocks. Various cooperative management approaches are being considered. Could climate change make a difference in

any of these conflicts? Extra-regional issues are considered for the Arctic, U.S.–Mexican, and U.S.–Caribbean borders.

15.3.2.2. Pacific Subregion

This subregion includes the Columbia River basin—the fourth-largest in North America, and one of the most valuable and heavily developed watersheds. The Columbia system produces 18,500 MW of hydroelectricity; it also is managed for flood control, agriculture, navigation, sport and commercial fisheries, log transportation, recreation, wildlife habitat, and urban, industrial, and aboriginal uses. Climate variability affects the total volume and temporal pattern of natural runoff, although binational management agreements have substantially altered this pattern. Any hydrological changes caused by long-term climatic change will have impacts that may affect the management of the system and the nature of conflicts among various users.

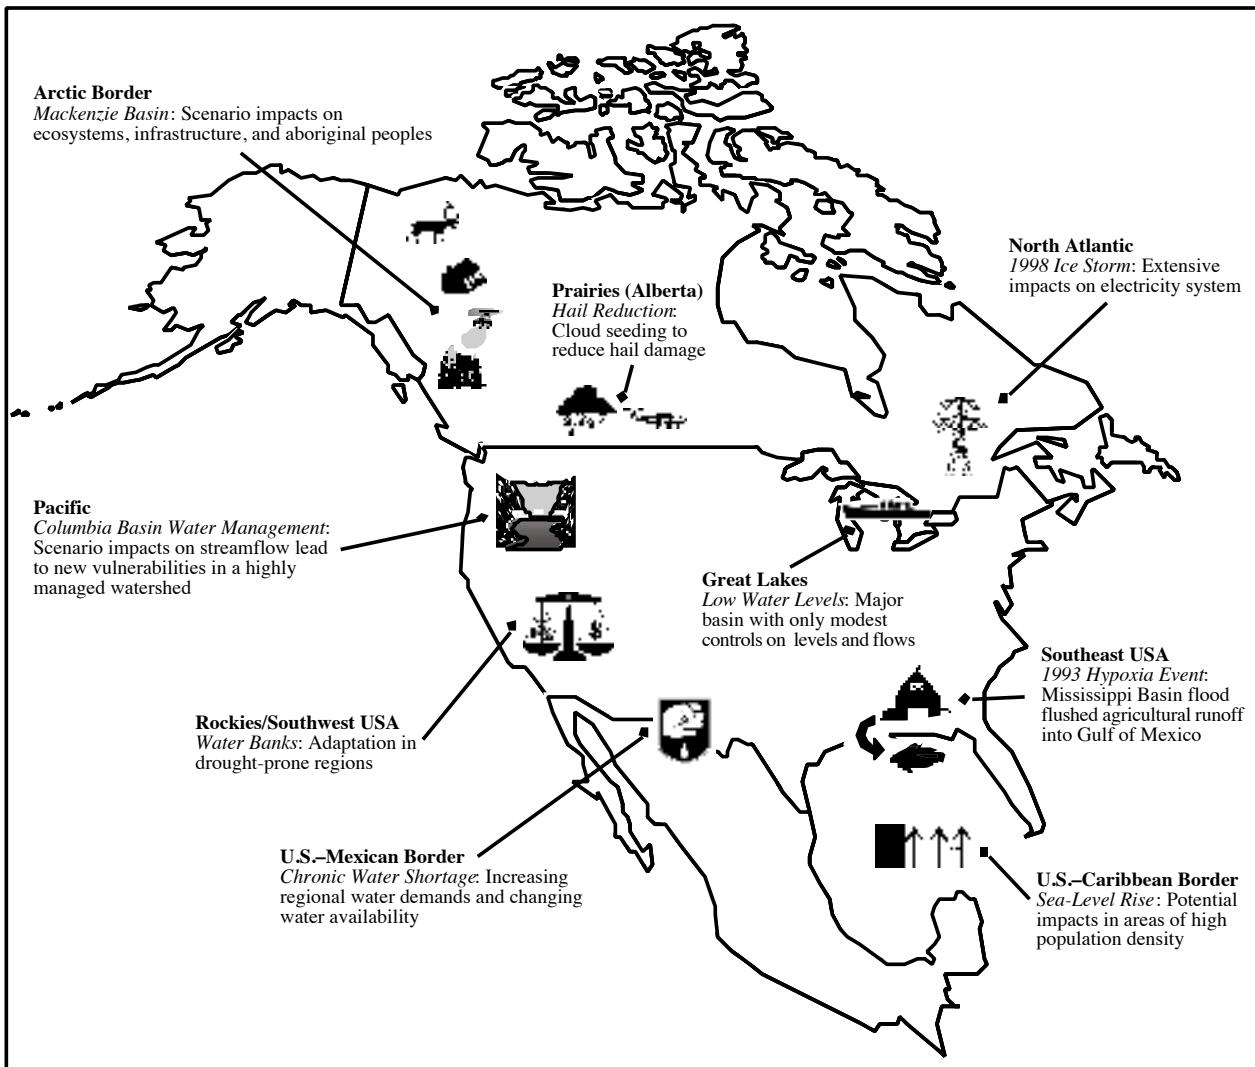

Figure 15-9: Subregional cases from North America (described in Section 15.3.2).

Recent management and policy changes have led to changes in system operations; fish habitat protection now is regarded as a high priority—on par with hydroelectricity production and flood control (Cohen *et al.*, 2000).

Climatic change is expected to lead to reductions in annual streamflow. Estimates for three warming scenarios range from a small increase to a decrease of 16% by 2050, with an earlier annual peak, higher winter flows, and lower summer flows (Lettenmaier *et al.*, 1996, 1999; Hamlet and Lettenmaier, 1999; Miles *et al.*, 2000). This would affect system reliability. Results from a reservoir system model for the driest of the three scenarios [based on the Max Planck Institute (MPI) GCM, ECHAM-4] indicate reductions of 15% in reliability for Snake River irrigation, 11% for McNary Dam “biological flow” (to support fish habitat), 14% for firm energy production, and 19% for nonfirm energy production. Reliability for flood control would remain relatively unchanged in this case but would decrease in the wetter scenarios (Hamlet and Lettenmaier, 1999; Miles *et al.*, 2000).

Interviews were held in 1997 with water resources managers and other stakeholders in the upstream portion of the Columbia, on the Canadian side. Their responses to the MPI scenario were similar to those obtained from the reservoir system model. For example, they noted that flood risk would not necessarily be reduced because upstream storage facilities may be releasing high discharges for fish habitat protection or other reasons. Similarly, irrigation supply and hydroelectricity production would be reduced because of lower annual flow combined with fish protection requirements. In these circumstances, regional utilities might have to purchase electricity from fossil fuel sources, thereby affecting the region’s ability to meet GHG emission targets (Cohen *et al.*, 2000).

This case study suggests that despite the high level of development and management in the Columbia basin, vulnerabilities would still exist and impacts could still occur in scenarios of natural streamflow changes caused by global climate change. It also suggests that expanded development of hydroelectric facilities, as a means of reducing GHG emissions, will create considerable challenges to management, given increases in the sensitivity of regional energy supplies and other water-related resources to climate.

15.3.2.3. Rocky Mountains–Southwest U.S. Subregion

Rapid population growth coupled with water supplies that are limited, heavily utilized, and highly variable present significant challenges to governments and the private sector in this region. The effects of climate change may add further stresses (Frederick and Schwarz, 1999). One strategy that has been developed to cope with these issues is use of water banks. Water banks can be used to mitigate the economic impacts of drought periods by increasing the reliability of water supply or by facilitating short-term reallocation of water among users. Water banks can be used for environmental purposes—for

example, Idaho’s water banks have provided significant quantities of water to assist anadromous fish passage (Miller, 2000b). However, to the extent that water banking entails increased water withdrawals from surface sources, there could be further adverse impacts on aquatic ecosystems.

There are two types of arrangements to which the term “water bank” has been applied. “Groundwater storage banks” include active conjunctive-use programs whereby surface water is used to recharge an aquifer, which is then used as a source of water supply during periods when surface water is less abundant. Another use of the term “water bank” refers to a formal mechanism created to facilitate voluntary changes in the use of water under existing rights. We can distinguish these as “water transfer banks.” The defining feature of this type of water bank is that it provides an established process or procedure for accomplishing such transfers. California has pioneered the development of both types of water banks. Various groundwater recharge programs have been developed in California, some of which incorporate features of groundwater banks and water transfer banks. One such example, the Bakersfield Recharge Facility in Kern County, is discussed below. The Emergency Drought Water Banks set up by the state of California in 1991, 1992, and 1994 are examples of water transfer banks.

In 1987, at the beginning of a severe multi-year drought, California had relatively little experience with privately arranged water transfers outside the confines of individual irrigation districts and major project service areas. The lack of market development may have been related, in part, to the predominance of large state and federal water projects in California and, in part, to the difficulty of obtaining approval for such transfers from the California State Water Resources Control Board (SWRCB) (MacDonnell, 1990; NRC, 1992). As the drought persisted, it became clear that neither within-project water transfers nor those requiring approval of the SWRCB were likely to occur in sufficient volume to alleviate the very uneven impacts of the drought on major urban centers and irrigated agriculture. In 1991, the state responded to the growing crisis by creating the first Emergency Drought Water Bank. California’s Department of Water Resources (DWR) acted as the manager of these water banks because most of the anticipated transfers required conveyance of the water through State Water Project (SWP) facilities (primarily the state’s pumping plant in the Sacramento/San Joaquin delta and the California aqueduct). DWR personnel negotiated the purchase contracts, monitored compliance with those contracts, obtained SWRCB approval where needed, and coordinated deliveries of water to purchasers. Despite initial difficulties in estimating the quantity of water needed and the appropriate price, as well as some concerns about uncompensated third-party impacts, the program generally is considered to have been a major success—with net economic benefits far exceeding any negative impacts (Howitt *et al.*, 1992; Dixon *et al.*, 1993; MacDonnell *et al.*, 1994).

Another successful California water bank is the 1,135-ha recharge facility operated by the city of Bakersfield. This groundwater-banking program also facilitates water transfers.

The city owns Kern River water rights, which yield a highly variable quantity of water from 1 year to the next. A portion of these rights is leased on long-term contracts to neighboring irrigation districts. The city has constructed a recharge facility into which it spreads much of its remaining Kern River water. This activity has increased the amount of water that potentially is available for extraction in the underlying aquifer. Three other water districts also are allowed to bank their surplus water by spreading it in the recharge facility. Each bank participant can withdraw the water in its own account, as needed (e.g., during drought periods), or transfer the water to another party:

“The banked water can be extracted and transported for direct use, sold or exchanged, with the stipulation that extracted water must be used in the San Joaquin Valley portion of Kern County for irrigation, light commercial and industrial, and municipal or domestic purposes, unless otherwise specified. Located upstream of the facility, the city of Bakersfield often sells its banked water to users downstream, or exchanges it for water from other sources” (Wong, 1999).

Operation of this recharge facility provides county water users with drought insurance and flood control benefits. “Banking recharge operations during flood release periods serve to minimize downstream flooding problems while maximizing recharge of water on the Kern River for local benefit” (Wong, 1999). For example, the bank participants successfully used the recharge facility in 1995 to manage heavy runoff.

15.3.2.4. Prairies–Great Plains Subregion

An attempt at proactive “mitigation” of an atmospheric threat is the cloud seeding program underway in Alberta since 1996 to reduce the severity of hailstorms. Central North America is one of the most hail-prone regions in the world. A 1995 hailstorm did more than US\$1.1 billion damage in Dallas, a 1990 storm did US\$600 million damage in Denver, and a 1991 hailstorm did about US\$240 million (CDN\$340 million) damage in Calgary. Hailstorms account for more than half of the catastrophic events in this region. In the Alberta program, storms with the potential to generate hail damage are intensively treated through cloud seeding. Since the program began, there has been an increase in the number of potential hailstorms, yet a pronounced reduction in actual hail damage. Indeed, during the first 4 years of the program, only one storm has done damage in the area under supervision (IBC, 2000).

Throughout the long history of hail suppression in North America and elsewhere, success has been mixed (e.g., Changnon *et al.*, 1978), so it is not yet clear whether this approach will work over the long term. The experimental program in Alberta is expected to continue indefinitely because the modest US\$1 million (CDN\$1.5 million) annual operating cost appears to be more than offset by the reduction in observed hail damage (IBC, 2000).

15.3.2.5. Great Lakes–St. Lawrence Subregion

Scenario-based studies in the Great Lakes–St. Lawrence basin conducted over the past 15 years (see Section 15.2.1) have indicated consistently that a warmer climate would lead to reductions in water supply and lake levels (Cohen, 1986; Croley, 1990; Hartmann, 1990; Mortsch and Quinn, 1996; Mortsch, 1998). Observed low-level events have been rare during the past several decades, but when they have occurred (e.g., 1963–1965, 1988), conflicts related to existing water diversions and competing stakeholders have led to legal challenges and political stress (Changnon and Glantz, 1996).

In 1998–1999, dry and record warm weather combined to reduce ice extent and lower water levels (Assel *et al.*, 2000). In November 1998 and again in spring 1999, cargo limits were placed on ships travelling through the Great Lakes and the St. Lawrence Seaway when water levels fell by more than 25 cm. Some commercial ships ran aground. Lower water levels significantly increased the distance between docks and waters at some tourism facilities and marinas. Recreational boaters had access to fewer waterways. In addition, hydroelectric facilities are very dependent on water flows and have expressed concern about maintaining production (Mittelstaedt, 1999). These observed impacts are similar to the impact scenarios described earlier. The reduction in ice cover did provide some offsetting benefits by reducing the need for icebreakers during the winter and spring (Assel *et al.*, 2000).

Water resources management, ecosystem and land management, and health concerns are highlighted in the Great Lakes–St. Lawrence Basin Project (GLSLB) and the Toronto–Niagara Region Study (TNR). The former is a binational exercise that used analogs and model-based scenarios to assess impacts and adaptation responses. Reduced lake levels continue to be projected, leading to potential conflicts over water regulation and diversions, water quality, and rural water use (Mortsch *et al.*, 1998). The TNR exercise is in its initial stages. Within the GLSLB region, the TNR represents a highly urbanized area that has a significant impact on surrounding agricultural and forest landscapes. Urban influences on land use, air quality, and human health will be a major focus. In addition, concerns about vulnerabilities of the built environment (transportation and energy infrastructure, etc.) have been identified as high-priority research questions (Mills and Craig, 1999).

There also have been studies of alternative scenarios for lake-level management. Decision support systems can facilitate this process (Chao *et al.*, 1999).

15.3.2.6. North Atlantic Subregion

Severe winter storms combined with a loss of power can have devastating consequences, even in a highly developed region such as Ontario–Quebec and the northeast United States. In January 1998, a severe winter storm struck; instead of snow, some areas accumulated more than 80 mm of freezing rain—double the

Table 15-5: Estimated damages from 1998 ice storm.^a

Type of Loss	Canada (CDN\$)	United States (US\$)	Total (US\$)
Insured losses	\$1.44 billion	\$0.2 billion	\$1.2 billion
Insurance claims	696,590	139,650	835,240
Deaths	28	17	45
People (customers) without power	4,700,000 (1,673,000)	546,000	5,246,000
Electricity transmission towers/distribution poles toppled	130/30,000	unknown	unknown
Electric transmission system damage	\$1 billion	unknown	unknown
Manufacturing, transportation, communications, and retail business losses	\$1.6 billion	unknown	unknown
Forests damaged	unknown	17.5 million acres	unknown
Loss of worker income	\$1 billion	unknown	unknown
Dairy producers experiencing business disruption	5,500	unknown	unknown
Loss of milk	\$7.3 million	\$12.7 million	\$18 million
Agricultural sector (poultry, livestock, maple syrup)	\$25 million	\$10.5 million	\$28 million
Quebec and Ontario governments	\$1.1 billion		

^aBased on analysis conducted by the Canadian Institute for Catastrophic Loss Reduction and U.S.-based Institute for Business and Home Safety, both of which are insurance industry organizations (Lecomte *et al.*, 1998). Losses as of 1 October 1998 (1 CDN\$ = 0.7 US\$).

amount of precipitation experienced in any prior ice storm. The result was a catastrophe that produced the largest estimated insured loss in the history of Canada. The same storm ran across northern New York and parts of Vermont, New Hampshire, and Maine in the United States (see Table 15-5). The basic electric power infrastructure, with its lengthy transmission lines, was severely damaged, stranding some residents and farmers without power for as many as 4 weeks. Almost 5 million people were without power at some point during the storm, and consideration was given to evacuation of Montreal. In Canada, there were 28 deaths, and damages were US\$2–3 billion (CDN\$3–4 billion) (Kovacs, 1998; Kerry *et al.*, 1999). The same storm caused 17 deaths in the United States, as well as damages exceeding US\$1 billion in New York and the New England states—one-third of which was from losses to electric utilities and communications (DeGaetano, 2000). Combined Canadian and U.S. insured losses stood in excess of US\$1.2 billion as of October 1, 1998. Total Canadian insured and uninsured economic losses were approximately US\$4 billion (CDN\$6.4 billion).

The ice storm produced more than 835,000 insurance claims from policyholders in Canada and the United States. This was

20% more claims than were created by Hurricane Andrew, the costliest natural disaster in the history of the United States.

The event served as a grim learning laboratory for the insurance and disaster recovery communities. It revealed the wide spectrum of insured and noninsured losses that can materialize from a single natural catastrophe, including:

- Property losses (e.g., roof damages and destruction of perishable goods as a result of loss of electric power)
- Business interruption losses (19% of the employed Canadian workforce was unable to get to work)
- Health/life losses (including losses incurred during recovery operations)
- Additional living expense costs for people relocated to temporary housing
- A host of agricultural losses, ranging from livestock deaths, to interrupted maple syrup production, to milk production
- Disruption and damage to recreation and tourism infrastructure

- Disaster recovery costs, including personnel and overtime expenses, provision of backup electric generators and fuel, debris clearing, temporary shelter for displaced citizens, and disaster assistance payments to victims.

Ice storms occur regularly in North America, although severe and prolonged damage is rare. Several urban centers are vulnerable to major storms, including Minneapolis, Winnipeg, Chicago, Detroit, Toronto, Buffalo, Montreal, Boston, and even New York. Many communities are not prepared for an extreme winter storm, particularly combined with the loss of electric power. In the 1998 storm, total losses exceeded insured losses by a substantial margin. The event also raised questions about the connection between such events, the El Niño phenomenon, and global climate change.

15.3.2.7. Southeast United States

The Gulf of Mexico has a problem with hypoxia (low oxygen) during summer over an area of approximately 15,000 km² (Turner and Rabalais, 1991; Rabalais *et al.*, 1996). The hypoxia has been shown to be a result of excess nutrients—primarily nitrogen—transported to the Gulf from the Mississippi River basin. This basin is heavily fertilized for crop production. The causes of, and proposed solutions for, this hypoxia problem are an excellent example of a complex interaction between climate and other human stresses on natural ecosystems. Specific “lessons” from this problem include the following:

- The hypoxia problem was greatly exacerbated by the 1993 Mississippi basin flood that appeared to “flush” large amounts of residual nitrogen from agriculture to the Gulf (Rabalais *et al.*, 1996). Increases in extreme precipitation events, which are likely to occur with climate change, are likely to exacerbate coastal eutrophication problems in many locations.
- Recommended solutions to the hypoxia problem include creation of approximately 60,000 km² of wetlands to remove ~1,000 t yr⁻¹ of nitrogen by denitrification (Mitsch *et al.*, 2001). If such “eco-technologies” become a common solution to eutrophication problems on a global basis, they could result in a significant flux of N₂O to the atmosphere.

Management practices designed to reduce nitrogen losses from agricultural watersheds—from improved fertilizer management to the construction of wetlands—will be strongly affected by climate (NRC, 1993). Climate change will decrease the reliability of these practices. Increases in climate extremes almost certainly will decrease their long-term performance.

15.3.2.8. Arctic Border

A case study of the regional impacts of climate change scenarios has been completed in the Mackenzie basin, a watershed that extends from the mid-latitudes to the subarctic in northwest

Canada. A lengthy description of this case study, known as the Mackenzie Basin Impact Study, is available in Cohen (1994, 1996, 1997a,b,c). A sketch of the MBIS integrating framework is shown in Figure 15-10. Within this process, several types of integration exercises were used, including models, stakeholder consultation, and thematic discussions.

As a high-latitude watershed, the Mackenzie basin has been regarded as an area that might benefit in certain ways from a warmer climate. Taken individually, economic impacts could be quantified, and these impacts might show substantial benefits for the region. Other factors must be considered, however, and some of these factors may constrain the potential benefits:

- The current system of land transportation, much of which is based on a stable ice and snow cover for winter roads
- Current ranges and habitats of wildlife, which underpin conservation plans and native land claims
- Scientific uncertainty, which hampers anticipatory responses to projected beneficial conditions.

Potential negative impacts of climate warming also must be considered because they may offset possible benefits. An example is the implication of hydrological and landscape changes on water management agreements. Initial projections of runoff and lake levels are for declines below observed minima (Soulis *et al.*, 1994; Kerr, 1997). Peace River ice cover will be affected by temperature changes and changes in outflow from the Bennett Dam in northeast British Columbia (Andres, 1994). There continue to be uncertainties in projections of hydrological impacts; the Global Energy and Water Cycle Experiment (GEWEX) is addressing these uncertainties (see Chapter 16). There has been a strong warming trend in the region during the past 40 years, and Great Slave Lake experienced new record minimum lake levels in 1995.

It would appear that the other main threats to the Mackenzie landscape are accelerated erosion and landslides caused by permafrost thaw and extreme events (fire, storm surges), especially in sloping terrain and the Beaufort Sea coastal zone (Aylsworth and Egginton, 1994; Solomon, 1994; Aylsworth and Duk-Rodkin, 1997; Dyke *et al.*, 1997); increased fire hazard (Hartley and Marshall, 1997; Kadonaga, 1997); changes in climate conditions that influence the development of peatlands (Nicholson *et al.*, 1996, 1997; Gignac *et al.*, 1998); and invasion of new pests and diseases from warmer regions (Sieben *et al.*, 1997).

Impacts on fisheries and wildlife are difficult to project, as a result of lack of long-term data, complexity of life cycles, and incomplete information on responses to previous environmental changes (Brotton and Wall, 1997; Gratto-Trevor, 1997; Latour and MacLean, 1997; Maarouf and Boyd, 1997; Melville, 1997). Outside of MBIS, there have been few impact studies on North American boreal and Arctic freshwater fisheries (Weatherhead and Morseth, 1998). Some information is available on terrestrial wildlife and Arctic marine fisheries (see Chapter 16). Others have outlined the potential for freshwater ecosystem

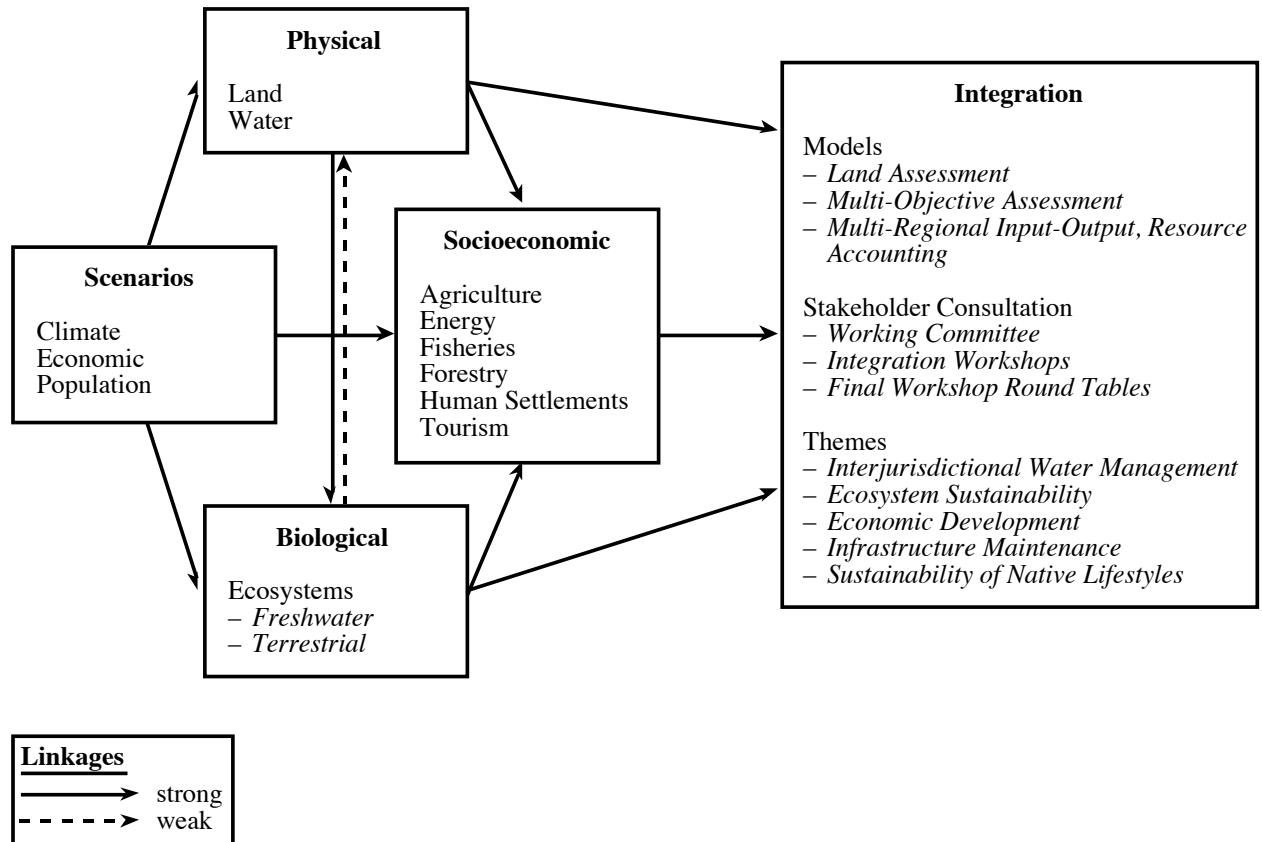

Figure 15-10: Research framework for MBIS (Cohen, 1997b). Scenarios were generated for use by physical and biological system studies. Socioeconomic component used results from these assessments, as well as climate scenario information where appropriate. Integration exercises were based on outputs from sectoral studies.

impacts, including loss or reduction of deltaic lakes, increased pondwater temperatures, side effects of permafrost thaw (including sedimentation of rivers), and changes in primary productivity depending on nutrient levels (Rouse *et al.*, 1997; Schindler *et al.*, 1997; Meyer *et al.*, 1999).

First-order and second-order impacts eventually lead to others that are considerably more difficult to address. Will land claims or water resources agreements be affected? Would it be appropriate to artificially maintain historic water levels in the Peace-Athabasca delta within this scenario of climate change (see Chapter 16)? Could there be new conflicts over land use, especially if agriculture expands northward to take advantage of improved soil capability to support crop production (Brklacich *et al.*, 1996, 1997b)? What might be the effects on parks and other protected areas (Pollard and Benton, 1994) and tourism (Staple and Wall, 1996; Brotton and Wall, 1997; Brotton *et al.*, 1997; Wall, 1998a,b)? Could climate change affect the economics of commercial forestry (Rothman and Herbert, 1997) or oil and gas production in the Beaufort Sea (Anderson and DiFrancesco, 1997)?

Two exercises dealt with individual perceptions of aboriginal responses to future scenarios. The first asked for a listing of

physical and biological impacts, as well as how aboriginal people would be affected if they continued to pursue a traditional aboriginal lifestyle or if they became more active in the formal wage economy (similar to the dual-economy situation described by Shukla, 1997). Results showed that perceptions of impact and vulnerability were influenced by visions of future lifestyles (Aharonian, 1994). The second exercise used input-output modeling and a community survey to look at responses to a potential benefit of warming—an opportunity for expanded activity in the formal wage economy (because of the longer summer) that would force people to relocate from their traditional community if they wanted the employment. Results showed a willingness to accept the opportunity, but there were concerns about social impacts on the community of relocation or creation of commuter workers who would be absent for extended periods (Lonergan and Kavanagh, 1997).

Potential land-use impacts and adaptation responses also were considered. One issue was whether the region could take advantage of a longer growing season to expand wheat production. Results showed that this was possible (given the constraints of the model), but only if expanded irrigation services would be made available (Brklacich *et al.*, 1997a). The side effects of this are unknown. The second case was a

forestry study that showed that commercial yields of softwood lumber would decline because of changing growth potential for these species, combined with increased fire frequency. This would offset improvements for hardwood species (Hartley and Marshall, 1997; Rothman and Herbert, 1997). Integrated modeling exercises, using these sectoral outputs, indicated that agriculture production would be able to achieve its goals, but there would be shortfalls in softwood (spruce) production and a substantial increase in erosion (Yin and Cohen, 1994; Huang *et al.*, 1998; Yin *et al.*, 2000).

Stakeholders were asked to react to the various research results through thematic roundtable discussions. One of these themes was infrastructure maintenance. Engineers suggested that physical infrastructure—such as roads, airstrips, and pipelines—could be repaired or designed differently to meet changing climatic conditions, but there certainly would be increased costs in doing so. It also was suggested that the notion of infrastructure should include education and insurance mechanisms, emergency response, and social and cultural institutions that pool risk and support people in times of stress (Zdan, 1997). Changes in community development already have influenced emergency response to floods and could affect adaptation to future climate changes (Newton, 1995, 1997).

In another thematic context—ecosystem sustainability—it is unclear whether current institutions in the region would be capable of coping with a scenario of simultaneous changes in renewable resources and dependent communities, superimposed on other nonclimate stresses affecting the region. During the past few years in northern Canada, co-management processes have been developing for aboriginal and non-aboriginal (and government) stakeholders concerned with wildlife and water resources. This has been part of a larger trend of devolution of responsibility from central to regional authorities in Canada—a trend that is taking place for reasons other than climate change. Regional stakeholders regard these processes as their best approach to coping with climate change, although it was noted that climate change would be a new experience for everyone (Irlbacher, 1997).

Climate change joins a long list of factors that affect the lifestyles and livelihoods of people who live in the north. With or without climate change, however, native lifestyles are in flux, and any potential impacts should be considered in that context. Communities already are being affected by changes in wildlife harvesting opportunities and wage-based employment. Education and transportation have improved, and some native people are opting for jobs in the wage economy. As the “two economies” continue to evolve, communities will be trying to provide opportunities in traditional and wage-based activities, but if climate change affects wildlife numbers or habitats, traditional patterns of wildlife harvesting would have to be modified.

Native people have adapted to change, but the predictability of the extent, duration, and speed made such adaptation possible. There is real concern that if future changes were to be fast,

dramatic, and surprising, native communities would be left in a very vulnerable position. Traditional lifestyles would be at risk of disappearing.

Stakeholders have proposed that monitoring and adaptation could be undertaken through more effective partnerships between governments and native communities. Traditional knowledge, along with western science, should be used in modern management practices as well as in traditional activities. Training in renewable resource management for aboriginal youth would be an important component of preparing for the future (Pinter, 1997).

15.3.2.9. U.S.-Mexican Border

The U.S.-Mexican border is characterized by a semi-arid climate, with higher precipitation toward both coasts. Evaporation exceeds precipitation for many months of the year, causing a soil moisture deficit. Many studies relate climate and hydrology along the U.S. border states (Green and Sellers, 1964; Hastings and Turner, 1965; Norwine, 1978; Cayan and Peterson, 1989) and along the Mexican border states (Mosíño and García, 1973; Schmidt, 1975; Acosta, 1988; Cavazos, 1998). The western border has an annual rainfall of about 250 mm yr⁻¹, with temperatures ranging from 10 to 28°C. The Arizona-Sonora border has a much more extreme and desert climate, with only 80 mm yr⁻¹ of precipitation and maximum temperatures reaching 45°C. Around the Ciudad Juarez (Mexico)-El Paso (Texas) border, annual precipitation is around 220 mm, with maximum temperatures reaching 40°C. Finally, in the easternmost part of the border (Brownsville, Texas-Matamoros, Mexico), annual precipitation is close to 675 mm, with temperatures ranging from 11 to 38°C.

There is large climate variability along the U.S.-Mexican border states. Drought and floods occur frequently (Powell Consortium, 1995), some influenced by the occurrence of El Niño (Cavazos and Hastenrath, 1990; Cayan and Webb, 1992). The Mexican states along the border are highly vulnerable to drought, particularly along the Rio Grande region, areas with low precipitation rates (less than a 100 mm yr⁻¹) (Mundo and Martínez Austria, 1993; Hernández, 1995; Mendoza *et al.*, 1997). Strong El Niño events during the summer result in severe water deficit in northern Mexico (Magaña and Quintanar, 1997), and serious negative impacts in agricultural activities. Such vulnerable conditions during drought periods have resulted in legal disputes between Mexico and the state of Texas with regard to rights to Rio Grande water.

It is unclear what the signs of future changes in precipitation and water availability will be along the border (Mearns *et al.*, 1995; Magaña *et al.*, 1997; Mendoza *et al.*, 1997). Some scenarios suggest increased winter precipitation and decreased summer precipitation (Magaña *et al.*, 1998). Without reliable predictions of precipitation changes across drainage basins, little confidence can be placed in hypothesized effects of global warming on annual runoff (Karl and Riebsame, 1989).

Therefore, to examine potential impacts of climate change on water availability, most studies make use of long instrumental records of precipitation and streamflow. Some analyses indicate that in recent decades there is a positive trend in streamflow and even precipitation, corresponding to more water availability along the U.S.–Mexican border (Magaña *et al.*, 1998; Magaña and Conde, 2000). However, demand for water in agriculture, industries, and cities is increasing steadily, surpassing recent increases in water availability (Mundo and Martínez Austria, 1994).

The signal of climate change along the U.S.–Mexican border may be exacerbated along the Mexican side by differences in land use. Along the U.S. side, the presence of gardens and green areas lead to a cooler environment relative to the Mexican side. Currently, maximum temperatures in contiguous border towns may differ by as much as 3°C as a result of different characteristics in vegetation (Balling, 1988). This cross-border contrast is possible because water consumption in U.S. border cities is four times larger than in Mexican border cities. Surface water distribution along the border (Rio Grande and Colorado watersheds) is regulated by the Binational Treaty of 1944. Yet, there are no regulations for subsurface water (Sanchez, 1994).

15.3.2.10. The U.S.–Caribbean Border

Some of the U.S.–Caribbean border problems that may increase as a result of climate change are related to:

- Effects of sea-level changes on coastal ecosystems
- Effects of temperature increases on terrestrial and aquatic ecosystems, including possible effects on economically important species
- Effects of climate change on socioeconomic structures and activities.

Considering the high population density in part of the Caribbean islands and coastal areas, human settlements will be highly affected by sea-level rise and saline intrusion (Vincente *et al.*, 1993). Coral reefs in the region may be severely affected by coral bleaching induced by warmer water temperatures (Milliman, 1993).

Tourism is a major economic activity in most of the region. A change in rainfall patterns, tropical storms, and warming of the climate in temperate countries may affect the comparative advantages of this sector in the region (Alm *et al.*, 1993). Narrow beaches combined with projected sea-level rise contribute to the vulnerability of the tourism sector to changes in climate (Gable, 1997).

Potential consequences of changes in extreme events (e.g., hurricanes) are not well-defined. Other trends, such as changing demographic patterns, may exacerbate impacts. Recent large losses of life from rainfall-induced floods, mudflows, and landslides reflect increasing concentrations of residents in high risk areas (Rodriguez, 1997; Pulwarty, 1998).

15.4. Synthesis

Our impacts and adaptation assessment indicates that changing climate and changing patterns of regional development have challenged North America and will continue to do so. Damage costs from recent climatic events have increased, and conflicts over climate-sensitive resources (e.g., fish) continue to occur. Future climatic changes may exacerbate these problems and indeed create new ones. Opportunities may arise from a warming climate, and some innovative adaptation mechanisms (e.g., water banks) are being tested to address current problems. However, the literature provides few cases on how adaptive strategies could be implemented in the future as regional climates continue to change.

Recent studies in agriculture point to greater crop diversity and possibilities for adaptation as factors in reducing estimates of future damage. Production forestry is regarded in much the same way, except in high-latitude regions where vulnerabilities to changing climate-related risks (pests, fire, permafrost thaw) still are considered significant challenges for management. Estimates of future damage to U.S. coastal zones have declined despite the recent series of high-cost extreme events. However, studies also have documented changing vulnerabilities of built (urban) environments to atmospheric events, risks to indigenous lifestyles, and the challenge of managing resources within a changing climatic regime to meet multiple objectives. Climate change along the U.S.–Mexican border may result in social and economic problems related to transboundary water resources. Unique natural ecosystems such as prairie wetlands, alpine tundra, and coldwater ecosystems are at risk, and effective mitigation is unlikely.

As impact studies of North America attempt to include adaptation in a more significant way, damage estimates in some sectors decline or become benefits. Mendelsohn and Neumann (1999) illustrate this trend for agriculture, production forestry, and coastal zone impacts in the United States. What also emerges, however, is that high damage costs are still calculated for water-related activities and summer energy demand. Most important, there are several outstanding methodological issues related to the evolution of economic activities, adaptation assumptions, and the value of nonmarket components, resulting in continued difficulties in estimating the cost of impacts and the costs and benefits of adaptation responses. If optimistic views about adaptation were realistic, North America should have been better able to plan for extreme events. Recent experience demonstrates high capability in emergency response, but long-term problems remain.

During recent extreme weather events, synergies between development pressures and environmental changes have resulted in substantial damages. Examples documented in Sections 15.2.1, 15.2.3, 15.2.7, and 15.3.2 include water-quality problems resulting from North Carolina hurricanes, damage from the 1998 ice storm, reductions in fish stocks as a result of climatic shifts combined with fishing pressure, and various impacts

Table 15-6: Climate change adaptation issues in North American subregions. Unique issues for certain locations also are indicated.

North American Subregions	Development Context	Climate Change Adaptation Options and Challenges
Most or all subregions	<ul style="list-style-type: none"> – Changing commodity markets – Intensive water resources development over large areas—domestic and transboundary – Lengthy entitlement/land claim/treaty agreements—domestic and transboundary – Urban expansion – Transportation expansion 	<ul style="list-style-type: none"> – Role of water/environmental markets – Changing design and operations of water and energy systems – New technology/practices in agriculture and forestry – Protection of threatened ecosystems or adaptation to new landscapes – Increased role for summer (warm weather) tourism – Risks to water quality from extreme events – Managing community health for changing risk factors – Changing roles of public emergency assistance and private insurance
Arctic border	<ul style="list-style-type: none"> – Winter transport system – Indigenous lifestyles 	<ul style="list-style-type: none"> – Design for changing permafrost and ice conditions – Role of two economies and co-management bodies
Coastal regions	<ul style="list-style-type: none"> – Declines in some commercial marine resources (cod, salmon) – Intensive coastal zone development 	<ul style="list-style-type: none"> – Aquaculture, habitat protection, fleet reductions – Coastal zone planning in high-demand areas
Great Lakes	<ul style="list-style-type: none"> – Sensitivity to lake-level fluctuations 	<ul style="list-style-type: none"> – Managing for reduction in mean levels without increased shoreline encroachment

from recent water-level fluctuations in the Great Lakes. Unfortunately, only a few climate change scenario studies explore these kinds of synergies. Besides the challenge of projecting future economies, scenario studies of impacts and adaptation also have to consider the varied demands of regional stakeholders from the same resource and/or location. A summary of adaptation issues for North American subregions is provided in Table 15-6.

A wide range of factors—including changing political and institutional arrangements, technologies, and perceptions—may influence regional development futures. Concerns about development, equity, and sustainability are emerging in international negotiations of the United Nations Framework Convention on Climate Change and the Kyoto Protocol, and regional impacts/adaptation concerns can play an important role in this debate (Munasinghe and Swart, 2000). How could development paths alter a region's vulnerability to climate change? Could incentives related to emission reduction also enhance adaptation? Or, could management for certain environmental objectives lead to difficulties in meeting others? The example from the Columbia basin (Section 15.3.2), in which managing for fish protection could lead to increases in GHG emissions (Cohen *et al.*, 2000), illustrates the dilemma

that many subregions could face as they consider options for responding to climate change scenarios. How can these interactions be addressed in scenario studies? How can the various economic and social dimensions be accounted for so that there could be more confidence in estimates of impacts damages and adaptation costs/benefits?

Additional information on alternative climate scenarios and regional development futures will be needed in order to improve estimates of the costs of subregional impacts of climate change and the costs and benefits of adaptation responses. As measures associated with the Kyoto Protocol attract more attention from governments and industries, consideration also should be directed at studies on the interplay of mitigation and adaptation at the subregional scale.

EXECUTIVE SUMMARY

In this summary we indicate our uncertainty in observations, mechanisms, and scenarios by using a five-point scale, from “very high confidence” (*****) to “very low confidence” (*).

Climate Changes in the 20th Century

Although there are some regional anomalies, there is strong evidence that climate change has had an impact in the Arctic and the Antarctic. Many documented changes already parallel those forecast to result from climate change:

- In the Arctic, extensive land areas show a 20th-century warming trend in air temperature of as much as 5°C. Over sea ice, there has been slight warming in the 1961–1990 period.***** Precipitation has increased.*
- Arctic sea-ice extent has decreased by 2.9% per decade over the 1978–1996 period; sea ice has thinned, and there are now more melt days per summer. Sea-ice extent in the Nordic seas has decreased by 30% over the past 130 years.***** It is not yet clear whether changes in sea ice of the past few decades are linked to a natural cycle in climate variability or have resulted explicitly from global warming.
- Atlantic water flowing into the Arctic Ocean has warmed, and the surface layer has become thinner. The mixed layer in the Beaufort Sea has become less saline.****
- Regions underlain by permafrost have been reduced in extent, and a general warming of ground temperatures has been observed in many areas.*****
- There has been a statistically significant decrease in spring snow extent over Eurasia since 1915.****
- In summary, many observations of environmental change in the Arctic show a trend that is consistent with warming and similar to that predicted by general circulation models (GCMs).
- In the Antarctic, over the past half-century there has been a marked warming trend in the Antarctic Peninsula.**** Elsewhere there is a general but not unambiguous warming trend.**
- Precipitation in the Antarctic has increased.*
- Satellite observations show no significant change in Antarctic sea-ice extent over the 1973–1996 period.***** Analysis of whaling records and modeling studies indicate that Antarctic sea ice retreated south by 2.8 degrees of latitude between the mid-1950s and the early 1970s.***
- Surface waters of the Southern Ocean have warmed and become less saline.***

Impacts

Substantial warming and increases in precipitation are projected for polar regions over the 21st century by almost all climate models. There are eight key concerns related to the impact of this climate change in the Arctic and Antarctic. Associated with these concerns will be changes to the atmosphere and the oceans that will propagate to other regions of the world:

- 1) *Changes in ice sheets and polar glaciers:* Increased melting is expected on Arctic glaciers and the Greenland ice sheet, and they will retreat and thin close to their margins. Most of the Antarctic ice sheet is likely to thicken as a result of increased precipitation. There is a small risk, however, that the West Antarctic and Greenland ice sheets will retreat in coming centuries. Together, these cryospheric changes may make a significant contribution to sea-level rise.***
- 2) *Changes around the Antarctic Peninsula:* This region has experienced spectacular retreat and collapse of ice shelves, which has been related to a southerly migration of the January 0°C isotherm resulting from regional warming. The loss of these ice shelves has few direct impacts. Projected warming is likely, however, to break up ice shelves further south on the Antarctic Peninsula, expose more bare ground, and cause changes in terrestrial biology, such as introduction of exotic plants and animals.***
- 3) *Changes in the Southern Ocean and impacts on its life:* Climate change is likely to produce long-term—perhaps irreversible—changes in the physical oceanography and ecology of the Southern Ocean. Projected reductions in sea-ice extent will alter under-ice biota and spring bloom in the sea-ice marginal zone and will cause profound impacts at all levels in the food chain, from algae to krill to the great whales. Marine mammals and birds, which have life histories that tie them to specific breeding sites, will be severely affected by shifts in their foraging habitats and migration of prey species. Warmer water will potentially intensify biological activity and growth rates of fish. Ultimately, this should lead to an increase in the catch of marketable fish, and retreat of sea ice will provide easier access to southern fisheries.***
- 4) *Changes in sea ice:* There will be substantial loss of sea ice in the Arctic Ocean. Predictions for summer ice indicate that its extent could shrink by 60% for a doubling of carbon dioxide (CO₂), opening new sea routes. This will have major trading and strategic implications. With more open water, there will be a moderation of temperatures

- and an increase in precipitation in Arctic lands. Antarctic sea-ice volume is predicted to decrease by 25% or more for a doubling of CO₂, with sea ice retreating about 2 degrees of latitude.****
- 5) *Changes in permafrost:* Thickening of the seasonally thawed layer above permafrost (active layer) is expected. Modeling studies indicate that large areas of permafrost terrain will begin to thaw, leading to changes in drainage, increased mass movements, thermal erosion, and altered landscapes in much of the Arctic and subarctic. Warming of permafrost, thawing of ground ice, and development of thermokarst terrain have been documented over the past several decades. In developed areas of the Arctic, continuation of such changes may lead to costly damage to human infrastructure.****
- 6) *Changes in Arctic hydrology:* The hydrology of the Arctic is particularly susceptible to warming because small rises in temperature will result in increased melting of snow and ice, with consequent impacts on the water cycle. There will be a shift to a runoff regime that is driven increasingly by rainfall, with less seasonal variation in runoff. There will be more ponding of water in some areas, but peatlands may dry out because of increased evaporation and transpiration from plants. In some areas, thawing of permafrost will improve infiltration. An expected reduction in ice-jam flooding will have serious impacts on riverbank ecosystems and aquatic ecology, particularly in the highly productive Arctic river deltas. Changes in Arctic runoff will affect sea-ice production, deepwater formation in the North Atlantic, and regional climate. A major impact would result from a weakening of the global thermohaline circulation as a result of a net increase in river flow and the resulting increased flux of freshwater from the Arctic Ocean.***
- 7) *Changes in Arctic biota:* Warming should increase biological production; however, the effects of increased precipitation on biological production are unclear. As warming occurs, there will be changes in species compositions on land and in the sea, with a tendency for poleward shifts in species assemblages and loss of some polar species. Changes in sea ice will alter the seasonal distributions, geographic ranges, patterns of migration, nutritional status, reproductive success, and ultimately the abundance and balance of species. Animals that are dependent on sea ice—such as seals, walrus, and polar bears—will be disadvantaged. High-arctic plants will show a strong growth response to summer warming. It is unlikely that elevated CO₂ levels will increase carbon accumulation in plants, but they may be damaged by higher ultraviolet-B radiation. Biological production in lakes and ponds will increase.***
- 8) *Impacts on human communities:* Climate change, in combination with other stresses, will affect human communities in the Arctic. The impacts may be particularly disruptive for communities of indigenous peoples following traditional lifestyles. Changes in sea ice, seasonality of snow, and habitat and diversity of food species will affect hunting and gathering practices and could threaten longstanding traditions and ways of life. On the other hand, communities that practice these lifestyles may be sufficiently resilient to cope with these changes. Increased economic costs are expected to affect infrastructure, in response to thawing of permafrost and reduced transportation capabilities across frozen ground and water. However, there will be economic benefits—including new opportunities for trade and shipping across the Arctic Ocean, lower operational costs for the oil and gas industry, lower heating costs, and easier access for ship-based tourism.*****

Feedbacks and Interactions

Climate change and global warming will affect key polar drivers of further climate change. These effects will have impacts that affect other regions of the world. Models indicate that once triggered, these impacts will continue for centuries and lead to further change elsewhere in the world:

- Warming will reduce sea-ice and snow extent, particularly in the Arctic, causing additional heating of the surface—which, in turn, will further reduce ice/snow cover.*****
- Deep ocean water around the Antarctic and in the north Atlantic is a crucial part of the ocean's thermohaline circulation. Its rate of production is likely to decrease because of freshening of waters from increased Arctic runoff from glacial icemelt, from increases in precipitation over evaporation, and from reduced sea-ice formation. Models indicate that the impact will be a prolonged, major slowing of the thermohaline circulation and ocean ventilation, even with stabilization of greenhouse gases (GHGs).***
- Polar regions have oceans, wetlands, and permafrost that act as major sources and sinks for atmospheric CO₂ and methane (CH₄) over vast areas. Projected climate change will alter these features and increase their contributions to GHGs. The Southern Ocean's uptake is projected to decline; CO₂ emissions from Arctic tundra may rise initially as a result of changes in water content, peat decomposition, and thawing of permafrost.***

Vulnerability and Adaptation

- Localities within the Antarctic and Arctic where water is close to its melting point are highly sensitive to climate change; this sensitivity renders their biota and socioeconomic life particularly vulnerable to climate change. In the Antarctic Peninsula, as ice melts, changes are likely to be rapid, but overall the Antarctic and the Southern Ocean are likely to respond relatively slowly to climate change, so there will be less impact in this region compared with elsewhere by 2100. Nevertheless, climate change in the Antarctic will initiate

- processes that could last for millennia—long after greenhouse emissions have stabilized—and these changes will cause irreversible impacts on ice sheets, oceanic circulation of water, and sea-level rise.
- The Arctic is extremely vulnerable to climate change, and major ecological, sociological, and economic impacts are expected. A variety of positive feedback mechanisms induced by climate change are likely to operate in the Arctic; these mechanisms will cause rapid and amplified responses, with consequential impacts on the thickness and extent of sea ice, thawing of permafrost, runoff into the Arctic Ocean, and coastal erosion.
 - Biota are particularly vulnerable to climate change in the polar regions. Less sea ice will reduce ice edges, which are prime habitats for marine organisms. Habitat loss for some species of seal, walrus, and polar bear results from ice melt, and apex consumers—with their low-reproductive outputs—are vulnerable to changes in the long polar marine food chains.
 - Adaptation to climate change in natural polar ecosystems is likely to occur through migration and changing species assemblages, but the details of these effects are unknown. Some animals may be threatened (e.g., walrus, polar bear, and some species of seal), whereas others may flourish (e.g., some species of fish and penguins).
- Loss of sea ice in the Arctic will provide increased opportunities for new sea routes, fishing, and new settlements, but also for wider dispersal of pollutants. Collectively, these changes emphasize the need for an adequate infrastructure to be in place before they occur. Disputes over jurisdiction in Arctic waters, sustainable development of fisheries and other marine resources, and construction of navigational aids and harbor facilities, as well as problems arising from oil and gas development, including pollution and environmental monitoring, will all have to be resolved by polar and associated nations as climate-induced change becomes widespread. Just as important is the need for new building codes for roads, railways, runways, and buildings to cope with the effects of permafrost thawing.
- Although most indigenous peoples are highly resilient, the combined impacts of climate change and globalization create new and unexpected challenges. Because their livelihood and economy increasingly are tied to distant markets, they will be affected not only by climate change in the Arctic but also by other changes elsewhere. Local adjustments in harvest strategies and in allocation of labor and capital will be necessary. Perhaps the greatest threat of all is to maintenance of self-esteem, social cohesion, and cultural identity of communities.
-

16.1. Polar Regions

For the purposes of this assessment, the Arctic is defined as the area within the Arctic Circle. It covers the Arctic Ocean and the islands and northern continental land areas (see Figure 16-1). Thus, it extends far enough south to include parts of the boreal forest and discontinuous permafrost zone. Note that the Arctic, thus defined, overlaps with other regions covered in this report—namely, North America, Asia, and Europe—and that important physical and biological processes that are typical of the Arctic also occur south of the Arctic Circle. The Antarctic is defined here as the Antarctic continent, together with the surrounding Southern Ocean south of the Antarctic Convergence (polar front), an oceanographic barrier that shifts with time and longitude but generally is close to 58°S. Also included in the polar regions are sub-Antarctic islands such as Campbell Island, Heard Island, and South Georgia, some of which are north of the Antarctic Convergence (see Figure 16-2).

The two polar regions are dominated by cold conditions and the presence of ice, snow, and water. They are different in that the Arctic is a frozen ocean surrounded by continental landmasses and open oceans, whereas Antarctica is a frozen continent surrounded solely by oceans. Antarctica tends to be thermally isolated from the rest of the planet by the surrounding Southern Ocean and the atmospheric polar vortex, whereas the Arctic is influenced strongly by seasonal atmospheric transport and river flows from surrounding continents. Both regions have major influences on the global ocean.

The Arctic and Antarctic influence climate over a significant part of the globe. Many unique climatic processes operate in these regions. Some involve complex interactions and feedback loops (Simmonds, 1998) that may lead ultimately to glacial-interglacial climate transitions (Petit *et al.*, 1999). Processes in polar regions greatly influence sea level. The Arctic and Antarctic have food webs and natural ecosystems with remarkable productivity. The Arctic is on the periphery of human settlement, where people must adapt to harsh, cold regimes; the Antarctic is uninhabited apart from research bases.

16.1.1. Previous Work—Summary of Special Report on Regional Impacts of Climate Change

The IPCC, in its *Special Report on Regional Impacts of Climate Change* (RICC), produced an assessment of the impacts of climate change on the Arctic and the Antarctic (Everett and Fitzharris, 1998). In addition, the impact of climate change on the cryosphere is discussed in the IPCC Second Assessment Report (SAR) (Fitzharris, 1996). The main points arising from the regional assessment were that the Arctic is extremely vulnerable to projected climate change—major physical, ecological, sociological, and economic impacts are expected. Because of a variety of positive feedback mechanisms, the Arctic is likely to respond rapidly and more severely than any other area on Earth, with consequent effects on sea ice, permafrost, and hydrology. On the other hand, the Antarctic

would respond relatively slowly to climate change, with much smaller impacts expected by 2100, except in the Antarctic Peninsula.

RICC noted that substantial loss of sea ice in the Arctic Ocean would have major implications for trade and defense (Everett and Fitzharris, 1998). With more open water, there would be moderation of temperatures and increased precipitation. Considerable thawing of permafrost would lead to changes in drainage, increased slumping, and altered landscapes over vast areas of northern parts of North America and Eurasia. RICC also purported that polar warming probably should increase biological production, but different species compositions are likely on land and in the sea, with a tendency for poleward shifts in major biomes and associated animals. Animals that are dependent on ice would be disadvantaged. Human communities in the Arctic—especially indigenous peoples following traditional lifestyles—would be affected by these changes.

RICC also pointed out that changes in polar climate are likely to affect other parts of the world through changes in sea level, decreased oceanic heat transport, and increased emissions of GHGs from thawing permafrost. However, there would be economic benefits as well as costs. Potential benefits include new opportunities for shipping across the Arctic Ocean, lower operational costs for the oil and gas industry, lower heating costs, and easier access for tourism. Increased costs could be expected from changes such as disruptions to land and infrastructure caused by thawing of permafrost and reduced transportation capabilities across frozen ground and water.

Since these IPCC reports, there have been important advances in knowledge about climate change in polar regions. These advances include more information about decreases in Arctic and Antarctic sea-ice extent, verification of substantial thinning of Arctic sea ice, documentation of important changes in polar oceans, and more analyses of continental snow-cover trends. Many observations of environmental change in the Arctic show a trend that is consistent with GHG warming and similar to that predicted by climate models.

This report is different from earlier IPCC reports in that it focuses on eight key concerns of climate impact. The risk of collapse of the West Antarctic ice sheet is now considered to be lower than first thought. Changes around the Antarctic Peninsula are given prominence, and the implications for the whole continent are discussed in more detail. Previous reports said little about the impacts on polar oceans and consequences for marine life. New information, especially for the Southern Ocean and its role in the global thermohaline circulation, is presented here. There also are improved predictions of sea ice over the 21st century, and the role of Arctic hydrology and the implications of altered river flows into the Arctic Ocean for the Atlantic driver of the thermohaline circulation are addressed. More information is now available regarding the impacts of climate change on Arctic biota. More detail is supplied about impacts on human communities, especially indigenous peoples following traditional lifestyles. This research has highlighted

the role of climate change in the Arctic and Antarctic and its impact on polar drivers of the global system. New modeling has identified the large role of polar regions in affecting the global thermohaline circulation, sea-level rise, and greenhouse

exchanges between the atmosphere, cold oceans, and tundra. It is now clearer that climate change could initiate processes that could last for millennia and persist long after greenhouse emissions have stabilized.

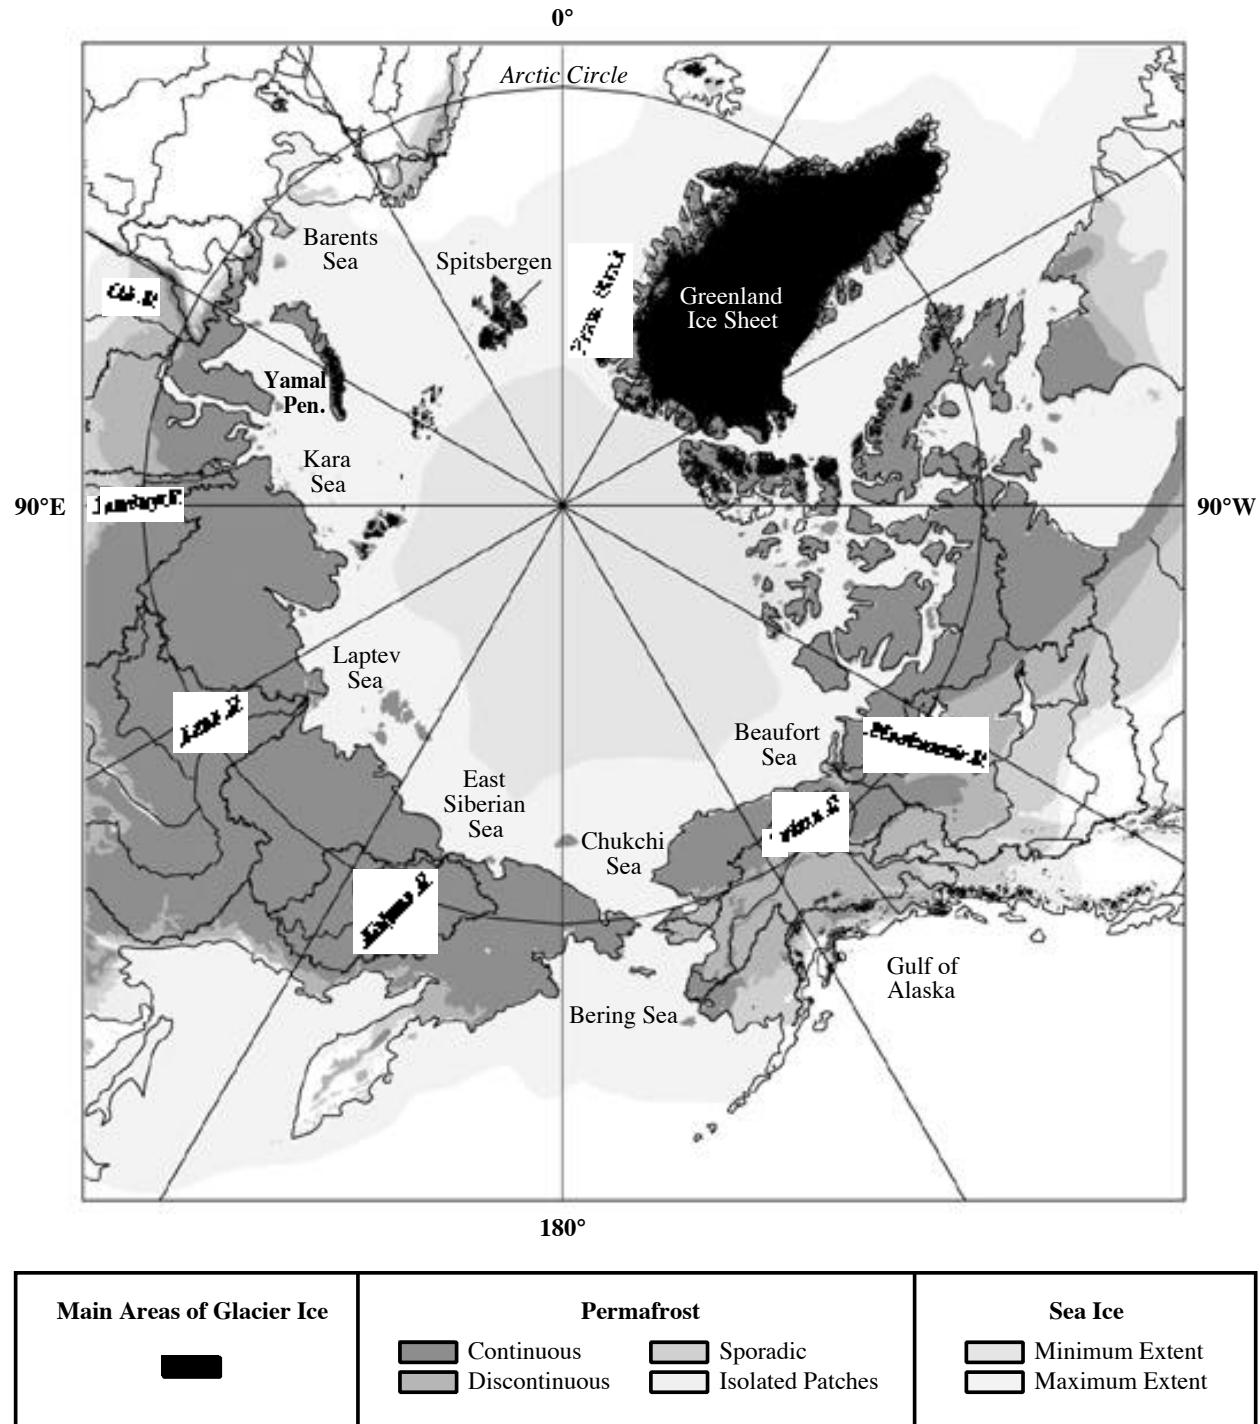

Figure 16-1: Location map for the Arctic. Permafrost zonation, drainage basins, sea ice, and main areas of glacier ice are shown. Drainage basins are delimited by solid black lines. Permafrost zonation is based on a digital version of the map by Brown *et al.* (1997).

16.1.2. Distinctive Characteristics of Polar Regions

The most distinctive feature of polar regions is the large seasonal variation in incoming solar radiation—from very little in winter to 24 hours of continuous sunlight in summer. Although the poles receive less solar radiation annually than

equatorial locations, near the time of the solstices they receive more per day. The high albedo of the snow- and ice-covered polar regions, together with the large loss of long-wave radiation through the very clear and dry atmosphere, ensures a net loss of radiation in most months of the year. These losses of radiation are particularly large during the long polar night and help

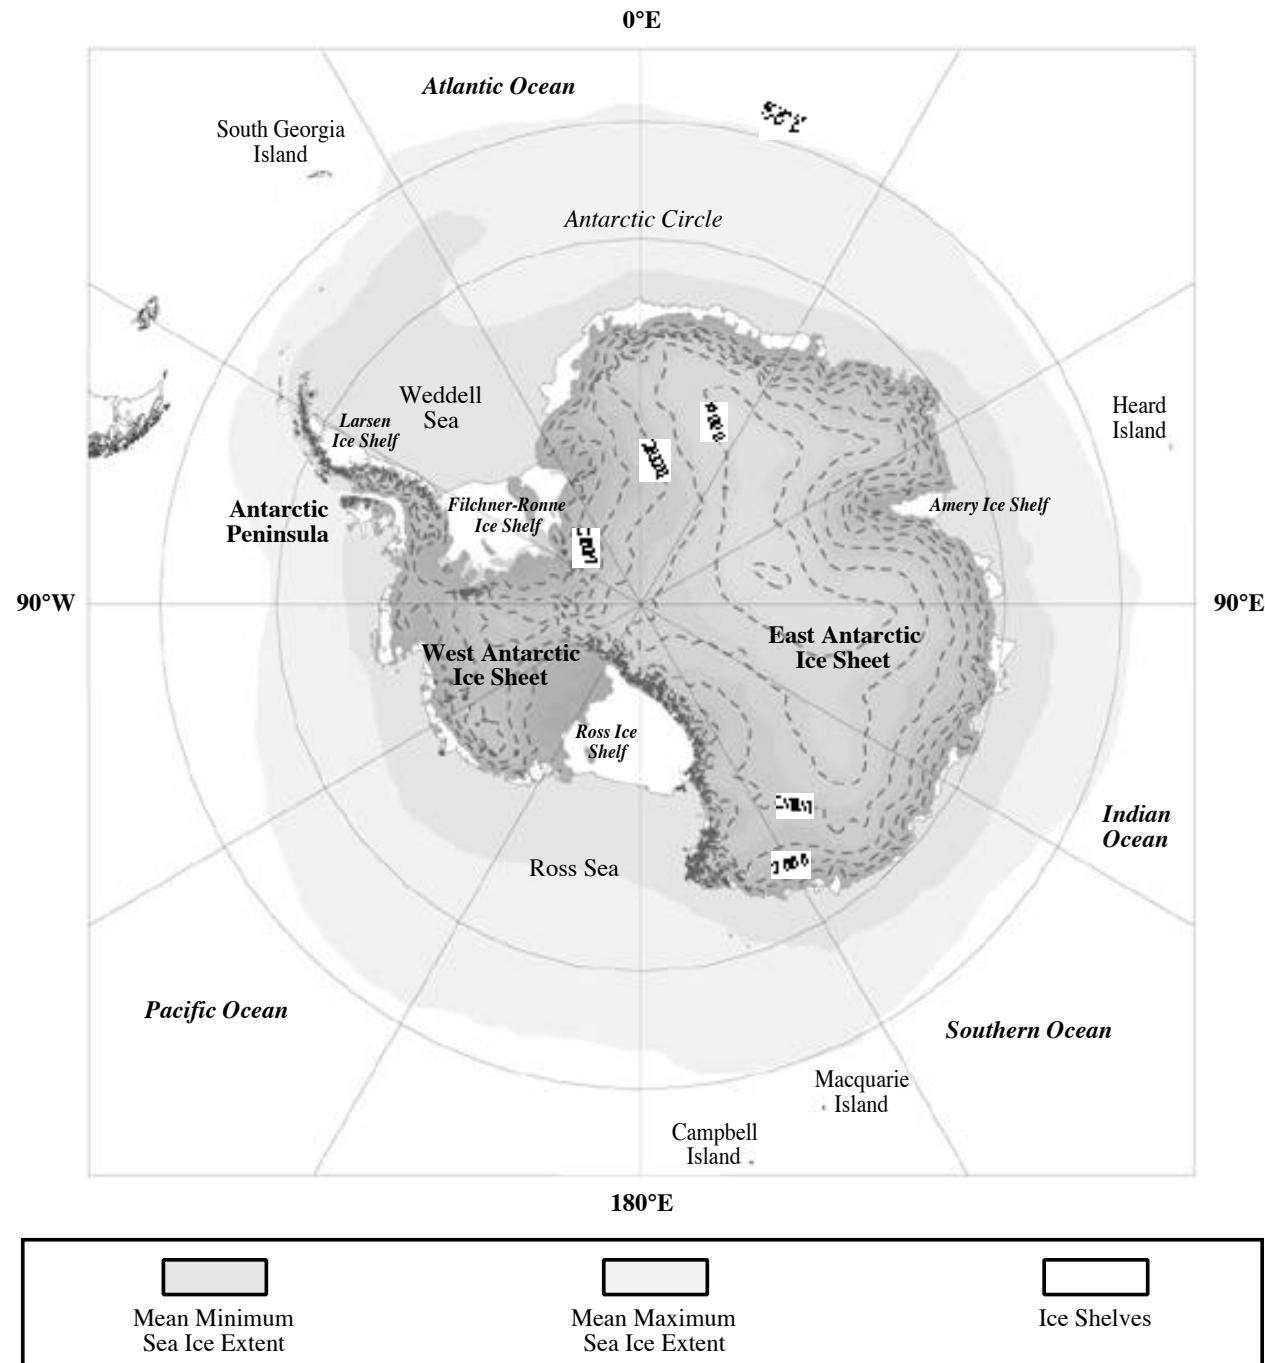

Figure 16-2: Location map for the Antarctic. Elevations on Antarctic continent are indicated by dashed contour lines (500-m interval). Topography and ice shelf outlines are from U.S. Geological Survey and British Antarctic Survey data. Sea-ice extent data are from Couper (1989).

create a deep, stable boundary layer of very cold, dry air at the surface.

These processes ensure sustained, very low temperatures in winter. Even in the summer, many areas—especially in the Antarctic—remain below freezing. Thus, much water remains frozen throughout the year. In Antarctica, snow and ice have continued to accumulate on the continent for millions of years. On the other hand, there are large volumes of liquid water in polar regions in the Arctic and Southern Oceans, although their surface is partially covered with sea ice, whose extent varies seasonally over vast areas. Sea ice insulates the underlying water from heat loss and, because of its high albedo, reflects much of the incoming solar radiation.

Formation of sea ice has important oceanographic consequences in that much latent heat is released, and highly saline, dense water is created. The dense water sinks in the north Atlantic and Southern Oceans, helping maintain the ocean conveyor belt and carrying nutrients and carbon. Production of deep ocean water is a consequence of processes that are operating in both polar regions. There is little evaporation from the vast tracts of sea ice and glacier ice. Extensive areas of the polar regions have very low precipitation; most comes from cyclonic storms that penetrate from the surrounding belt of subpolar depressions.

The polar regions incorporate important environmental thresholds, many of which are associated with water-phase changes. Together with the large seasonal changes in solar radiation, polar regions stimulate important geophysical and biological processes with high sensitivity to impacts. Sustained warming or cooling across the freezing threshold brings dramatic physical changes over land and sea. As a result, the physical environment, biota, and socioeconomic factors are all vulnerable to climate change. The climate and vast areas of ice make the polar regions very inhospitable and marginal for many species, including humans. However, specially adapted species thrive in some terrestrial and marine polar ecosystems. Consequently, the Arctic and Antarctic are characterized by the presence of highly distinctive biomes and are important places for many migratory species. Although the Antarctic continent essentially is a pristine wilderness, the great whales and some species of seals in the Southern Ocean were commercially exploited to virtual commercial extinction in the 19th and 20th centuries. Human activities on many sub-Antarctic islands have altered their biota dramatically.

The Antarctic has limited resource use, apart from growing fishing and tourism industries. There is a multinational approach to natural resources and environmental management, with mineral exploration and exploitation banned by international agreement. The area is managed by the Consultative Parties to the Antarctic Treaty to the dedication of science and peace (UNEP, 1997). By contrast, the Arctic has been populated for thousands of years. There is considerable economic activity, based on fishing, herding, and shipping. Recent decades have seen the establishment of urban areas and resource developments,

based on the petroleum, gas, and mining industries. The extreme environment requires unique cold-region engineering and infrastructure solutions. There is a distinct contrast—and sometimes conflict—between the developments of modern society and indigenous peoples. The Arctic lies within the political boundaries of some of the world's richest and most powerful nations. During the Cold War, it was a critical strategic area, and substantial defense establishments remain in the region.

16.1.3. Climate Change in the 20th Century

There has been substantial climate change during the past 2 million years in the Arctic and the Antarctic. These changes are well documented in several natural archives, such as ice cores and marine sediments. The quasi-periodic sequence of glacial-interglacial periods and corresponding changes in GHGs is shown clearly in the record of atmospheric composition and climate derived from the ice cores for the past 420,000 years (e.g., White and Steig, 1998; Petit *et al.*, 1999). Longer term climate changes are not discussed in this chapter, which focuses on observed 20th-century changes as well as those predicted for the 21st century. The following subsections provide a brief discussion of the main climatic changes in the 20th century. More details are provided in TAR WGI Chapter 2.

16.1.3.1. The Arctic

Instrumental observations of climatic parameters over the 20th century are available from standard climate stations on land and measurements taken on drifting ice floes in the Arctic Ocean. The land stations show that warming in the Arctic, as indicated by daily maximum and minimum temperatures, has been as great as in any other part of the world. Although not geographically uniform, the magnitude of the warming is about 5°C per century, with areas of cooling in eastern Canada, the north Atlantic, and Greenland (Koerner and Lundgaard, 1996; Borzenkova, 1999a,b; Jones *et al.*, 1999; Serreze *et al.*, 2000). Data from ice floe measurements show a slight warming on an annual basis, with statistically significant warming in May and June over the 1961–1990 period. Air temperature anomalies in the Arctic basin have been strongly positive since 1993. In the period 1987–1997, air temperature in the Arctic increased by 0.9°C (Alexandrov and Maistrova, 1998).

Significant warming from the beginning of the 20th century has been confirmed by many different proxy measurements (Maslanik *et al.*, 1996; Bjorgo *et al.*, 1997; Smith, 1998). Magnuson *et al.* (2000) found consistent evidence of later freeze-up (5.8 days per 100 years) and earlier breakup (6.5 days per 100 years) of ice on lakes and rivers around the northern hemisphere from 1846 to 1995 and an increase since 1950 in interannual variability of both dates. Glaciers and ice caps in the Arctic also have shown retreat in low-lying areas since about 1920. Numerous small, low-altitude glaciers and perennial snow patches have disappeared. However, no increasing melting

trend has been observed during the past 40 years (Jania and Hagen, 1996; Koerner and Lundsgaard, 1996; Dowdeswell *et al.*, 1997). Glaciers in Alaska have receded, with typical ice-thickness decreases of 10 m over the past 40 years, but some glaciers have thickened in their upper regions (BESIS, 1997). Greenland's ice sheet has thinned dramatically around its southern and eastern margins. Above 2,000-m elevation, the ice sheet is in balance, on average. The net effect is a loss of about $51 \text{ km}^3 \text{ yr}^{-1}$. (Krabill *et al.*, 1999, 2000).

Snow-cover extent in the northern hemisphere has been reduced since 1972 by about 10%, largely as a result of spring and summer deficits since the mid-1980s (Brown, 2000; Serreze *et al.*, 2000). Most Arctic regions have experienced increases in precipitation since at least the 1950s (Groisman *et al.*, 1991; Groisman and Easterling, 1994; Georgiyevskii, 1998). Measurements from Spitsbergen show a statistically significant increase in precipitation during all seasons, except winter (Hanssen-Bauer and Forland, 1998).

Groisman *et al.* (1994) analyzed seasonal snow extent in the northern hemisphere and demonstrated an inverse relationship with near-surface air temperature. Recent findings have provided evidence of a significant decrease in spring snow extent since 1915 over Eurasia (Brown, 1997) and southern Canada (Brown and Goodison, 1996). Such trends may be related to low-frequency fluctuations in hemispheric atmospheric circulation patterns (Serreze *et al.*, 2000).

Arctic sea-ice extent decreased by approximately 3% per decade between 1978 and 1996 (Cavalieri *et al.*, 1997; Parkinson *et al.*, 1999; Johannessen *et al.*, 1999; Serreze *et al.*, 2000). The most significant contractions were detected in 1990, 1993, and 1995 (Maslanik *et al.*, 1996). Ice composition also has changed, with a reduction in the area of multi-year ice in winter. Summer sea-ice extent has shrunk by 20% ($880,000 \text{ km}^2$) over the past 30 years in the Atlantic part of the Arctic Ocean (Johannessen *et al.*, 1999), but the shrinkage has only been 5% in the Canadian Arctic Sea. Sea-ice extent in the Bering Sea experienced a dramatic reduction when a regime shift occurred in 1976 and has continued to decrease (BESIS, 1997). New compilations of Arctic sea-ice extent, using historical

data from the past 135 years (Vinje, 2001), show that overall sea-ice extent in April has been reduced in the Nordic seas by $0.79 \times 10^6 \text{ km}^2$ (33%) (see Figure 16-3). Nearly half of this reduction took place between 1860 and 1900. Although there are large interannual and seasonal variations in sea-ice extent, the reduction is greatest in spring. This is consistent with the 1912–1996 temperature record from Svalbard, which shows significant warming (3°C) in spring (Hanssen-Bauer and Forland, 1998). There is an approximate 10-year climate signal in the Arctic and subarctic, with a clockwise propagating signal in sea-ice concentration anomalies and a standing oscillation in sea-level pressure anomalies—the latter linked to the two phases of the North Atlantic Oscillation (NAO) (Mysak and Venegas, 1998). Comparison of these trends with outputs from climate models (forced by observed GHGs and tropospheric sulfate aerosols) reveals that the observed decrease in northern hemisphere sea-ice extent agrees with transient simulations (see Figure 16-6) and that both trends are much larger than would be expected from natural climate variations (Vinnikov *et al.*, 1999).

The most effective method for determining the thickness of sea ice is to use sonar, directed upward at the floating ice from submarines or moorings (Melling *et al.*, 1995). The results indicate great variability. Average thinning of sea ice has been observed since 1976 on some transects of the Atlantic and Arctic Oceans (Wadhams, 1997). A thinning by about 0.13 m over the period 1970–1992, with the maximum decrease detected in the eastern Siberian Sea, was found by Russian scientists (Nagurduy, 1995). Rothrock *et al.* (1999) found that ice draft at the end of the melt season has decreased by about 1.3 m in most of the deepwater portion of the Arctic Ocean, from 3.1 m in 1958–1976 to 1.8 m in the 1990s (~15% per decade). The decrease is greater in the central and eastern Arctic than in the Beaufort and Chukchi seas (Rothrock *et al.*, 1999). Vinje *et al.* (1998), however, claim that no significant change in ice thickness can be observed in Fram Strait. Their conclusion is in agreement with submarine observations from 1960–1982. Although there is large variability, ice cover has continued to become thinner and has decreased by 40% over the past 3 decades (Rothrock *et al.*, 1999). Analysis of the duration of summer melt over a large fraction of the perennial Arctic sea ice from 1979 to 1996 reveals an increase of 5.3 days (8%) per decade in the number of melt days each summer (Smith, 1998).

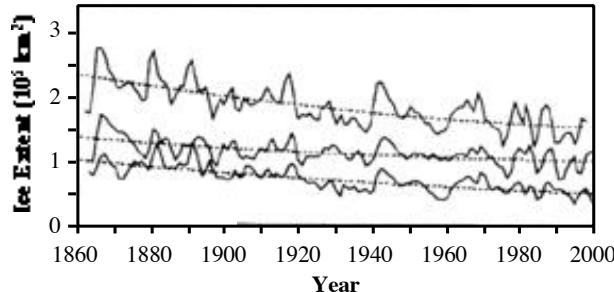

Figure 16-3: Time series of April sea-ice extent in Nordic Sea (1864–1998) given by 2-year running mean and second-order polynomial curves. Top: Nordic Sea; middle: eastern area; bottom: western area (after Vinje, 2000).

Changes to below 1,000 m in the Arctic Ocean have been observed, with less sea ice and freshening of the Beaufort Sea mixed layer (Maslanik *et al.*, 1996; and McPhee *et al.*, 1998). Atlantic water inflow to the Arctic Ocean has warmed (Carmack *et al.*, 1995). The halocline, which isolates the surface from this warmer Atlantic water, has grown thinner (Steele and Boyd, 1998). Data gathered from submarines indicate that sea-surface temperature (SST) in the Arctic basin increased by 1°C over the past 20 years, and the area of warm Atlantic water in the polar basin increased by almost $500,000 \text{ km}^2$ (Kotlyakov, 1997). Field measurements in 1994 and 1995 showed consistent Arctic seawater warming of $0.5\text{--}1.0^\circ\text{C}$, with a maximum detected in the Kara Sea (Alekseev *et al.*, 1997). It is not yet clear whether these changes are part of low-frequency natural

variability or whether they represent the early impacts of long-term climate change.

Thickening of the active layer and changes in the distribution and temperature of permafrost are further important indicators of warming in the Arctic. Permafrost thawing has led to major erosion problems and landslides in the Mackenzie basin (Cohen, 1997a) and has caused major landscape changes from forest to bogs, grasslands, and wetland ecosystems in Alaska, affecting land use. In central and western Canada and in Alaska, contraction in the extent of permafrost has occurred during the 20th century (Halsey *et al.*, 1995; Weller, 1998; Weller and Lange, 1999; Osterkamp *et al.*, 2000). However, a cooling trend has been noted for permafrost in eastern Canada (Allard *et al.*, 1995; Allard and Kasper, 1998). Permafrost degradation during the 20th century in subarctic and boreal peatlands of Quebec is discussed by Laberge and Payette (1995).

Temperatures at the top of permafrost along a several hundred kilometer north-south transect in central Alaska warmed by 0.5–1.5°C between the late 1980s and 1996. Thawing rates of about 0.1 m per year were calculated for two sites (Osterkamp and Romanovsky, 1999). On the north slope of Alaska and in northwestern Canada, the temperature-depth profile indicates a temperature rise of 2–4°C over the past century (Lachenbruch and Marshall 1986). In the western Yamal Peninsula, temperatures at a depth of 10 m in ice-rich permafrost increased 0.1–1.0°C between 1980 and 1998; the largest increases in Siberian permafrost temperatures have occurred in relatively cold permafrost in the continuous zone.

Palaeoclimate reconstructions based on dendrochronology also indicate a steady increase in temperature during the past 150 years (Bradley and Jones 1993; Szeicz and MacDonald 1995; see TAR WGI Chapter 2). Growth rings in *Larix Sibirica* from northern Siberia show that mean temperatures during the 20th century were the highest in 1,000 years, exceeding even those during the Medieval Warm Period (Briffa *et al.*, 1995). Changes in diatom assemblages in lake sediments in the High Arctic over the same period also are thought to be a consequence of climatic warming (Douglas *et al.*, 1994).

Other changes in terrestrial ecosystems include northward movement of the treeline, reduced nutritional value of browsing for caribou and moose, decreased water availability, and increased forest fire tendencies (Weller and Lange, 1999). There are altered plant species composition, especially forbs and lichen, on the tundra. In the marine ecosystem, northern fur seal pups on the major Bering Sea breeding grounds declined by half between the 1950s and the 1980s. In parts of the Gulf of Alaska, harbor seal numbers are as much as 90% below what they were in the 1970s. There have been significant declines in the populations of some seabird species, including common murres, thick-billed murres, and kittiwakes. Comprehensive interviews by Gibson and Scullinger (1998) have revealed notable impacts on food sources and natural environments of native Alaskan communities. Warmer climate has increased growing degree days by 20% for agriculture and forestry in

Alaska, and boreal forests are expanding northward at a rate of about 100 km per °C (Weller and Lange, 1999).

16.1.3.2. The Antarctic

Instrumental records analyzed by Jacka and Budd (1998) and summarized in Figure 16-4 have shown overall warming at

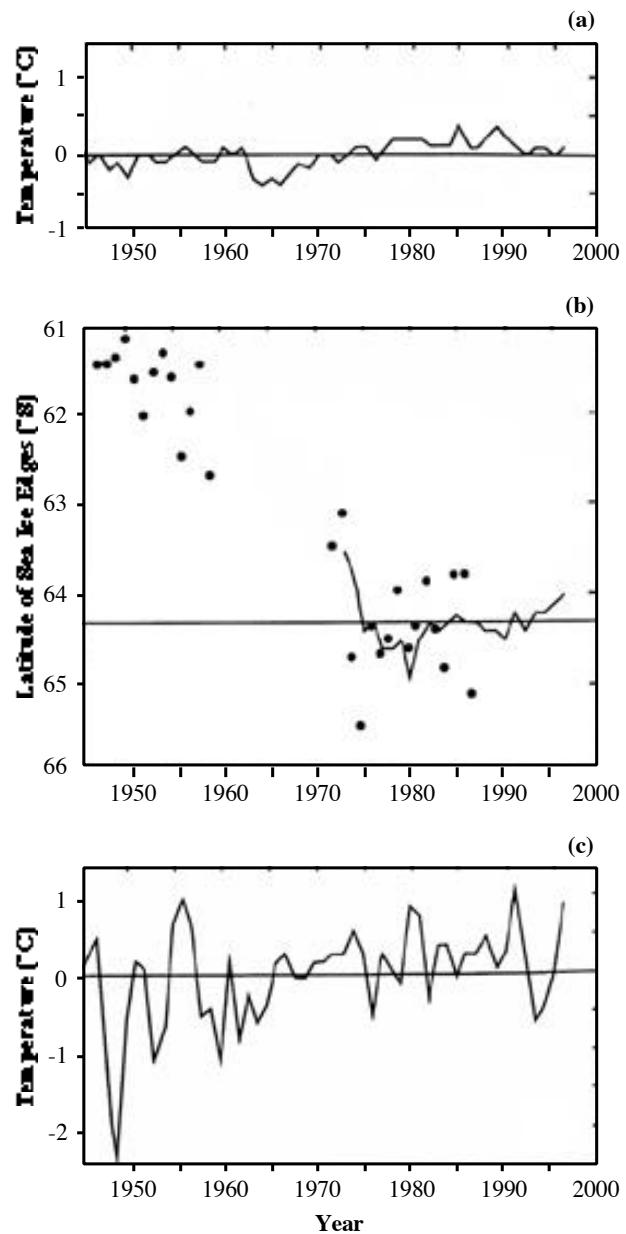

Figure 16-4: (a) Mean temperature anomalies for Southern Ocean climate stations; (b) summer sea-ice extent [dots are from estimates based on southernmost positions of whaling-factory ships (de la Mare, 1997)]; (c) mean temperature anomalies of coastal Antarctic climate stations (after Jacka and Budd, 1998).

permanently occupied stations on the Antarctic continent (1959–1996) and Southern Ocean island stations (1949–1996). Using two different statistical techniques, they found that the 16 Antarctic stations have warmed at a mean rate of 0.9–1.2°C per century, and the 22 Southern Ocean stations have warmed at 0.7–1.0°C per century. Antarctic Peninsula stations show a consistent regional rate of warming that is more than twice the average for other Antarctic stations. King and Harangozo (1998) suggest that this warming is associated with an increase in the northerly component of the atmospheric circulation over the Peninsula and perhaps changes in sea-ice extent. For Antarctic stations, warming trends are largest in winter and smallest in autumn. For the Southern Ocean stations, warming trends are largest in autumn and smallest in spring and summer. However, three GCMs were unable to reproduce these trends (Connolley and O'Farrell, 1998).

Another analysis of a 21-station data set from Antarctica by Comiso (1999) found a warming trend equivalent to 1.25°C per century for a 45-year record beginning in the 1950s but a slight cooling trend from 1979 to 1998. The slight cooling trend for this later 20-year period also was confirmed via analysis of surface temperatures over the whole continent, as inferred from satellite data. These changes can be placed in a long-term context by comparison with results from the high-accumulation ice coring sites on Law Dome, East Antarctica, which show clear climate signals with sufficient resolution to identify seasonal variations (van Ommen and Morgan, 1996, 1997; Curran *et al.*, 1998). There was a cooling period in the late 1700s and 1800s and a warming over the 19th century, with greater variability and change in winter than in summer.

Changes in precipitation in the Antarctic are more poorly understood. Model estimates from Smith *et al.* (1998a) indicate that the accumulation rate for the East Antarctic ice sheet surface has increased by a rate of 1.9 mm yr⁻¹ (water equivalent) over the period 1950–1991. Their estimate of sensitivity is 12.5 mm yr⁻¹ per degree of warming. Examination of water-mass properties of oceans shows that significant changes have occurred over the past 30 years. Bindoff and McDougall (2000) and Wong *et al.* (1999) point out that sub-Antarctic

mode water (SAMW) and Antarctic intermediate water (AAIW) have become less saline and cooler, and both water masses are now deeper. These changes indicate surface warming in the source region of SAMW and increased precipitation in the source region of AAIW.

Jacka and Budd (1998) found no significant trends in Antarctic sea-ice data over the satellite era (1973–1996). Although the mean trend is zero, the sector from 0° to 40°E has a clear trend toward increased sea ice. This is matched by a larger sector of decreasing extent near the Bellingshausen and Amundsen Seas, from about 65°W to 160°W. Elsewhere, sea-ice extent trends are relatively small (see Figure 16-4)—a finding that also is supported by Cavalieri *et al.* (1997). Analysis of whaling records by de la Mare (1997) suggests that the Antarctic summer sea-ice edge has moved southward by 2.8 degrees of latitude between the mid-1950s and the early-1970s. This suggests a decline in the area covered by sea ice of 25%. It should be noted, however, that the data used in this analysis span two distinct periods, during which differing whale species were harvested. Using atmosphere-ocean sea-ice models, the computations of Wu and Budd (1998) indicate that sea ice was more extensive over the past century, on the annual average by 0.7–1.2 degrees of latitude. It also was thicker by 7–13 cm than at present. Wu *et al.* (1999) conclude that the sea-ice extent reduced by 0.4–1.8 degrees of latitude over the 20th century.

16.1.4. Scenarios of Future Change

The IPCC commissioned a *Special Report on Emissions Scenarios* (SRES). Four “marker scenarios” representing different world storylines are used to estimate emissions and climate change to 2100 (IPCC, 2000). Table 16-1 summarizes these climate projections for the polar regions. In almost all cases, predicted climates are well beyond the range of variability of current climate. However, these estimates cover a very large range of precipitation and temperatures, so future climate remains uncertain except that it will be wetter and warmer. Some of the projected increases in precipitation and temperatures are larger than for any other part of the globe.

Table 16-1: IPCC SRES climate scenarios for 2080. Values are changes from present climate summarized from Carter *et al.* (2000), and are scaled output of nine AOGCMs.

Region	Summer		Winter	
	Precipitation (%)	Temperature (°C)	Precipitation (%)	Temperature (°C)
Arctic				
– Land	+10–20 ^a	+4.0–7.5	+5–80	+2.5–14.0
– Arctic Ocean	+2–25 ^b	+0.5–4.5	+2–45 ^c	+3.0–16.0
Antarctica Land	+1–28	+1.0–4.8	+4–32	+1.0–5.0
Southern Ocean	+2–17	+0.0–2.8	+5–20	+0.5–5.0

^aCSIRO-mk2 model predicts +38%.

^bCSIRO-mk2 model predicts +42%.

^cECHAM4 model predicts +70%.

Models predict that land areas in the Arctic will receive substantially increased snowfall in winter and that the climate will be markedly warmer. Summer could be much warmer and wetter than present. The climate over the Arctic Ocean does not change as dramatically, but it will become warmer and wetter by 2080. For the Antarctic continent, the models tend to predict more snow in winter and summer. Although temperatures are forecast to increase by 0.5°C, there will be little impact on melt because they will remain well below freezing, except in limited coastal localities. The Southern Ocean warms least, especially in summer. Precipitation increases by as much as 20%, so there will be more freshwater input to the ocean surface. This chapter also refers to other climate models. Some are equilibrium models for the atmosphere only; others are transient, coupled atmosphere-ocean models. Some deal with aerosols and others do not. In polar regions there can be large differences in predictions, depending on the model chosen, although most predict large changes in climate over the next 100 years. Assessments of impacts will vary, depending on the climate model chosen. This should be kept in mind in assessing the impacts described in this chapter.

Discrepancies among climate models and problems of downscaling (Shackley *et al.*, 1998) mean that alternative methods of prediction that are based on analysis of empirical climate data (e.g., palaeoclimatic analogs and extrapolation of recent instrumental records) still have value. Anisimov and Poljakov (1999) analyzed modern temperature trends over the northern hemisphere; they suggest that warming in the Arctic will be most pronounced in the continental parts of North America and Eurasia. The potential impacts of continued deepening of the winter polar vortex would include weakening of the wind-driven Beaufort Gyre. This would further reduce the extent and thickness of the Arctic pack ice (McPhee *et al.*, 1998) and change ocean temperatures and sea-ice boundaries (Dickson *et al.*, 1999).

16.2. Key Regional Concerns

This chapter follows the agreed TAR template for WGI regional assessments. Rather than assessing all possible impacts of climate change, emphasis is placed on eight key regional concerns. These concerns are chosen for the Arctic and the Antarctic on the basis of earlier findings by the IPCC (Everett and Fitzharris, 1998) and on discussions at various workshops of the TAR. They represent what are considered to be the most important impacts of future climate change in the Arctic and Antarctic in the wider global perspective. Although some other impacts (e.g., Arctic glaciers and terrestrial Antarctic biota) may be very important locally, space does not permit a comprehensive review.

16.2.1. Changes in Ice Sheets and Glaciers

Changes in the polar climate will have a direct impact on the great ice sheets, ice caps, and glaciers of the polar regions.

How each responds will depend on several climatological parameters; some will grow, whereas others shrink. We have high confidence that their overall contribution to rising sea level will be positive, with glaciers and the Greenland ice sheet shrinking. The contribution from Antarctica, however, is uncertain at present. There is a high likelihood that increasing temperatures over the continent and changing storm tracks will cause increased precipitation and thickening of the ice sheet, but there still exists at low confidence the possibility that the West Antarctic ice sheet will retreat dramatically in coming centuries (Vaughan and Spouge, 2000). Such a change would not result from recent and future climate change (Bentley, 1998) but more probably from continuing readjustment to the end of the last glacial period (Bindschadler, 1998), as a result of internal dynamics of the ice sheet (MacAyeal, 1992), or as a result of ice shelf-ocean interaction. This subject and the general issue of sea-level rise are reviewed more comprehensively in TAR WGI Chapter 11; we include only a summary of the main points here.

The Greenland ice sheet suffers melting in summer at its margin. There is a trend toward an increase in the area and duration of this melt (Abdalati and Steffen, 1997). This trend is likely to continue. Airborne altimetric monitoring has shown that over the period 1993–1998, the Greenland ice sheet was slowly thickening at higher elevations; at lower elevations, thinning (about 1 m yr⁻¹) was underway (Krabill *et al.*, 1999, 2000). If warming continues, the Greenland ice sheet will shrink considerably, as occurred in previous interglacial periods (Cuffey and Marshall, 2000), and if the warming is sustained, the ice sheet will melt completely (see TAR WGI Chapter 11).

Over the Antarctic ice sheet, where only a few limited areas show summer melting (Zwally and Fiegles, 1994), a slight thickening is likely as precipitation rates increase (e.g., Ohmura *et al.*, 1996; Smith *et al.*, 1998a; Vaughan *et al.*, 1999). In the past decade there has been some change in the ice cover in local areas (e.g., on the Antarctic Peninsula; see Section 16.2.2), but the majority of the Antarctic ice sheet appears, from satellite altimetry, to be close to a state of balance (Wingham *et al.*, 1998). Only the Thwaites and Pine Island glacier basins show any spatially coherent trend, but it is not yet known if their thinning is related to a decrease in precipitation or some dynamic change in the ice sheet. Chinn (1998) reports that recession is the dominant change trend of recent decades for glaciers of the Dry Valleys area of Antarctica. The future of glaciers in the Arctic will be primarily one of shrinkage, although it is possible that in a few cases they will grow as a result of increased precipitation.

This report is concerned primarily with the impacts of climate change on particular regions. An important question is: How will changes in glacial ice in the polar regions impact local human populations and ecological systems, and what will be the socioeconomic consequences? The short answer is that impacts on ice systems will be substantial, but because the populations of humans and other biota within polar region are low, impacts may be relatively minor. In Antarctica, the

continental human population is only a few thousand. A few localities may undergo changes such as that at Stonington Island on the Antarctic Peninsula (Splettoesser, 1992), where retreat of the ice sheet has left the station stranded on an island. In general, however, changes to ice sheets will directly cause few significant life-threatening problems.

16.2.2. Changes around the Antarctic Peninsula

At least five meteorological records from scientific stations on the Antarctic Peninsula show marked decadal warming trends (King, 1994; Harangozo *et al.*, 1997; King and Harangozo, 1998; Marshall and King, 1998; Skvarca *et al.*, 1998). Although the periods and seasons of observations have been different, the records show consistent warming trends—as much as $0.07^{\circ}\text{C yr}^{-1}$, considerably higher than the global mean. This atmospheric warming has caused several notable changes in the ice cover of the Antarctic Peninsula, including changes in snow elevation (Morris and Mulvaney, 1995; Smith *et al.*, 1999a) and the extent of surface snow cover (Fox and Cooper, 1998). The most important change has been the retreat of ice shelves. Seven ice shelves on the Antarctic Peninsula have shown significant, progressive, and continued retreat. On the West Coast, the Wordie Ice Shelf, Müller Ice Shelf, George VI Ice Shelf, and Wilkins Ice Shelf have retreated (Ward, 1995; Vaughan and Doake, 1996; Luchitta and Rosanova, 1998). On the east coast, the ice shelves that occupied Prince Gustav Channel and Larsen Inlet and Larsen Ice Shelf Ahave retreated (Rott *et al.*, 1996; Vaughan and Doake, 1996; Skvarca *et al.*, 1998). Following Mercer (1978), Vaughan and Doake (1996) show that the pattern of retreat could be explained by a southerly movement of the 0°C January isotherm, which appears to define a limit of viability for ice shelves. To date, about 10,000 km 2 of ice shelf have been lost.

Retreat of the ice shelves on the Antarctic Peninsula has attracted considerable media coverage, and environmental campaigns of some nongovernmental organizations (NGOs) have expressed concern that these events presage a more important collapse of the West Antarctic ice sheet. However, few direct impacts result from the loss of these ice shelves. The ice shelves were floating, so their melting does not directly add to sea level, and they usually are replaced by sea-ice cover, so overall albedo changes very little. Because the Antarctic Peninsula is steep and rugged, there is no evidence that removal of ice shelves will cause melting of the glaciers that fed them to accelerate and add to sea-level rise (Vaughan, 1993). Terrestrial ecosystems generally will be unaffected by ice-shelf retreat. Most polar benthic organisms, especially in the Antarctic, grow extremely slowly, so colonization of exposed seabed will be slow.

Because warming on the Antarctic Peninsula exceeds that over much of the rest of the continent (Jacka and Budd, 1998), migration of the limit of viability for ice shelves probably will not affect the Ronne-Filchner or Ross ice shelves in the next 100 years (Vaughan and Doake, 1996). A substantial increase

in Antarctic summer temperatures, however, would threaten other large ice shelves beyond the Antarctic Peninsula. The real implications of ice-shelf retreat are that it highlights issues of risk perception and public understanding of climate change, rather than real physical impacts. These issues include questions such as: Does the Antarctic Peninsula warming result from a global effect, or simply from natural regional climate variations? Such problems of attribution of climate change will recur, especially if the costs of adaptation are to be spread across nations. The inherent nonlinearity of natural systems sometimes causes exaggerated local responses to small climate changes. In the present generation of climate models, the Antarctic Peninsula is not well resolved, so local effects on these scales cannot yet be reproduced. Confidence in predicting such changes in the natural ecosystems of the Antarctic Peninsula comes from observed changes on the terrestrial biota of southern ocean islands (Bergstrom and Chown, 1999).

Rapidly increasing temperatures have been directly implicated in colonization by introduced species and displacement of indigenous biota. Thus, the extent of higher terrestrial vegetation on the Antarctic Peninsula currently is increasing (Fowber and Lewis Smith, 1994). In the marine environment, the warming trend on the Antarctic Peninsula has been linked statistically to an associated change in sea ice for this region (Stammerjohn and Smith, 1996). For example, Smith *et al.* (1999b) show that rapid climate warming and associated reduction in sea ice are concurrent with a shift in the population size and distribution of penguin species in the Antarctic Peninsula region.

16.2.3. Changes in the Southern Ocean and Impacts on its Life

16.2.3.1. Overview

The Southern Ocean is an active component of the climate system that causes natural climate variability on time scales from years to centuries. It is a major thermal regulator and has the potential to play an active role in climate change by providing important feedbacks. If climate change is sustained, it is likely to produce long-term and perhaps irreversible changes in the Southern Ocean. These changes will alter the nature and amount of life in the ocean and on surrounding islands, shores, and ice. The impact of climate change is likely to be manifest in the large-scale physical environment and in biological dynamics. There even is the possibility that changes in the Southern Ocean could trigger abrupt and very long-term changes that affect the climate of the entire globe.

16.2.3.2. Role of Ocean Changes

The Southern Ocean is of special significance to climate change because of the variety of water masses produced there and the ability of these waters to spread throughout the global ocean. In particular, shelf waters with temperatures near the freezing point (about -1.9°C) are produced along the margin of

the Antarctic continent. They contribute to the formation of Antarctic bottomwater and continuing ventilation of this water in the world's oceans (Whitworth *et al.*, 1998). There already is evidence that climate change has altered SAMW and AAIW (Johnson and Orsi, 1997; Wong *et al.*, 1999; Bindoff and McDougall, 2000). Wong *et al.* (1999) compared trans-Pacific sections 20 years apart and found temperature and salinity changes that are consistent with surface warming and freshening in formation regions of the water masses in the Southern Ocean and their subsequent subduction into the ocean.

The main contributions to the production of Antarctic bottomwater come from cooling and transformation of seawater under the floating Filchner-Ronne and Ross ice shelves, as well as from dense water formed as a result of freezing of sea ice. Polynyas also are important. These areas of combined open water and thin sea ice (surrounded by sea ice or land ice) play an important role in ocean-atmosphere heat transfer, ice production, formation of dense shelf water, spring disintegration of sea ice, and sustenance of primary and secondary productivity in polar regions. Their formation is linked to the strength and persistence of cold outflow winds off the Antarctic continent and the position of the polar jet stream and Southern Ocean atmospheric circulation patterns (Bromwich *et al.*, 1998).

Research by Wu *et al.*, (1997), Budd and Wu (1998), and Hirst (1999)—using the CSIRO coupled, transient model and IPCC IS92a emissions scenario—suggests that certain aspects of Southern Ocean circulation may be very sensitive to climate change. With an increase in atmospheric equivalent CO₂, there is a substantial increase in the strength of the near-surface halocline and a potential reduction in the formation of Antarctic bottomwater and convection in the Southern Ocean. The decrease in downwelling of cold, dense water, as shown in Figure 16-5, leads to a slowdown in the thermohaline circulation

(Broecker *et al.*, 1985). A tripling of GHGs is sufficient to induce a shutdown of the thermohaline circulation. Furthermore, this shutdown continues for at least several centuries, to the end of the model integration. The main processes causing a decline in the thermohaline circulation are an increase in precipitation minus evaporation, an increase in glacial melt from the Antarctic, and reduced sea-ice formation, so there is less brine injection into the ocean.

According to this simulation, if concentrations of GHGs continue to grow to the end of the 21st century, there will be significant weakening of the ocean's thermohaline circulation and even potential for its shutdown. These changes might become irreversible in subsequent centuries, despite possible stabilization of GHG concentrations. Modeling by Cai and Baines (1996) indicates that the Antarctic Circumpolar Current is driven at least partly by the thermohaline circulation associated with the formation of Antarctic bottomwater, so this major current of the Southern Ocean also can be expected to slow down. This result is confirmed by Cai and Gordon (1998), who found a clear decreasing trend in the magnitude of the Antarctic Circumpolar Current as CO₂ increases. The foregoing results indicate an ocean circulation that is significantly more sensitive to climate change than that found by Manabe and Stouffer (1994). The possibility remains that certain factors and parameterizations in the Hirst (1999) model could make it overly sensitive and that future changes may not be as dramatic as indicated. For example, in other models the ocean component is much less diffusive, allowing for prolonged maintenance of an enhanced halocline. None of the present generation of climate models can resolve polynyas, where the majority of brine rejection takes place and dense water masses form. These processes need to be better represented in coupled ocean-climate models before the timing of any substantial slowing of Antarctic bottomwater production or of any shutdown of the ocean thermohaline circulation can be predicted confidently. Changes in this circulation also may be driven by variable fluxes at lower latitudes, and results from different ocean models indicate uncertainty about the magnitude and timing of thermohaline slowdown (see TAR WGI Chapter 7 for more detailed discussion of the global thermohaline circulation).

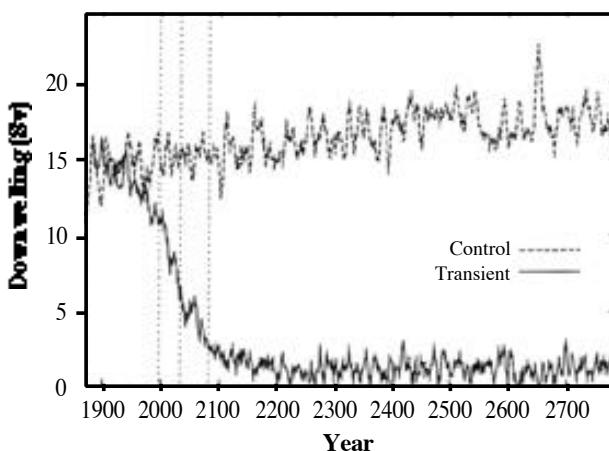

Figure 16-5: Volume transport of Antarctic downwelling past 1,250-m depth level for control and transient climate integrations. Values are in Sverdrups (Sv), filtered using a 7-year running mean, and are for the area of the Southern Ocean between Antarctic coast and 45°S (from Hirst, 1999, Figure 11).

16.2.3.3. Role of Ice Shelves

The sensitivity of the Southern Ocean to changes in ice shelves remains uncertain (Williams *et al.*, 1998a,b); it depends on whether there is free access of oceanic water to their underside (Nicholls, 1997). Circulation of meltwater under the ice shelves is complex. Any increase in melting as a result of global warming initially will introduce a fresher layer of water (see Jacobs *et al.*, 1992; Jenkins *et al.*, 1997; O'Farrell *et al.*, 1997). This could restrict further melting, unless the current or tides are strong enough to flush the fresher layer away or entrain it into other water masses. Using a three-dimensional model adapted to the underside of the Amery Ice Shelf, Williams *et al.* (1998b) conclude that when the adjacent seas were warmed by 1°C, net melt increased more than three-fold.

Grosfeld and Gerdes (1998) also show increased net melt with warming, but the situation stabilizes if there is less sea-ice formation. In considering the long-term response of the Antarctic ice sheet to global warming of 3°C, Warner and Budd (1998) show that it takes at least several centuries for the ice shelves to disappear in their model.

16.2.3.4. Impacts on Biology of Southern Ocean

No single factor controls overall primary production in the Southern Ocean. The organisms in Antarctic marine communities are similar to the inhabitants of marine systems at lower latitudes, although there is substantial endemism in Antarctica (Knox, 1994). Ice cover and vertical mixing influence algae growth rates by modulating the flux of solar radiation (Priddle *et al.*, 1992). Micronutrients, especially iron, are likely to limit phytoplankton growth in some areas. Experiments involving addition of iron to the ocean show dramatic increases in the biological activity of phytoplankton (de Baar *et al.*, 1995; Coale *et al.*, 1996; Sedwick *et al.*, 1999). Findings by Boyd *et al.* (2000) demonstrate that iron supply controls phytoplankton growth and community composition during the summer, but the fate of algal carbon remains unknown and depends on the interplay between processes that control export, remineralization, and water-mass subduction. Grazing by zooplankton also may be important.

Several of the physical controls on phytoplankton production are sensitive to climate change. Although it is presently impossible to make numerical predictions, these controls have been outlined in a qualitative way by Priddle *et al.* (1992). They consider that projected changes in water temperature and wind-induced mixing of the Southern Ocean will be too small to exert much effect but that changes in sea ice are likely to be more important. Release of low-salinity water from sea ice in spring and summer is responsible for developing the shallow mixed layer in the sea-ice marginal zone—an area of the Southern Ocean that is nearly as productive as the coastal zone (Arrigo *et al.*, 1998)—and plays a major role in supporting other marine life. Projected reductions in the amount of sea ice (Section 16.2.4.2) may limit the development of the sea-ice marginal zone, with a consequential impact on biota there. On the other hand, greater freshening of the mixed ocean layer from increased precipitation, ice-sheet runoff, and ice-shelf melting might have a compensating effect. It seems that the sea-ice marginal zone, under-ice biota, and subsequent spring bloom will continue, but shift to more southern latitudes, as a consequence of the retreat of the ice edge.

Research also demonstrates that the biological production of the Antarctic food web is linked closely to physical aspects of the ocean and ice ecosystem. Matear and Hirst (1999) point out that changes in ocean circulation will impact ocean biological production. They project a reduction in biological export from the upper ocean and an expansion of the ocean's oligotrophic regions. This will alter the structure and composition of the marine ecosystem. For example, interdecadal variations in

sponge/predator population and in anchor/platelet ice at depths shallower than 30 m appear to be related to alterations in regional currents and ocean climate shifts (Jacobs and Giulivi, 1998). Changes in ocean currents could bathe new areas of the sea floor in near-freezing water, so that anchor ice and ice crystals will rise through the water column. This will be a liability for some benthic species. On the other hand, there could be a fresher and more stable layer, which could lead to changes in phytoplankton community structure (Arrigo *et al.*, 1999), and stronger ocean fronts. Both of these physical changes would be beneficial to many parts of the marine ecosystem. A 20% decline in winter and summer sea ice since 1973 west of the Antarctic Peninsula region (Jacobs and Comiso, 1997) has led to a decline in Adelie penguins, which are obligate inhabitants of pack ice. By contrast, Chinstrap penguins in open water have increased in numbers (Fraser *et al.*, 1992; Ainley *et al.*, 1994). Krill recruitment around the Antarctic Peninsula seems to be dependent on the strength of the westerlies and sea-ice cover, with a 1-year lag (Naganobu *et al.*, 2000). Both will decrease in the future, so there will be less krill.

The direct effect of a change in temperature is known for very few Antarctic organisms. Much of the investigation on ecophysiology has concentrated on adaptations to living at low temperature, with relatively little attention devoted to their response to increasing temperatures. Few data are available to assess quantitatively the direct and indirect impacts of climate change. Perhaps the best-studied example of temperature affecting the abundance of marine microorganisms is the increased rate of production of the cyanobacterium *Synechococcus* with increasing temperature, which approximately doubles for an increase in temperature of 2.5°C (Marchant *et al.*, 1987).

The virtual absence of cyanobacteria represents a fundamental difference between the microbial loop in Antarctic waters compared to that in temperate and tropical waters. As discussed by Azam *et al.* (1991), metazoan herbivores apparently cannot directly graze *Synechococcus*; their production must be channelled through heterotrophic protists able to consume this prokaryote. Adding another trophic step reduces the energy available to higher trophic levels. Coupled with the direct utilization of nanoplankton by grazers, this may account in part for high levels of tertiary production in the Southern Ocean, despite relatively low levels of primary production (but see Arrigo *et al.*, 1998). Any increase in water temperature will increase the concentration of cyanobacteria and the heterographs that graze them. It is possible that the prey for krill and other grazers also will change, but the ultimate effects are unknown. Changes in the microbial loop may lessen carbon drawdown because of increased respiration by heterotrophs. Furthermore, there is an apparent uncoupling of bacterioplankton and phytoplankton assemblages that contrasts with temperate aquatic ecosystems (Bird and Kalff, 1984; Cole *et al.*, 1988; Karl *et al.*, 1996). The structure and efficiency of the Antarctic marine food web is temporally variable, and Karl (1993) has suggested that it is reasonable to expect several independent (possibly overlapping in space and time) food webs. There is

no consensus with respect to the importance of bacteria and their consumers within this food web or their degree of interaction with photoautotrophs. Bird and Karl (1999) have demonstrated, however, that uncoupling of the microbial loop in coastal waters during the spring bloom period was the direct result of protistan grazing. Although underlying mechanisms remain unclear, the distinct difference of the microbial loop in Antarctic waters, compared to more temperate waters, suggests that climate change will have profound effects on the structure and efficiency of the Southern Ocean food web.

An increase in temperature is likely to lead to shifts in species assemblages. Organisms that are unable to tolerate the present low-temperature regime will invade the Southern Ocean. Some that already are there will exhibit increased rates of growth. Predicted reductions in the extent and thickness of sea ice will have ramifications not only for the organisms directly associated with sea ice but also for those that rely on oceanographic processes that are driven by sea-ice production. In the open ocean, there is a correlation between the standing crop and productivity of phytoplankton with wind speed (Dickson *et al.*, 1999). Diatoms—the dominant phytoplanktonic organisms in the Southern Ocean—have high sinking rates and require a turbulent mixed zone to remain in the photic zone. If climate change results in diminution of wind forcing of surface mixing, a reduced biomass of diatoms can be expected. This would lead to less available food for the higher trophic levels and diminution

in the vertical flux of carbon and silicon. Together, these effects are likely to have a profound impact on Antarctic organisms at all trophic levels, from algae to the great whales.

Any reduction in sea ice clearly represents a change in habitat for organisms that are dependent on sea ice, such as Crabeater seals and Emperor penguins. Some species of penguins and seals are dependent on krill production. Increased ultraviolet irradiance from ozone depletion is likely to favor the growth of organisms with UV-protecting pigments and/or repair mechanisms (Marchant, 1997; Davidson, 1998). This will lead to a change in species composition and impact trophodynamics and vertical carbon flux. Naganobu *et al.* (2000) show evidence that ozone depletion impacts directly and indirectly on krill density. The growth, survival, and hatching rates of penguin chicks and seal pups are directly influenced by krill abundance in the sea. Animals that migrate great distances, such as the great whales and seabirds, are subject to possible disruptions in the timing and distribution of their food sources. Contraction of sea ice may alter migration patterns but would not be expected to present a major problem to such mobile animals. Other marine mammals (seals, sea lions) have life histories that tie them to specific geographic features such as pupping beaches, ice fields, or sub-Antarctic islands; they may be more severely affected by changes in the availability of necessary habitats and prey species that result from climate change.

Box 16-1. Climate Change and Fisheries

The Southern Ocean has large and productive fisheries that constitute part of the global food reserve. Currently, there are concerns about sustainability, especially with regard to species such as Patagonian toothfish. There are likely to be considerable changes in such fisheries under the combined pressures of exploitation and climate change. Spawning grounds of coldwater fish species are very sensitive to temperature change. Warming and infusion of more freshwater is likely to intensify biological activity and growth rates of fish (Everett and Fitzharris, 1998). Ultimately, this is expected to lead to an increase in the catch of marketable fish and the food reserve. This could be offset in the long term by nutrient loss resulting from reduced deepwater exchange. Fisheries on the margin of profitability could prosper because the retreat of sea ice will provide easier access to southern waters. Everett and Fitzharris (1998) discuss catch-per-unit-effort (CPUE) statistics from the commercial krill fishery operating around South Georgia and demonstrate that there is correlation with ice-edge position. The further south the ice, the lower the CPUE in the following fishing season. Fedoulov *et al.* (1996) report that CPUE also is related to water temperature and atmospheric circulation patterns, and Loeb *et al.* (1997) document the close relationships between seasonal sea-ice cover and dominance of either krill or salps (pelagic tunicates). Ross *et al.* (2000) identify that maximum krill growth rates are possible only during diatom blooms and that production in Antarctic krill is limited by food quantity and quality. Consequently, differences in the composition of the phytoplankton community caused by changes in environmental conditions, including climate change, will be reflected at higher trophic levels in the grazer community and their levels of productivity.

Arctic fisheries are among the most productive in the world. Changes in the velocity and direction of ocean currents affect the availability of nutrients and disposition of larval and juvenile organisms, thereby influencing recruitment, growth, and mortality. Many groundfish stocks also have shown a positive response to recent climate change (NRC, 1996), but Greenland turbot—a species that is more adapted to colder climates—and King crab stocks in the eastern Bering Sea and Kodiak have declined (Weller and Lange, 1999). Projected climate change could halve or double average harvests of any given species; some fisheries may disappear, and other new ones may develop. More warmer water species will migrate poleward and compete for existing niches, and some existing populations may take on a new dominance. These factors may change the population distribution and value of the catch. This could increase or decrease local economies by hundreds of millions of dollars annually.

16.2.4. Changes in Sea Ice

Sea ice is a predominant feature of the polar oceans. Its extent expands and contracts markedly from winter to summer. Sea ice has a dramatic effect on the physical characteristics of the ocean surface. The normal exchange of heat and mass between the atmosphere and ocean is strongly modulated by sea ice, which isolates the sea surface from the usual atmospheric forcing (Williams *et al.*, 1998a). In addition, sea ice affects albedo, the exchange of heat and moisture with the atmosphere, and the habitats of marine life. Finally, sea ice plays a significant role in the thermohaline circulation of the ocean. Changes in air temperature expected with projected climate change are likely to alter the sea-ice regime and hence have impacts on the foregoing mechanisms.

Warming is expected to cause a reduction in the area covered by sea ice, which in turn will allow increased absorption of solar radiation and a further increase in temperature. In some climate models, this sea ice-albedo feedback has led to amplification of projected warming at higher latitudes, more in the Arctic Ocean than in the Southern Ocean. At some point, with prolonged warming a transition to an Arctic Ocean that is ice-free in summer—and perhaps even in the winter—could take place. The possibility of a transition to an ice-free Arctic Ocean that is irreversible also must be considered. Climate models predict a wide range of changes for polar sea ice by the year 2100 (see TAR WGI Chapter 1). Many of the earlier models treated sea ice very simplistically and were not coupled with the ocean, so their results are unlikely to be reliable. More recent climate models include sophisticated sea-ice routines that take into account the dynamics and thermodynamics that control sea-ice formation, transport, and melt (Everett and Fitzharris, 1998). These models, however, still are limited in their ability to reproduce detailed aspects of sea-ice distribution and timing.

Snow on sea ice controls most of the radiative exchange between the ocean and atmosphere, but its exact role in energy transfer is uncertain (Iacozza and Barber, 1999) and difficult to model because of a lack of adequate data (Hanesiak *et al.*, 1999; Wu *et al.*, 1999). A further complication is the timing of snowfall in relation to formation of sea ice (Barber and Nghiem, 1999). Accumulation of snow on sea ice also plays a significant role in sub-ice primary production and for habitats of marine mammals (e.g., polar bear and seals).

16.2.4.1. Sea Ice in the Arctic Ocean

Whether the sea ice in the Arctic Ocean will shrink depends on changes in the overall ice and salinity budget, the rate of sea-ice production, the rate of melt, and advection of sea ice into and out of the Arctic Basin. The most important exit route is through Fram Strait (Vinje *et al.*, 1998). The mean annual export of sea ice through Fram Strait was $\sim 2,850 \text{ km}^3$ for the period 1990–1996, but there is high interannual variability caused by atmospheric forcing and, to a lesser degree, ice

thickness variations. Other important passages are the northern Barents Sea and through the Canadian Arctic Archipelago (Rothrock *et al.*, 1999). Analyses by Gordon and O'Farrell (1997), using a dynamic ice routine with a transient coupled atmosphere-ocean climate model (Commonwealth Scientific and Industrial Research Organisation—CSIRO), predict a 60% loss in summer sea ice in the Arctic for a doubling of CO₂. The summer season, during which ice retreats far offshore, increases from 60 to 150 days. The likely distance between northern coasts and Arctic pack ice will increase from the current 150–200 to 500–800 km.

In a more recent study, there is good agreement between Arctic sea-ice trends and those simulated by control and transient integrations from the Geophysical Fluid Dynamics Laboratory (GFDL) and the Hadley Centre (see Figure 16-6). Although the Hadley Centre climate model underestimates sea-ice extent and thickness, the trends of the two models are similar. Both models predict continued decreases in sea-ice thickness and extent (Vinnikov *et al.*, 1999), so that by 2050, sea-ice extent is reduced to about 80% of area it covered at the mid-20th century.

GCM simulations for Arctic sea ice predict that warming will cause a decrease in maximum ice thickness of about 0.06 m per °C and an increase in open water duration of about 7.5 days per °C (Flato and Brown, 1996). These projections are somewhat lower than changes observed during the latter part of the 20th century (see Section 16.1.3). Increased snowfall initially causes a decrease in maximum thickness (and corresponding increase in open-water duration), but beyond 4 mm per day (1.33 mm per day water equivalent), formation of “slush ice” by surface

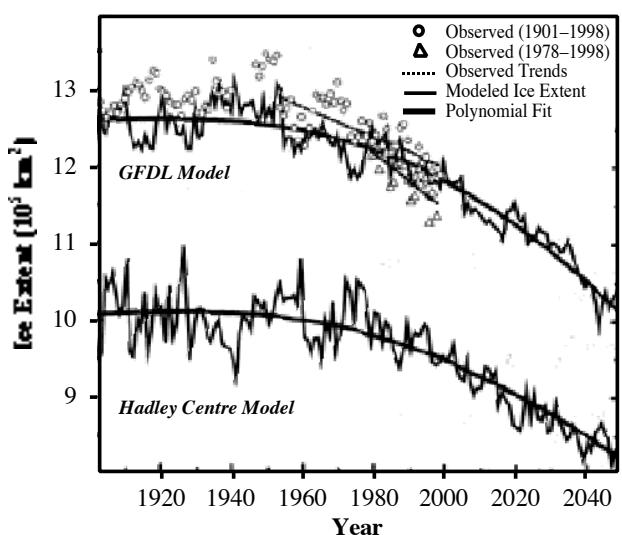

Figure 16-6: Observed and modeled variation of annual averages of Arctic sea-ice extent, based on Vinnikov *et al.* (1999). Observed data are from Chapman and Walsh (1993) and Parkinson *et al.* (1999). Sea-ice curves are produced by GFDL low-resolution R15 climate model and by HADCM2 climate model, both forced by CO₂ and aerosols.

flooding offsets the insulating effect of snow and causes an increase in maximum thickness and a decrease in the duration of open water.

Without sea ice, wave heights will increase, and the Arctic coast will be more exposed to severe weather events such as storm surges that cause increased coastal erosion, inundation, and threat to structures. Areas of ice-rich permafrost are particularly vulnerable to coastal erosion (Nairn *et al.*, 1998; Wolfe *et al.*, 1998). A portent of the future is severe coastal erosion—as much as 40 m yr⁻¹—along the Siberian coast. Deposited organic material changes the entire biogeochemistry of the nearshore waters (Weller and Lange, 1999). More open water may lead to increased precipitation and further amelioration of temperatures. Projected losses in sea ice are likely to have considerable impacts on Arctic biology through the entire food chain, from algae to higher predators (e.g., polar bears and seals). Loss of sea ice also will affect indigenous peoples and their traditional ways of life. A more open ocean will favor increased shipping along high-latitude routes and could lead to faster and cheaper ship transport between eastern Asia, Europe, and eastern North America.

16.2.4.2. Sea Ice in the Southern Ocean

Antarctic sea ice is not confined by land margins but is open to the Southern Ocean. Sea-ice extent contracts and expands on an annual cycle in a roughly concentric zone around Antarctica. The ultimate extent is controlled by a balance of air temperature, leads, wind direction, upper ocean structure, and pycnocline depth. Some of these parameters are controlled in the atmosphere by the relative position of the subpolar trough with respect to the sea ice. In the ocean, variations in the Antarctic Circumpolar Current are important. The extent and thickness of Antarctic sea ice are sensitive to the depth and thermal properties of overlying snow, about which relatively little is known.

A reduction in Antarctic sea ice volume of about 25–45% is predicted for a doubling of CO₂, with sea ice retreating fairly evenly around the continent (Gordon and O'Farrell, 1997). This CSIRO model assumes a 1% yr⁻¹ compounding increase of CO₂, corresponding to global warming of 2.1°C. Using a similar but modified model that has a higher albedo feedback and predicted global warming of 2.8°C, Wu *et al.* (1999) calculate a reduction in mean sea-ice extent of nearly two degrees of latitude, corresponding to 45% of sea-ice volume. These estimates do not represent the equilibrium state, and sea ice can be expected to shrink further, even if GHGs are stabilized. Changes in Antarctic sea ice will have little impact on human activity except where they allow shipping (mostly research, fishing, and tourist vessels) to get closer to the Antarctic continent. However, there are important biological and oceanographic impacts derived from reductions in sea ice, as well as significant ecological consequences attributable to changes in the magnitude and timing of seasonal sea-ice advance and retreat (Smith *et al.*, 1999b).

16.2.5. Permafrost

The term *permafrost* refers to layers of earth materials at relatively shallow depth that remain below 0°C throughout 2 or more consecutive years, independent of material composition or ice content. The role of permafrost in the context of global change is three-fold (Nelson *et al.*, 1993): It records temperature changes (Lachenbruch and Marshall, 1986), translates changes to other components of the environment (Osterkamp *et al.*, 2000), and facilitates further climatic changes through release of trace gases (Rivkin, 1998; Robinson and Moore, 1999). Permafrost is highly susceptible to long-term warming. Although it is an important factor in ice-free parts of Antarctica (Bockheim, 1995), permafrost is far more extensive in the continental areas of the subarctic and Arctic (Brown *et al.*, 1997; Zhang *et al.*, 1999), and changes there have great potential to affect human activities adversely. Accordingly, frozen ground activity has been designated as a “geoindicator” for monitoring and assessing environmental change (Berger and Iams, 1996).

Most biological and hydrological processes in permafrost terrain are confined to the active (seasonally thawed) layer, which forms a boundary across which exchanges of heat, moisture, and gases occur between the atmospheric and terrestrial systems. Its thickness is a response to a complex interplay among several factors, including aboveground climate, vegetation type and density, snow-cover properties, thermal properties of the substrate, and moisture content. If other conditions remain constant, the thickness of the active layer could be expected to increase in response to climate warming. Long-term records of active-layer thickness are rare; those that do exist, however, indicate that variations occur at multiple temporal scales and are determined by climatic trends and local conditions at the surface and in the substrate (Nelson *et al.*, 1998b).

16.2.5.1. Temperature Archive

Because heat transfer within thick permafrost occurs primarily by conduction, the shallow earth acts as a low-pass filter and “remembers” past temperatures. Temperature trends are recorded in the temperature-depth profile over time scales of a century or more (e.g., Lachenbruch and Marshall, 1986; Clow *et al.*, 1998; Osterkamp *et al.*, 1998; Taylor and Burgess, 1998). Permafrost is affected primarily by long-term temperature changes and thus contains a valuable archive of climate change (Lachenbruch and Marshall, 1986), although changes in snow cover must be taken into account. In contrast, the temperature regime of the overlying seasonally thawed active layer is highly complex, owing to nonconductive heat-transfer processes that operate much of the year (Hinkel *et al.*, 1997).

Multi-decadal increases in permafrost temperature have been reported from many locations in the Arctic, including northern and central Alaska (Lachenbruch and Marshall, 1986; Osterkamp and Romanovsky, 1999), northwestern Canada (Majorowicz and Skinner, 1997), and Siberia (Pavlov, 1996). Temperature increases are not uniform, however, and recent cooling of

permafrost has been reported in northern Quebec (Wang and Allard, 1995). To obtain a more comprehensive picture of the spatial structure and variability of long-term changes in permafrost, the Global Terrestrial Network for Permafrost or (GTNet-P) (Brown *et al.*, 2000; Burgess *et al.*, 2000b) was developed in the 1990s. The program has two components: long-term monitoring of the thermal state of permafrost in a network of boreholes, and monitoring of active-layer thickness and processes at representative locations. The latter network—the Circumpolar Active Layer Monitoring (CALM) program (Nelson and Brown, 1997)—has been in operation since the mid-1990s and incorporates more than 80 stations in the Arctic and Antarctic. The CALM network includes components in which regional mapping (Nelson *et al.*, 1999) and spatial time series analysis of active-layer thickness (Nelson *et al.*, 1998a) are performed.

16.2.5.2. Predicted Changes in Permafrost

Figure 16-1 illustrates the geographic distribution of permafrost and ground ice in the northern hemisphere. Computations based on a digital version of the map by Brown *et al.* (1997) indicate that permafrost currently underlies 24.5% of the exposed land area of the northern hemisphere (Zhang *et al.*, 1999). Under climatic warming, much of this terrain would be vulnerable to subsidence, particularly in areas of relatively warm, discontinuous permafrost (Osterkamp *et al.*, 2000). Anisimov and Nelson (1997) conducted experiments with a simple model of permafrost distribution driven by three transient GCMs (as reported by Greco *et al.*, 1994). Figure 16-7 shows the mid-range result from this study; the area of the northern hemisphere occupied by permafrost eventually could be reduced by 12–22% of its current extent. Experiments by Smith and Burgess (1999) with a $2\times\text{CO}_2$ GCM indicated that permafrost eventually could disappear from half of the present-day Canadian permafrost region. Thawing of ice-rich permafrost is subject, however, to considerable lag resulting from the large latent heat of fusion of ice. Simulations by Riseborough and Smith (1993), for example, indicate that areas of 5 m thick ice-rich permafrost near the southern limit of the discontinuous zone in subarctic Canada could thaw in less than 70 years. Where permafrost currently is thick, it could persist in relict form for centuries or millennia. Figure 16-7 therefore is best regarded as indicating areas in which considerable potential exists for changes in permafrost distribution. Nonetheless, pronounced changes in permafrost temperature, surface morphology, and distribution are expected (Smith and Burgess, 1998, 1999; Osterkamp and Romanovsky, 1999).

16.2.5.3. Environmental Impacts

The geological record of the Arctic shows abundant evidence for regional-scale deterioration of permafrost in response to climatic change. Thawing of ice-rich permafrost can result in subsidence of the ground surface and development of uneven and frequently unstable topography known as thermokarst

terrain. In unglaciated parts of Siberia, alases (coalescing thaw depressions) formed during Holocene warm intervals occupy areas as large as 25 km^2 . Cryostratigraphic studies in northwestern Canada have documented thaw unconformities in the form of truncated ice wedges associated with climatic warming during the early Holocene (Burn, 1997, 1998). Warming of permafrost and thaw subsidence has been reported widely from subarctic regions in recent years (Fedorov, 1996; Osterkamp and Romanovsky, 1999; Osterkamp *et al.*, 2000; Wolfe *et al.*, 2000; Zuidhoff and Kolstrup, 2000).

Changes in active-layer thickness could have marked impacts on local environments (Anisimov *et al.*, 1997; Burgess *et al.*, 2000a; Dyke, 2000). Thawing of perennially frozen subsurface materials will create few problems where permafrost is “dry” (Bockheim and Tarnocai, 1998). However, thawing of ice-rich permafrost can be accompanied by mass movements and subsidence of the surface, possibly increasing delivery of sediment to watercourses and causing damage to infrastructure in developed regions. Many recent examples of such phenomena already have been reported, and a poll conducted for the Canadian Climate Centre showed that most of the engineers interviewed think that climate warming is a very important factor for the stability of structures in permafrost regions (Williams, 1995; Vyalov *et al.*, 1998; Weller and Anderson, 1999). Weller and Lange (1999) note that the bearing capacity of permafrost has decreased with warming, resulting in failure of pilings for buildings and pipelines, as well as roadbeds. Accelerated permafrost thawing has led to costly increases in road damage and maintenance. In Alaska, for example, it costs as much as US\$1.5 million to replace 1 km of road system. However, eventual disappearance of permafrost reduces construction problems.

Degradation of permafrost, which depends on the precipitation regime and drainage conditions, poses a serious threat to Arctic biota through oversaturation or desiccation of the surface (Callaghan and Jonasson, 1995). Changes in permafrost and active-layer thickness will produce a complicated response. Development of thermokarst in relatively warm, discontinuous permafrost in central Alaska has transformed some upland forests into extensive wetlands (Osterkamp *et al.*, 2000). In contrast, climatic warming in the northern foothills of the Brooks Range could lead to increasing plant density, resulting in evolutionary transitions from nonacidic to acidic tundra or shrub tundra. Despite increasing air temperature, such changes could prevent increases in active-layer thickness (Walker *et al.*, 1998).

16.2.6. Arctic Hydrology

The hydrological regime of the Arctic is particularly susceptible to predicted climate change because of the dominance of the thermally sensitive cryosphere and its controlling influence on the water cycle. Virtually all major hydrological processes and related aquatic ecosystems are affected by snow and ice processes, including the major Arctic rivers. Although these rivers originate in more temperate southern latitudes, they pass

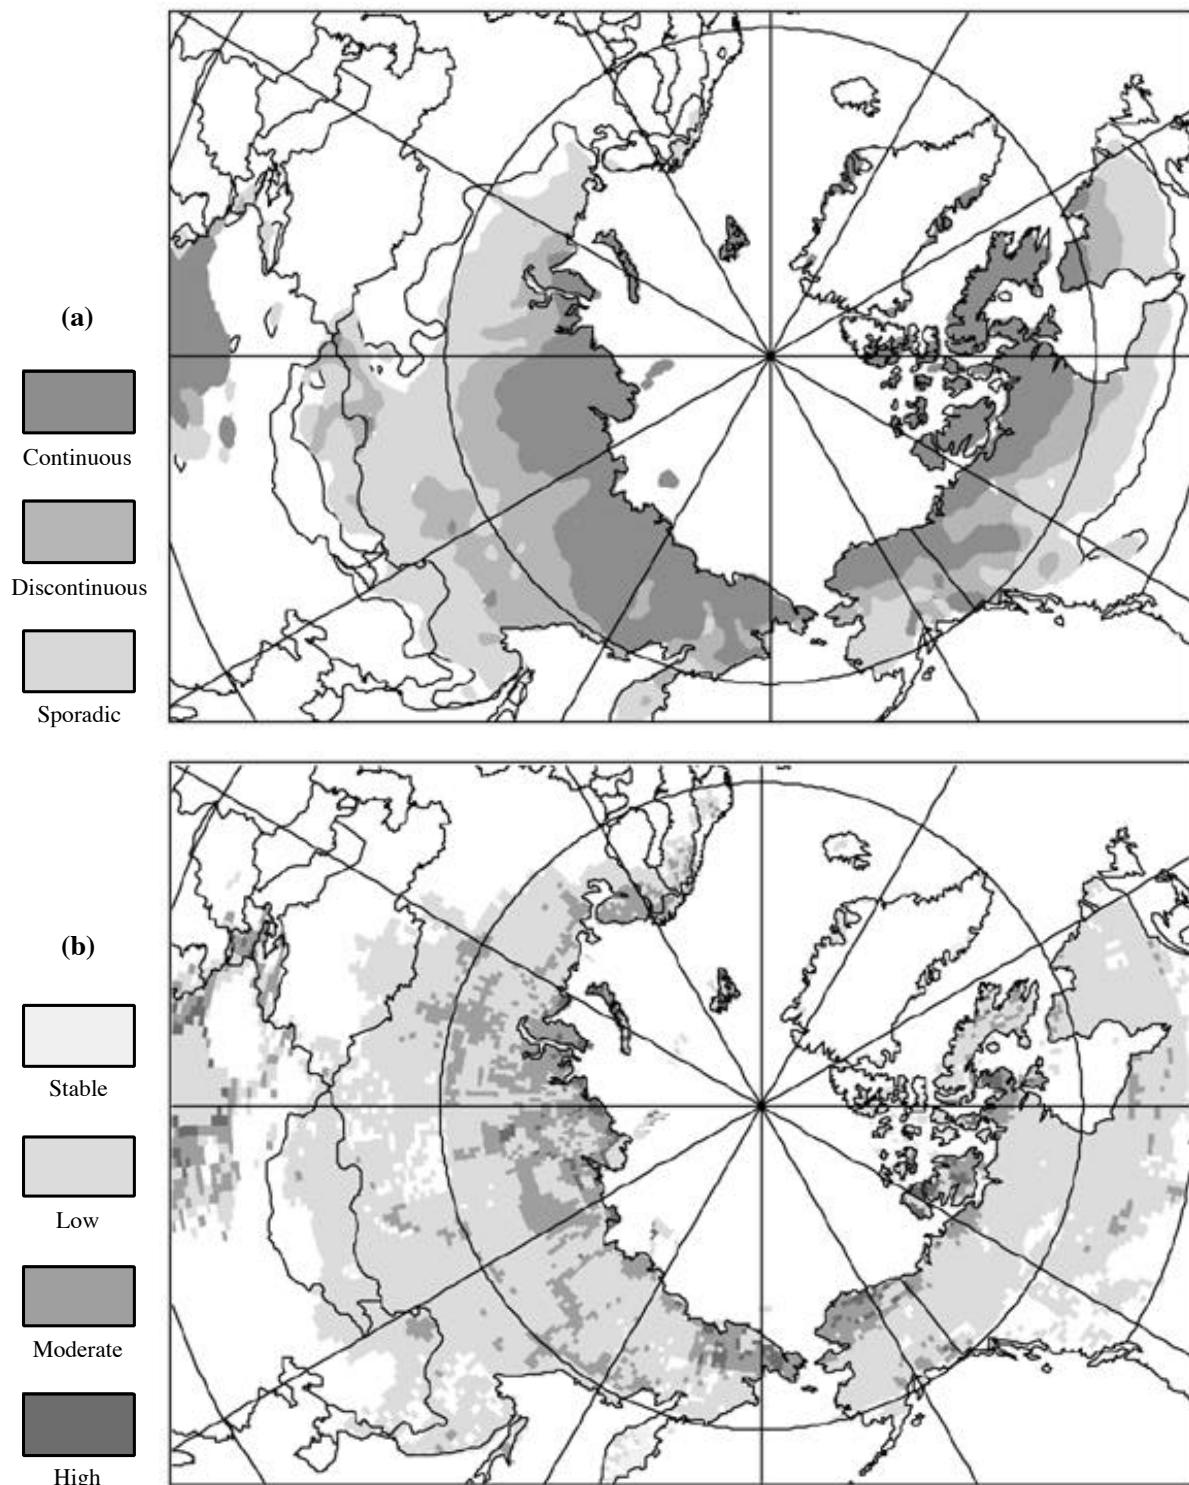

Figure 16-7: (a) Zonation of permafrost in the northern hemisphere under climate scenario predicted by ECHAM1-AGCM (Cubasch *et al.*, 1992). (b) Hazard potential associated with degradation of permafrost under ECHAM1-A climate change scenario. Map represents areas of stable permafrost and low, moderate, and high susceptibility to subsidence. Classification is based on a “thaw-settlement index” calculated as the product of existing ground-ice content (Brown *et al.*, 1997) and predicted increases in depth of thaw (Anisimov *et al.*, 1997). Hazard-zone intervals were derived through division of resulting frequency distribution, using a nested-means procedure (Scripter, 1970).

through cold regions before reaching the Arctic Ocean. Changes in precipitation also have great potential for modifying the hydrology and sediment load in rivers, which could affect aquatic life (Michel and van Everdingen, 1994).

16.2.6.1. Changes in Precipitation, Snow Accumulation, and Spring Melt

Almost all climate models forecast increases in precipitation; but estimates vary widely and are complicated by many other factors, such as clouds (Stewart, 2000). Combined changes in temperature and precipitation will produce changes in the pattern of snow storage and, ultimately, Arctic hydrology. Warmer conditions generally will reduce the length of winter. Seasonal snow accumulation could increase in higher elevation zones, especially above the freezing level, where there would be little summer melt. Increased summer storminess will reduce melt at intermediate elevations as a result of increased cloud and summer snowfall, so many existing semi-permanent snowpacks will continue to exist (Woo, 1996). At lower elevations, particularly in the more temperate maritime zones, rainfall and rain-on-snow melt events probably will increase.

An earlier transition from winter to spring will mean that snowmelt will be more protracted, with less intense runoff. This will be accentuated where increased active-layer thickness and loss of permafrost increases the water storage capacity of the ground, leading to a decrease in runoff. Summer base flow will increase. Overall, this means that there will be less seasonal fluctuation in runoff through the year (Rouse *et al.*, 1997).

16.2.6.2. Surface Water Budgets and Wetlands

Predicted climate change will lead to greater evaporation and transpiration. Transpiration should increase as nontranspiring lichens and mosses that currently dominate the tundra regions are replaced by a denser cover of vascular plants (Rouse *et al.*, 1997). These changes are likely to reduce the amount of ponded water and runoff. The unglaciated lowlands of many Arctic islands, where special ecological niches occur, are likely to be especially sensitive. For coastal areas, changes to local microclimates may occur because longer open-water seasons in the adjacent sea will lead to more frequent fog and low clouds, as well as reduced incident solar radiation. These changes may limit the expected increase in evaporation and transpiration (Rouse *et al.*, 1997).

The ability of Arctic wetlands to act as a source or sink of organic carbon and CH₄ depends on the position of the water. Analysis of subarctic sedge fens to increases in temperature of 4°C suggests reduced water storage of 10–20 cm over the summer in northern peatlands, even with a small increase in precipitation (Rouse, 1998). This is significant, given that Moore and Roulet (1993) suggest that a reduction of 0.1 m in water storage in northern forested peatland is sufficient to convert these areas from a source to a sink of atmospheric CH₄. Wider

questions concerning the carbon budget, including the level of uncertainty, are discussed in TAR WGI Chapter 3. Further predictions based on 2xCO₂ changes indicate a 200–300 km retreat of the southern boundary of peatlands in Canada toward the Arctic coast and significant changes in their structure (Gignac and Vitt, 1994). Degradation of permafrost, which currently forms an impermeable layer, will couple many ponds with the groundwater system and lead to their eventual drainage. Areas of special sensitivity include patchy Arctic wetlands on continuous permafrost and those along the southern limit of permafrost (Woo and Young, 1998). In contrast, warming of surface permafrost also could lead to formation of new wetlands, ponds, and drainage networks through the process of thermokarst development, especially in areas with high concentrations of ground ice.

16.2.6.3. Ecological Impact of Changing Runoff Regimes

A warmer climate will create a more pluvial runoff regime as a greater proportion of the annual precipitation is delivered by rain rather than snow and a flattening of the seasonal runoff cycle occurs. Enhancement of winter flow will mean streams that currently freeze to their beds will retain a layer of water beneath the ice. This will be beneficial to invertebrates and fish populations. However, such rivers will then be prone to ice jamming and hence larger annual flood peaks. Warming will lead to a shortened ice season and thinner ice cover. For large northward-flowing rivers, this could reduce the severity of ice jamming in spring, especially if the magnitude of the peak snowmelt that drives breakup also is reduced (Beltaos and Prowse, 2000). Decreased ice-jam flooding will benefit many northern communities located near river floodplains. In contrast, reductions in the frequency and severity of ice-jam flooding would have a serious impact on northern riparian ecosystems, particularly the highly productive river deltas, where periodic flooding has been shown to be critical to the survival of adjacent lakes and ponds (Marsh and Hey, 1989; Prowse and Conly, 1998).

Decreases in winter snowpack and subsequent spring runoff from upstream tributaries has led to reduced frequency and severity of ice jams affecting the very large Peace-Athabasca Delta (Prowse *et al.*, 1996). These changes are analogous to those expected with predicted climate warming. Ice breakup is a major control over aquatic ecology, affecting numerous physical and biochemical processes and the biodiversity and productivity of such northern rivers (Prowse, 1994; Scrimgeour *et al.*, 1994). Major adjustments in their ecology are expected in the future. A similar situation exists for northern ponds and lakes, where ice cover will be thinner, form later, and break up earlier—with consequent limnological changes. Total primary production should increase in all Arctic lakes and ponds with an extended and warmer ice-free season (Douglas *et al.*, 1994). Primary productivity of Arctic aquatic systems also should be boosted by a greater supply of organic matter and nutrients draining from a more biologically productive terrestrial landscape (Schindler, 1997; Hobbie *et al.*, 1999). Thinner ice cover will

increase the solar radiation penetrating to the underlying water, thereby increasing photosynthetic production of oxygen and reducing the potential for winter fish kills. However, a longer ice-free season will increase the depth of mixing and lead to lower oxygen concentrations and increased stress on coldwater organisms (Rouse *et al.*, 1997).

16.2.6.4. Sensitivity of Arctic Ocean to River Flow

Increased future melting from the Greenland ice sheet and Arctic glaciers and ice caps has potential to increase significantly freshwater runoff to the northern circumpolar seas on time scales as short as decades. Combined with changes in Arctic runoff, there will be an effect on Arctic sea ice. Freshwater input to the Arctic Ocean is important for growth, duration, and melt of sea ice, particularly on the large, shallow continental shelf areas that constitute 30% of the area of the Arctic basin. Spreading over the ocean of lower density freshwater from summer runoff, together with sinking of denser brine rejected during autumn and winter sea-ice production, maintain characteristic salinity and temperature layering. This leads to the Arctic halocline—a cold, salt-stratified layer that separates the upper mixed layer from underlying warm saline waters. The strength and position of surface and deep currents in the slope water south of Newfoundland are thought to vary as a coupled system in relation to the dipole in atmospheric sea-level pressure known as the NAO (Keigwin and Pickart, 1999).

Overall, runoff to the Arctic Ocean is approximately $3\text{--}4 \times 10^3 \text{ km}^3 \text{ yr}^{-1}$ (Prowse and Flegg, 2000)—twice that produced by precipitation minus evaporation for the Arctic Ocean or the influx of low-salinity ocean water (Barry and Serreze, 2000). Export of freshwater (as low-salinity water and sea ice) from the Arctic Ocean into the North Atlantic couples northern latitudes to the world thermohaline circulation.

Almost 70% of the total runoff to the Arctic Ocean is provided by four rivers: the Ob, Yenisey, and Lena in Russia and the Mackenzie in Canada. The three Russian rivers have flow measurements dating back to the 1930s, whereas the Mackenzie record begins only in 1972. Although there is no significant long-term trend in flow for these rivers, there has been a slight increase in runoff beginning in the late-1970s for other rivers in European Russia and western Siberia, with some dependence on season (Georgievskii *et al.*, 1996; Georgievskii, 1998; Grabs *et al.*, 2000; Shiklomanov *et al.*, 2000). Shiklomanov *et al.* (2000) found that historical temperature shifts of -0.5 to $+1.0^\circ\text{C}$ had little effect on river inflows to the Arctic Ocean, which remained within 3–5% of their long-term average.

For a range of future climate scenarios, results from hydrological routines embedded in climate models and from independent hydrological models that are driven by climate model output indicate that discharge from the major Arctic rivers will increase significantly (Miller and Russell, 1992; Shiklomanov, 1994; van Blarcum *et al.*, 1995; Shiklomanov, 1997; Hagemann and

Dümenil, 1998; Lewis *et al.*, 2000). Mackenzie basin studies, however, have projected some reduction in streamflow as a result of expected climate warming (MBIS, 1997). Summarizing the general results, Shiklomanov *et al.* (2000) note that with an atmospheric CO_2 doubling, total annual inflow to the Arctic Ocean will increase by 10–20%, with a 1.5- to 2.0-fold increase during winter, although most of the flow still will occur in summer. Such predictions must be treated cautiously, however, because most climate models have been found to overestimate Arctic precipitation and simulate soil moisture and evaporation poorly (Robock *et al.*, 1998; Walsh *et al.*, 1998). Uncertainty in hydrological modeling of high-latitude river systems must be resolved before the risk of changes to the Arctic Ocean freshwater budget and thermohaline circulation can be quantified accurately (Carmack, 2000; Prowse and Flegg, 2000).

16.2.7. Changes in Arctic Biota

16.2.7.1. Impacts of Climate Change on Arctic Terrestrial Environments

Northern environments are thought to be particularly sensitive to climate warming, owing to changes in surface albedo degradation of permafrost, increased active-layer thickness, and earlier snowmelt. Recent warming reflects partial replacement of dry Arctic air masses by wetter Atlantic, Pacific, and southerly air masses, particularly in the subarctic and southern Arctic (Rouse *et al.*, 1997). Most of the increase is related to higher late-winter and early-spring air temperatures ($+4.5^\circ\text{C}$), whereas summer temperatures in the region have increased by only about 2°C (Chapman and Walsh, 1993). In parts of Alaska, growing-season length has increased over the past 65 years as a result of reductions in snow and ice cover (Sharratt, 1992; Groisman *et al.*, 1994). The annual amplitude of the seasonal CO_2 cycle also has increased recently by as much as 40% (Keeling *et al.*, 1996). There has been an accompanying advance in the timing of spring by about 7 days and a delay in autumn by the same period, leading to an expected lengthening of the growing season (Keeling *et al.*, 1996). Such trends are likely to continue with projected climate change.

Precipitation will increase during the summer months, but evaporation and transpiration rates also are predicted to increase; this, together with earlier snowmelt, will lead to soil moisture deficits later in the summer (Oechel *et al.*, 1997). These changes in moisture and the thermal regimes of arctic soils ultimately will determine the fate of soil carbon stored in permafrost and the active layer (Miller *et al.*, 1983; Billings, 1987; Gorham, 1991; Schlesinger, 1991). Any change in physical properties in the active layer will have an impact on organisms and abiotic variables (Gates *et al.*, 1992; Kane *et al.*, 1992; Waelbroeck, 1993; Groisman *et al.*, 1994). The effects of changed drainage patterns and active-layer detachments (Dyke, 2000)—increasing sediment-nutrient loads in lakes and rivers—will alter biological productivity in aquatic ecosystems considerably (McDonald *et al.*, 1996).

Changes in the relative abundance of soil biota are predicted to affect soil processes, but only in a modest way. The rate of decomposition of organic matter is expected to rise with an increase in soil temperature and a longer growing season. This is likely to lead to enhanced rates of gross mineralization. However, the high carbon-to-nitrogen ratio of organic soils may still limit the availability of nitrogen to plants. If the thickened active layer extends into mineral layers, the release of mineral nutrients may be increased greatly, causing the upper organic layer to become more alkaline (Heal, 1998).

In summary, climate change probably will release more soil nutrients to biota, but nutrient limitations—especially of nitrogen and phosphorus—still are likely to occur. Studies have identified that the combination of nutrient and temperature increases results in the increasing importance of dominant plant species and suppression of subordinate ones. Species richness increased in an Arctic site, as a result of invasion of nitrophilous species, but decreased in a subarctic site. The impact of higher nutrient supplies and temperatures are likely to exceed those of elevated CO₂ and UV-B as measured in a related experiment (Press *et al.*, 1998). Because little is known about interactions between species within the soil and hence overall community response, the effect of climate change on rates of tundra soil decomposition and carbon loss is hard to predict (Smith *et al.*, 1998b).

16.2.7.2. Response of Arctic Plant Communities

There are a wide range of physiological responses of Arctic plants to climate change. Evidence indicates that changes will be at the level of individual species rather than groups of species (Chapin *et al.*, 1997; Callaghan *et al.*, 1998). Some responses to increased nutrient supply are specific to particular growth forms, such as the positive response of forbs, graminoids, and deciduous shrubs and the negative responses of mosses, lichens, and evergreen shrubs (Jonasson, 1992; Chapin *et al.*, 1995, 1996; Callaghan *et al.*, 1998; Shaver and Jonasson, 1999). The direct growth responses of evergreen dwarf shrubs to increased temperatures are small (Havström *et al.*, 1993; Wookey *et al.*, 1993; Chapin *et al.*, 1995, 1996). This is in contrast to the growth rates of graminoids, forbs, and deciduous dwarf shrubs (Wookey *et al.*, 1994; Henry and Molau, 1997; Arft *et al.*, 1999). In the Arctic, where these growth forms are abundant, there is a significant increase in plant biomass in response to increased temperatures in summer (Henry and Molau, 1997). The response of reproductive and vegetative structures to warming will vary, depending on abiotic constraints (Wookey *et al.*, 1994; Arft *et al.*, 1999). Warming in the winter and spring may encourage premature growth, so subsequent frost can lead to damage in plants (e.g., as discussed for *Vaccinium myrtillus* by Laine *et al.*, 1995, and for *Diapensia lapponica* by Molau, 1996). In northern Europe, processes that control the transition from boreal forest to tundra are more complicated than in North America because of infrequent large-scale defoliation of birch forest by geometrid moths. The eggs of the moths, which are killed at low temperatures, are

likely to survive if winter temperatures increase (Neuvonen *et al.*, 1999).

Increased CO₂ concentrations in the atmosphere also could directly affect photosynthesis and growth rates of Arctic plants, but the effects are not easily predictable. For example, a rise in CO₂ concentration in the air leads to an initial increase in photosynthesis in individual tussocks of *Eriophorum vaginatum*. However, this effect can disappear in as little as 3 weeks as a result of homeostatic adjustment, indicating a loss of photosynthetic potential has occurred (Oechel *et al.*, 1997). Such short-lived responses are thought to be caused by limitations in nutrient (especially nitrogen) availability (Chapin and Shaver, 1985; Oechel *et al.*, 1997). At the ecosystem level in tussock tundra plots, the homeostatic adjustment took 3 years—by which time enhanced rates of net CO₂ uptake had disappeared entirely, in spite of substantial photosynthetic carbon gain during the period (Oechel *et al.*, 1994). Adjustment of the photosynthetic rate was thought to be caused by nutrient limitation. Körner *et al.* (1996) also have reported an increase in net CO₂ accumulation of 41% in *Carex curvula* after 2 years of exposure to elevated CO₂, but plant growth changes were minimal. Exposure of plants to increased temperatures and levels of CO₂ indicated that the initial stimulation in net CO₂ flux persisted, for reasons that are not entirely clear, although it may be linked to increased nutrient availability (Oechel and Vourlitis, 1994; Oechel *et al.*, 1994, 1997).

Results from plants of *Nardus stricta* growing adjacent to springs in Iceland indicate that they have been exposed to elevated levels of CO₂ for at least 150 years. There was a reduction in photosynthetic capacity of high-CO₂ grown plants of this grass from the vicinity of the spring, compared with plants grown at ambient CO₂ concentrations—again linked to reduction in Rubisco content and the availability of nutrients (Oechel *et al.*, 1997). Collectively, these results indicate that it is unlikely that carbon accumulation will increase markedly over the long term as a result of the direct effects of CO₂ alone (Oechel *et al.*, 1997). A return to summer sink activity has occurred during the warmest and driest period in the past 4 decades in Alaskan arctic ecosystems, thereby eliminating a net summer CO₂ flux to the atmosphere that was characteristic of the early 1980s. The mechanisms are likely to include nutrient cycling, physiological acclimatization, and reorganization of populations and communities (Oechel *et al.*, 2000), but these systems are still net sources of CO₂.

A compounding consideration for Arctic plants is the impact of increased UV-B radiation. In Arctic regions, UV-B radiation is low, but the relative increase from ozone depletion is large, although the ancestors of present-day Arctic plants were growing at lower latitudes with higher UV-B exposure. Over the past 20 years, there has been a trend of decreasing stratospheric ozone of approximately 10–15% in northern polar regions (Thompson and Wallace, 2000). As a first approximation, a 1% decrease in ozone results in a 1.5–2% increase in UV-B radiation. Damage processes to organisms are temperature-independent, whereas repair processes are slowed at low temperatures. Hence, it is

predicted that Arctic plants may be sensitive to increased UV-B radiation, especially because many individuals are long-lived and the effects are cumulative. In a study of responses by *Ericaceous* plants to UV-B radiation, responses varied from species to species and were more evident in the second year of exposure (Bjorn *et al.*, 1997; Callaghan *et al.*, 1998). For unknown reasons, however, the growth of the moss *Hylocomium splendens* is strongly stimulated by increased UV-B, provided adequate moisture is available (Gehrke *et al.*, 1996). Increased UV-B radiation also may alter plant chemistry that could reduce decomposition rates and nutrient availability (Bjorn *et al.*, 1997, 1999). Soil fungi differ with regard to their sensitivity to UV-B radiation, and their response also will affect the processes of decomposition (Gehrke *et al.*, 1995).

Climate change is likely to result in alterations to major biomes in the Arctic. Ecosystem models suggest that the tundra will decrease by as much as two-thirds of its present size (Everett and Fitzharris, 1998). On a broad scale—and subject to suitable edaphic conditions—there will be northward expansion of boreal forest into the tundra region, such that it may eventually cover more than 1.6 million km² of the Arctic. In northern Europe, vegetation change is likely to be more complicated. This is because of the influence of the geometrid moths, *Epiprora autumnata* and *Operophtera spp.*, which can cause large-scale defoliation of boreal forests when winter temperatures are above 3.6°C (Neuvonen *et al.*, 1999). Boreal forests are protected from geometrid moths only during cold winters. Empirical models estimate that by 2050, only one-third of the boreal forests of northern Europe will be protected by low winter temperatures in comparison to the proportion protected during the period 1961–1991 (Virtanen *et al.*, 1998). However, the northward movement of forest may lag changes in temperature by decades to centuries (Starfield and Chapin, 1996; Chapin and Starfield, 1997), as occurred for migration of different tree species after the last glaciation (Delcourt and Delcourt, 1987). The species composition of forests is likely to change, entire forest types may disappear, and new assemblages of species may be established. Significant land areas in the Arctic could have entirely different ecosystems with predicted climate changes (Everett and Fitzharris, 1998). However, note that locally, climate change may affect boreal forest through decreases in effective soil moisture (Weller and Lange, 1999), tree mortality from insect outbreaks (Fleming and Volney, 1995; Juday, 1996), probability of an increase of large fires, and changes caused by thawing of permafrost.

16.2.7.3. Changes in Arctic Animals

In the immediate future, the greatest environmental change for some parts of the Arctic is likely to result from increased herding of reindeer rather than climate change (Crete and Huot, 1993; Manseau *et al.*, 1996; Callaghan *et al.*, 1998). Winter lichen pastures are particularly susceptible to grazing and trampling, and recovery is slow, although summer pastures in tundra meadows and shrub-forb assemblages are less vulnerable (Vilchek, 1997). The overall impact of climatic warming on the

population dynamics of reindeer and caribou ungulates is controversial. One view is that there will be a decline in caribou and muskoxen, particularly if the climate becomes more variable (Gunn, 1995; Gunn and Skoglund, 1997). An alternative view is that because caribou are generalist feeders and appear to be highly resilient, they should be able to tolerate climate change (Callaghan *et al.*, 1998). Arctic island caribou migrate seasonally across the sea ice between Arctic islands in late spring and autumn. Less sea ice could disrupt these migrations, with unforeseen consequences for species survival and gene flow.

The decrease in the extent and thickness of Arctic sea ice in recent decades may lead to changes in the distribution, age structure, and size of populations of marine mammals. Seal species that use ice for resting, pup-rearing, and molting, as well as polar bears that feed on seals, are particularly at risk (Tynan and DeMaster, 1997). If break-up of annual ice occurs too early, seal pups are less accessible to polar bears (Stirling and Lunn, 1997; Stirling *et al.*, 1999). According to observational data, recent decreases in sea ice are more extensive in the Siberian Arctic than in the Beaufort Sea, and marine mammal populations there may be the first to experience climate-induced geographic shifts or altered reproductive capacity (Tynan and DeMaster, 1997).

Ice edges are biologically productive systems, with diatoms and other algae forming a dense layer on the surface that sustains secondary production. Of concern as ice melts is the loss of prey species of marine mammals, such as Arctic cod (*Boreogadus saida*) and amphipods, that are associated with ice edges (Tynan and DeMaster, 1997). The degree of plasticity within and between species to adapt to these possible long-term changes in ice conditions and prey availability is poorly known and requires study. Regime shifts in the ocean will impact the distribution of commercially important fish stocks. Recruitment seems to be significantly better in warm years than in cold years, and the same is valid for growth (Loeng, 1989). The distribution of fish stocks and their migration routes also could vary considerably (Buch *et al.*, 1994; Vilhjalmsson, 1997).

For other species, such as the lesser snow goose, reproductive success seems to be dependent on early-season climatic variables, especially early snowmelt (Skinner *et al.*, 1998). Insects will benefit from temperature increases in the Arctic (Danks, 1992; Ring, 1994). Many insects are constrained from expanding northward by cold temperatures, and they may quickly take advantage of a temperature increase by expanding their range (Parmesan, 1998).

16.2.8. Impact on Human Communities in the Arctic

16.2.8.1. Impacts on Indigenous Peoples

Historically, most indigenous groups have shown resilience and ability to survive changes in resource availability (e.g., the transition from Dorset to Thule cultures), but they may be less well equipped to cope with the combined impacts of climate

change and globalization (Peterson and Johnson, 1995). Indigenous peoples, who number 1.5 million of a total Arctic population of 10 million, have a mixture of formal economies (e.g., commercial harvesting of fish, oil and mineral extraction, forestry, and tourism) and informal economies (e.g., harvesting of natural renewable resources). Increasingly, the overall economy is tied to distant markets. For example, in Alaska, gross income from tourism is US\$1.4 billion, and in Russia 92% of exported oil is extracted from wells north of the Arctic Circle (Nuttall, 1998). The distinction between formal and informal economies becomes blurred by transfer payments and income derived from commercial ventures. The value of native harvests of renewable resources has been estimated to be 33–57% of the total economy of some northern communities (Quigley and McBride, 1987; Brody, 1991). However, harvesting of renewable resources also must be considered in terms of maintaining cultural activities (Duerden, 1992). Harvesting contributes to community cohesion and self-esteem, and knowledge of wildlife and the environment strengthens social relationships (Warren *et al.*, 1995; Berkes, 1998). For example, hunting of wildlife is an essential part of Inuit tradition (Wenzel, 1995).

Climate change and economic development associated with oil extraction, mining, and fish farming will result in changes in diet and nutritional health and exposure to air-, water-, and food-borne contaminants in northern people (Bernes, 1996; Rees and Williams, 1997; Vilchek and Tishkov, 1997; AMAP, 1998; Weller and Lange, 1999; Freese, 2000). People who rely on marine systems for food resources are particularly at risk because Arctic marine food chains are long (Welch, 1995; AMAP, 1997). Low-lying Arctic coasts of western Canada, Alaska, and the Russian Far East are particularly sensitive to sea-level rise. Coastal erosion and retreat as a result of thawing of ice-rich permafrost already are threatening communities, heritage sites, and oil and gas facilities (Forbes and Taylor, 1994; Dallimore *et al.*, 1996; Cohen, 1997a,b; Shaw *et al.*, 1998; Wolfe *et al.*, 1998; Are, 1999).

Along the Bering and Chukchi Sea coasts, indigenous peoples report thinning and retreating sea ice, drying tundra, increased storms, reduced summer rainfall, warmer winters, and changes in the distribution, migration patterns, and numbers of some wildlife species. These peoples testify that they already are feeling some of the impacts of a changing, warming climate (Mulvaney, 1998). For example, when sea ice is late in forming, certain forms of hunting are delayed or may not take place at all. When sea ice in the spring melts or deteriorates too rapidly, it greatly decreases the length of the hunting season. Many traditional foods are dried (e.g., walrus, whale, seal, fish, and birds) in the spring and summer to preserve them for consumption over the long winter months. When the air is too damp and wet during the “drying” seasons, food becomes moldy and sour. The length of the wet season also affects the ability to gather greens such as willow leaves, beach greens, dock, and wild celery. These testimonies reflect the kinds of changes that could be expected as global warming affects the Arctic (Mulvaney, 1998). As climate continues to change, there will be significant impacts on the availability of key subsistence

marine and terrestrial species. At a minimum, salmon, herring, walrus, seals, whales, caribou, moose, and various species of waterfowl are likely to undergo shifts in range and abundance. This will entail local adjustments in harvest strategies as well as in allocations of labor and resources (e.g., boats, snowmobiles, weapons). As the climate changes, community involvement in decisionmaking has the potential to promote sustainable harvesting of renewable resources, thereby avoiding deterioration of common property. However, factors that are beyond the control of the local community may frustrate this ideal. For example, many migratory animals are beyond the hunters’ geographical range for much of the year—and thus beyond the management of small, isolated communities. Traditional subsistence activities are being progressively marginalized by increasing populations and by transnational commercial activities (Sklair, 1991; Nuttall, 1998).

In the past, when population densities of indigenous people were lower and economic and social structures were linked only weakly to those in the south, northern peoples showed significant flexibility in coping with climate variability (Sabo, 1991; Odner, 1992). Now, commercial, local, and conservation interests have reduced their options. Predicted climate change is likely to have impacts on marine and terrestrial animal populations; changes in population size, structure, and migration routes also are probable (Beamish, 1995; Gunn, 1995; Ono, 1995). Careful management of these resources will be required within a properly consultative framework, similar to recent agreements that are wide-ranging and endeavor to underpin the culture and economy of indigenous peoples (Nuttall, 1998). Langdon (1995) claims that “the combination of alternative cultural lifestyles and altered subsistence opportunities resulting from a warmer climate may pose the greatest threat of all to the continuity of indigenous cultures in northern North America.” An alternative view is that northern people live with uncertainty and learn to cope with it; this view suggests that “for indigenous people, climate change is often not a top priority, but a luxury, and Western scientists may well be indoctrinating Natives with their own terminology and agenda on climate change” (BESIS, 1999).

16.2.8.2. Impacts on Economic Activity

The following subsections summarize the impacts of climate change and adaptive responses for different economic sectors that are relevant to the Arctic. Within different regions of the Arctic, important economic sectors differ substantially; some sectors are underrepresented, and others are just developing in certain regions (e.g., tourism). This latter topic (like agriculture and forestry) receives little or no comment in this section because there is insufficient literature to address the effects of climate change from a polar perspective.

16.2.8.2.1. Oil and gas extraction

Exploration, production, transportation, and associated construction of processing facilities are likely to be affected by

climatic change (Maxwell, 1997). Changes in a large number of climate and related variables will affect on- and offshore oil and gas operations. Use of oil drilling structures or ice-strengthened drillships designed to resist ice, use of the ice itself as a drilling platform, and construction of artificial islands are likely to give way to more conventional drilling techniques employed in ice-free waters (Maxwell, 1997). These likely changes are not without concerns. Although the use of regular drillships may reduce operating costs by as much as 50% (Croasdale, 1993), increased wave action, storm surges, and coastal erosion may necessitate design changes to conventional offshore and coastal facilities (McGillivray *et al.*, 1993; Anderson and DiFrancesco, 1997). This may increase the costs of pipeline construction because extensive trenching may be needed to combat the effects of coastal instability and erosion, especially that caused by permafrost melting (Croasdale, 1993; Maxwell, 1997). Design needs for onshore oil and gas facilities and winter roads are strongly linked to accelerated permafrost instability and flooding. The impact of climate change is likely to lead to increased costs in the industry associated with design and operational changes (Maxwell, 1997).

16.2.8.2.2. Buildings and industrial facilities

The capacity of permafrost to support buildings, pipelines, and roads has decreased with atmospheric warming, so pilings fail to support even insulated structures (Weller and Lange, 1999). The problem is particularly severe in the Russian Federation, where a large number of five-story buildings constructed in the permanent permafrost zone between 1950 and 1990 already are weakened or damaged, probably as a result of climate change (Khroustalev, 1999). For example, a 2°C rise in soil temperature in the Yakutsk region has led to a decrease of 50% in the bearing capacity of frozen ground under buildings. Khroustalev (1999) has predicted that by 2030, most buildings in cities such as Tiksi and Yakutsk will be lost, unless protective measures are taken. The impact of warming is likely to lead to increased building costs, at least in the short term, as new designs are produced that cope with permafrost instability. Snow loads and wind strengths may increase, which also would require modifications to existing building codes (Maxwell, 1997). There will be reduced demand for heating energy with warmer climate (Anisimov, 1999).

16.2.8.2.3. Transportation and communications

The impact of climate warming on transportation and communications in Arctic regions is likely to be considerable. Within and between most polar countries, air transport by major commercial carriers is widely used to move people and freight. Irrespective of climate warming, the number of scheduled flights in polar regions is likely to increase. This will require an adequate infrastructure over designated routes, including establishment of suitable runways, roads, buildings, and weather stations. These installations will require improved engineering designs to cope with permafrost instability.

Because paved and snow-plowed roads and airfield runways tend to absorb heat, the mean annual surface temperature may rise by 1–6°C, and this warming may exacerbate climate-driven permafrost instability (Maxwell, 1997). Cloud cover, wind speeds and direction, and patterns of precipitation may be expected to change at the regional level in response to global warming. At present, the density of weather stations is relatively low in Arctic regions. Increased air (and shipping) travel under a changing climate will require a more extensive weather recording network and navigational aids than now exists.

The impact of climate warming on marine systems is predicted to lead to loss of sea ice and opening of sea routes such as the Northeast and Northwest passages. Ships will be able to use these routes without strengthened hulls. There will be new opportunities for shipping associated with movement of resources (oil, gas, minerals, timber), freight, and people (tourists). However, improved navigational aids will be needed, and harbor facilities probably will have to be developed. The increase in shipping raises questions of maritime law that will need to be resolved quickly. These issues include accident and collision insurance, which authority is responsible for removal of oil or toxic material in the event of a spill, and which authority or agency pays expenses incurred in an environmental cleanup. These questions are important because sovereignty over Arctic waters is disputed among polar nations, and increased ship access could raise many destabilizing international issues. Increased storm surges are predicted that will affect transport schedules.

16.2.8.2.4. Pollution associated with increased economic activity

There already are a large number of case studies in the Arctic that indicate the effects of different pollutants on terrestrial, freshwater, and marine ecosystems (Crawford, 1997). In the event of increased industrial activity (e.g., mining, oil and gas extraction) under climate warming, new codes will be needed for retention of toxic wastes and to limit emissions of pollutants from processing plants. In the oil industry, considerable progress has been made in revegetating disturbed and polluted sites (McKendrick, 1997), often with plant species that can survive at northern sites under climatic warming. Changes in hydrology, possible increases in catchment rates, and melting of ice may result in wider dispersion of pollutants from accidents. Current ice cover and the low productivity of Arctic lakes restrict sequestration of contaminants (Barrie *et al.*, 1997; Gregor *et al.*, 1998). Projected changes to ice cover and the hydrology of these lakes may cause them to become greater sinks for river-borne contaminants, similar to those in more temperate regions. In the Arctic Ocean, many persistent organic pollutants (e.g., hexachlorocyclohexane) are trapped under ice as “ghosts of the past” (de March *et al.*, 1998). Reductions in sea-ice cover may speed their introduction to the Arctic food chain and pose risks for the human population. Long-lived apex consumers with high lipid content have a high potential for long-term accumulation of contaminants (Alexander, 1995;

Tynan and DeMaster, 1997), and not all of these pollutants are derived within the Arctic. Development of Arctic haze is thought to result from aerosol loading (primarily sulfate particles) of the atmosphere in mid-latitude regions. These particles are then carried northward to the Arctic. The haze is most pronounced in the winter because the particles have a longer residence time in the stable Arctic air masses at that time of year. The increased presence of sulfate particles in the atmosphere is of concern because of their ability to reduce the flow of energy through the atmosphere to the Earth's surface (Shaw, 1987).

16.2.8.2.5. Fisheries

High-latitude marine fisheries are very productive. For example, those in the northern Pacific Ocean and the Bering Sea contribute more than 28% to total world landings of fish, mollusks, and crustaceans. In some northern countries, fisheries and fish products account for a large proportion of gross domestic product. In Greenland, the shrimp industry contributed more than 30% to GDP in 1986. Landings of fish in the Northwest Territories and in Nunavut, in the commercial and the subsistence sectors of the economy, are valued at CDN\$12 million.

Shifts in oceanic circulation associated with global warming are likely to affect the distribution of commercially important fish and their migration routes (Buch *et al.*, 1994; Vilhjalmsson, 1997). For example, the first catches of two species of Pacific salmon (*Oncorhynchus nerka*, *O. gorbuscha*) recently have been made in estuaries on Banks Island, Canada. These locations are well outside the known range for these Pacific species (Babaluk *et al.*, 2000). Changes in ocean currents, nutrient availability, salinity, and the temperature of ocean waters can be expected to influence the disposition of larval and juvenile organisms, the growth rates of individuals, and the population structure of different fish species (Otterson and Loeng, 2000). For example, recruitment appears to be significantly better in warm years (Loeng, 1989), an example of which is increased landings of cod (*Gadus morhua*) associated with warmer air and surface water temperatures (Brander, 1996). During a warm phase between the 1920s and the 1960s, Norwegian herring fed in Icelandic waters but disappeared when the water temperature cooled by 1°C (Vilhjalmsson, 1997). Quinn and Marshall (1989) report positive correlations between salmon returns and reduced sea ice. However, species that are adapted to cold water, such as the Greenland turbot and the Alaskan King crab, declined in numbers during these warm phases, although other factors also contributed to the decline of crab stocks (Weller and Lange, 1999). However, the underlying mechanisms that account for changes in population sizes are poorly understood. This topic is a high research priority, particularly because plankton production and trophic interactions may be significantly altered by changes in climate. Research and management advice for fish stocks is provided by the International Council for the Exploration of the Seas (ICES). This authority and others face formidable challenges if the distributions of fish populations change in response to global warming (Hønneland *et al.*, 1999; Freese, 2000).

16.2.8.2.6. Reindeer husbandry

Husbandry of different subspecies of *Rangifer tarandus* is widely practiced in different regions of the Arctic, particularly in Eurasia. Between 1991 and 1997, Russia's domestic reindeer stock declined from 2.3 million to 1.6 million animals. Whether climate change contributed to this decline is uncertain (Weller and Lange, 1999), but climate warming is likely to alter husbandry practices. Concerns include the presence of deep snow with an ice surface that stops animals from obtaining forage, lichens and graminoids that are ice-covered, destruction of vegetation as a result of "overgrazing," exposure of soil that encourages establishment of southerly weedy species under a warmer climate (Vilchek, 1997), and an increased likelihood of damage from more frequent tundra fires.

16.3. Synthesis

16.3.1. Feedbacks and Interactions—Polar Drivers

Climate change will affect some key polar drivers, creating impacts in the wider global arena. Many of these impacts will be self-amplifying and, once triggered, will affect other regions of the world for centuries to come. These impacts relate to probable changes in the cryosphere, sea level, thermohaline circulation and ocean ventilation, exchange of GHGs, and cloudiness:

- *Snow/ice-albedo feedback:* The amount of absorbed solar radiation, and thus surface heating, depends on surface albedo, which is very high for snow or ice surfaces and much lower in the absence of snow and ice. Thus, absorbed shortwave radiation over the vast areas of snow and ice in polar regions is about three times lower than over non-snow-covered surfaces. Warming will shrink the cryosphere, particularly in the Arctic, causing additional heating of the surface, which in turn will further reduce ice and snow cover. Thus, any significant alteration in albedo over large areas will have the potential to produce a nonlinear, accelerated change.
- *Sea-level rise:* Projected climate change in polar regions will have a critical impact on global sea levels. Expected sea-level rise is in the range 0.09–0.88 m by 2100, using the SRES scenarios (TAR WGI Chapter 11). Increased melting of the Greenland ice sheet and Arctic glaciers, as well as possible thinning of the West Antarctic ice sheet, is expected to make important contributions. However, increased snow accumulation on the East and West Antarctic ice sheets is a major process that can offset sea-level rise. Sea level will continue to rise long after atmospheric GHGs are stabilized, primarily because of the large heat capacity of the ocean and the slow response of glaciers and ice sheets. The rate of downwelling of cold, dense waters in polar regions is a major control on thermal expansion of the ocean and hence the rate of sea-level rise over the next centuries.

- Feedbacks that link sea-level rise to the size and health of the West Antarctic ice sheet remain the subject of research and debate and are discussed in more depth in TAR WGI Chapter 11.
- *Ocean circulation:* Ocean-climate models predict increased stability of the surface mixed layer, reduction in salt flux, less ocean convection, and less deepwater formation. This could lead to a prolonged, major reduction in thermohaline circulation and ocean ventilation (O'Farrell *et al.*, 1997; Budd and Wu, 1998; Hirst, 1999). Such changes will affect surface ocean currents and climates of Europe and mid-latitude landmasses in the southern hemisphere, where it could slow warming in some regions (Murphy and Mitchell, 1995; Whetton *et al.*, 1996) but amplify it in others. Changes in runoff from large Arctic rivers (especially in Siberia) and increased melt from the Greenland ice sheet and glaciers will lead to more freshwater in the Arctic Ocean. This may further weaken the thermohaline circulation in the North Atlantic. With less overturning in the ocean, there will be a reduction of upwelling in temperate and subtropical latitudes. Wood *et al.* (1999) present simulations of present-day thermohaline circulation, using a coupled ocean-atmosphere climate model without flux adjustments. The model responds to forcing with increasing atmospheric concentrations of GHGs with a collapse of circulation and convection in the Labrador Sea. These changes are similar in two separate simulations with different rates of increase of CO₂ concentrations. Although various models give differing results, any changes in the thermohaline circulation will have profound consequences for marine biology and fisheries because of inevitable changes in habitat and nutrient supply. Perturbations caused by projected climate change, such as a marked increase in freshwater inputs in polar regions, may cause reorganization of the global ocean thermohaline circulation, leading to abrupt climate change (e.g., Manabe and Stouffer, 1993; Wright and Stocker, 1993; Stocker and Schmittner, 1997). Palaeoclimatic effects of past large freshwater inputs are widely discussed for the Atlantic (e.g., Broecker *et al.*, 1990; Rasmussen *et al.*, 1996; Bianchi and McCave, 1999) and for extra melt from the Antarctic ice sheet (Mikolajewicz, 1998). These studies show that with past climate changes, shifts from one circulation mode to another have caused large, and sometimes abrupt, regional climate changes. Although there is low confidence that such events will occur, the associated impacts would be substantial.
 - *Greenhouse gases—reduced uptake by the Southern Ocean:* Projected climate change will alter vast areas of oceans, wetlands, and permafrost in the polar regions that act as major sources and sinks for atmospheric CO₂ and CH₄. Projected climate change will alter these features, thereby altering the exchange of these gases. Model results (Sarmiento and Le Quere, 1996) show that of all oceans, the Southern Ocean is likely to experience the greatest slowing in CO₂ uptake with climate change. Reduced downwelling also will limit the ability of the ocean to sequester anthropogenic CO₂ (Sarmiento *et al.*, 1998). Changing marine biology also must be considered. Using coupled climate model output under the IPCC IS92a GHG scenario, Matear and Hirst (1999) calculate that by the year 2100, there could be a reduction in cumulative oceanic uptake of carbon of 56 Gt. This reduced uptake is equivalent to a 4% yr⁻¹ increase in CO₂ emissions for 1995–2100.
 - *Greenhouse gases—emission by Arctic landscapes:* Whether the Arctic will be a net sink or a net source of CO₂ will depend largely on the magnitude and direction of hydrological changes and the rate of decomposition of exposed peat in response to temperature rise (Oechel *et al.*, 1993; McKane *et al.*, 1997a,b). Tundra ecosystems have large stores of nutrients and carbon bound in permafrost, soil, and microbial biomass and have low rates of CO₂ uptake as a result of low net primary production (Callaghan and Jonasson, 1995). The 25-year pattern of net CO₂ flux indicates that tundra in Alaska was a net sink during the cool, wet years of the 1970s; a net source of CO₂ during the warm, dry 1980s; and a net sink during the warm but less dry 1990s (Vourlitis and Oechel, 1999). These responses also may reflect a decrease in the rate of decomposition of soil organic matter because decay potential decreases with depth, as older, more recalcitrant carbon is exposed in soil profiles (Christensen *et al.*, 1998, 1999a,b). Sink activity will be altered by changes in soil water content, temperature, or longer term adjustment of biotic processes (Oechel and Billings, 1992; Shaver *et al.*, 1992; Oechel and Vourlitis, 1994; Chapin *et al.*, 1995; Jonasson, 1996; Nadelhoffer *et al.*, 1996; Rastetter *et al.*, 1996; Waelbroeck *et al.*, 1997). Increased frequency of disturbances such as fire in boreal forest also could contribute to increased seasonal amplitude of atmospheric CO₂ (Zimov *et al.*, 1999). CH₄ production also is related to the position of the water table in the active layer (Torn and Chapin, 1993; Vourlitis *et al.*, 1993; Johnson *et al.*, 1996). The gas is oxidized in unsaturated soils and in the uppermost layer of the soil water column (Gilmanov and Oechel, 1995; Rouse *et al.*, 1995; Tenhunen, 1996). Hence, the future magnitude of soil emissions of CH₄ and CO₂ will reflect the net outcome of anaerobic and aerobic processes. Thawing of permafrost has the potential to release considerable quantities of CH₄ and CO₂ (Fukuda, 1994; Michaelson *et al.*, 1996; Anisimov *et al.*, 1997; Goulden *et al.*, 1998; Bockheim *et al.*, 1999). Considering all of these effects, future warming is likely to further increase natural GHG emissions. Fluxes of these gases eventually may revert, however, to current levels after an initial pulse (Waelbroeck *et al.*, 1997).
 - *Hydrates of greenhouse gases:* Substantial amounts of natural gas may be released to the atmosphere as a result of climate-induced destabilization of gas hydrates beneath the surface of the Earth. On the continents, stable gas hydrates can be found only at depths of several hundreds of meters, making it unlikely that they will be

released by climate change in the coming centuries. In the northern seas, gas hydrates may be deposited in the near-bottom zone, and their decomposition is likely to occur if deepwater temperature rises by even a few degrees. Because there are large uncertainties in the estimated amounts of the near-bottom gas hydrates, their role in providing positive feedback to the climate system cannot be evaluated with reasonable accuracy. There is evidence of methane hydrate destabilization and release with warming of coastal ocean bottomwater from other parts of the world (Kennett *et al.*, 2000).

16.3.2 Adaptation Potential and Vulnerability

Parts of the Arctic and Antarctic where water is close to its melting point are highly sensitive to climate change, rendering their biota and socioeconomic life particularly vulnerable. Adaptation to climate change will occur in natural polar ecosystems mainly through migration and changing mixes of species. This may cause some species to become threatened (e.g., walrus, seals, polar bears), whereas others may flourish (e.g., fish, penguins). Although such changes may be disruptive to many local ecological systems and particular species, the possibility remains that predicted climate change eventually will increase the overall productivity of natural systems in polar regions.

For people, successful future adaptation to change depends on technological advances, institutional arrangements, availability of financing, and information exchange. Stakeholders must be involved in studies from the beginning as well as in discussions of any adaptive and mitigative measures (Weller and Lange, 1999). For indigenous communities following traditional lifestyles, opportunities for adaptation to climate change appear to be limited. Long-term climate change, combined with other stresses, may cause the decline and eventual disappearance of communities. Technologically developed communities are likely to adapt quite readily to climate change by adopting altered modes of transport and by increased investment to take advantage of new commercial and trade opportunities.

Except in the Antarctic Peninsula, the Antarctic and the Southern Ocean probably will respond slowly to climate change; consequently, there will be less obvious impact in this region by 2100. Nevertheless, these areas are vulnerable because climate change could initiate millennial-scale processes with the potential to cause irreversible impacts on ice sheets, global ocean circulation, and sea-level rise. Antarctic drivers of sea-level rise, slowdown of the ocean thermohaline circulation, and changes in marine ecological habitats will continue for several centuries, long after GHG emissions are stabilized.

16.3.3. Development, Sustainability, and Equity

Distinctive patterns of development in the Arctic arise from the special nature of northern communities. The region is marked by decentralized administration and the presence of relict

military establishments. The main forms of resource use are oil, gas, and mineral mining (e.g., lead, zinc, gold, diamonds), ecotourism, fishing, and traditional hunting and gathering by indigenous peoples. Further development of these resources is likely. Maintenance of existing infrastructure is likely to be more costly. Transportation may be affected as permafrost thaws and ice disappears. Waste disposal strategies also will have to change. Reduced sea ice will change strategic defense situations, especially for navies of the large powers flanking the Arctic. Sovereignty issues are of concern because of confusion over northern boundaries, the increased likelihood of territorial disputes as ice gives way to open water, and new northern sea routes create new trade patterns. Changes in sea ice and easier navigation may bring new policy initiatives, and improved sea access will greatly increase ecotourism. Overall, there will be increased human activity in the Arctic.

There are large regional differences across the Arctic in development, infrastructure, and ability of people to cope with climate change. Increasingly, Arctic communities are sustainable only with support from the south. Indigenous peoples are more sensitive to climate change than nonindigenous peoples. Their homelands and hunting habitats will be directly affected, and they cannot easily retreat to less affected areas. Some native peoples may be able to adapt, but probably at the expense of traditional lifestyles. Nonindigenous peoples also are vulnerable where links with the south are broken by changes in the physical environment and altered political circumstances. Their lifestyles require high capital investment, which will have to be maintained or even increased for them to be adaptable to climate change. With climate change, economies that rely on support from the south may become more expensive because of disrupted land-based transport, and this may not be sustainable. However, new transport opportunities, growing communities, and easier mining will create new wealth—but only for those who move away from traditional lifestyles.

In Antarctica, future use of the continent is governed by the Antarctic Treaty, and there are no permanent residents. With regard to policy issues, changes in the climate may mean less sea ice, easier access for ecotourism, and increased pressure on the environment. Sustaining the Antarctic's pristine nature may become more difficult.

16.3.4. Uncertainties and Risks

The polar regions will play a substantial role in driving global climate change through positive feedbacks to global warming. They also provide us with unparalleled records of that change. The most important uncertainties, risks, and thus targets for research are as follows:

- *Ocean thermohaline circulation:* Will downwelling in the North Atlantic and the Southern Ocean cease, causing a shutdown of the circulation of the global ocean? Or will this downwelling simply reduce and eventually recover with stabilization of GHGs? What

- is the role of changing input of freshwater from Arctic rivers?
- *Antarctic ice sheet*: What will be the contribution of the Antarctic ice sheets to global sea-level rise over the coming centuries? Although it is likely that the Antarctic ice sheet will provide some degree of mitigation of predicted sea-level rise, there is a small risk that the West Antarctic ice sheet (or portions of it) may retreat rapidly, causing a greater than predicted rise.
- *Marine biology*: What will be the response to predicted climate change of the structure of marine communities and the overall productivity of polar oceans? Uncertainty arises because existing biological models are not yet sufficiently developed to provide authoritative and quantitative estimates. There is some risk of unforeseen collapse of parts of the marine biological system, with consequent global effects—particularly on fisheries.
- *Arctic ice sheets, glaciers, and ice caps*: What is the current and future magnitude of freshwater input to the oceans from ice masses? What is the impact on global sea level and the thermohaline circulation on decadal to century time scales, and how can uncertainties in estimates be reduced?
- *Permafrost*: As ice-rich permafrost degrades, what will be the magnitude, spatial extent, and variability of its impacts? Will increases in the thickness of the active layer in currently cold, continuous permafrost be sufficient to cause widespread damage to human infrastructure? How important is soil organic carbon sequestered in the upper layer of permafrost in the context of the world carbon balance?
- *Arctic hydrology*: Will the balance between increased precipitation and evapotranspiration lead to a drier or wetter Arctic landscape? What will be the water balances of the large river basins that generate freshwater inflow to the Arctic Ocean?
- *Arctic sea ice*: Is it possible that with increased open water in the Arctic Ocean, summer sea ice in the Arctic eventually could disappear completely? The risk is that substantially more open water could generate large changes in regional climate for countries on the Arctic rim.
- *Fluxes of greenhouse gases*: What are the current and future fluxes of GHGs from polar oceans and landscapes? In particular, what is the likely future role of gas hydrates?
- *Stresses on human communities in the Arctic*: Can Arctic communities survive the combined stresses of globalization and marked changes in their local environments that may result from climate change? Traditional lifestyles will be threatened, but the communities that practice these lifestyles may be sufficiently resilient to cope with these changes, as they have in the recent and distant past.

EXECUTIVE SUMMARY

The small island states considered in this chapter are located mainly in the tropics and the subtropics. These island states span the ocean regions of the Pacific, Indian, and Atlantic, as well as the Caribbean and Mediterranean Seas. Because of the very nature of these states, the ocean exerts a major influence on their physical, natural, and socioeconomic infrastructure and activities.

Although small island states are not a homogeneous group, they share many common features that serve to increase their vulnerability to projected impacts of climate change. These characteristics include their small physical size and the fact that they are surrounded by large expanses of ocean; limited natural resources; proneness to natural disasters and extreme events; relative isolation; extreme openness of their economies, which are highly sensitive to external shocks; large populations with high growth rates and densities; poorly developed infrastructure; and limited funds, human resources, and skills. These characteristics limit the capacity of small island states to mitigate and adapt to future climate and sea-level change.

The most significant and immediate consequences for small island states are likely to be related to changes in sea levels, rainfall regimes, soil moisture budgets, and prevailing winds (speed and direction) and short-term variations in regional and local patterns of wave action. Owing to their coastal location, the majority of socioeconomic activities and infrastructure and the population are likely to be highly vulnerable to the impacts of climate change and sea-level rise.

Review of past and present trends of climate and climate variability indicates that temperatures have been increasing by as much as 0.1°C per decade, and sea level has risen by 2 mm yr^{-1} in regions in which small island states are located. Analysis of observational data for these regions suggests that increases in surface air temperatures have been greater than global rates of warming (e.g., in the Pacific Ocean and the Caribbean Sea regions). Observational evidence also suggests that much of the variability in the rainfall record of Caribbean and Pacific islands appears to be closely related to the onset of El Niño-Southern Oscillation (ENSO). However, part of the variability in these areas also may be attributable to the influence of the Inter-Tropical Convergence Zone (ITCZ) and the South Pacific Convergence Zone (SPCZ). It is acknowledged however, that for some small islands it is difficult to establish clear trends of sea-level change because of limitations of observational records, especially geodetic-controlled tide gauge records.

The use of the state-of-the-art coupled atmosphere-ocean general circulation models (AOGCMs) to estimate future response of climate to anthropogenic radiative forcing suggests an enhanced climate change in the future. Several AOGCMs have been analyzed for the Atlantic, Pacific, and Indian Ocean

regions and the Caribbean and Mediterranean Seas. The outputs from these models indicate general increases in surface air temperature for the 2050s and 2080s and an increase in rainfall of about 0.3% for the 2050s and 0.7% for the 2080s for the Pacific region. However, a marginal decline in rainfall is projected for the other regions, with a possible reduction of water availability. The diurnal temperature range is projected to decrease marginally for the regions of the small island states for both time horizons.

With respect to extreme events, AOGCM (CSIRO and ECHAM) transient experiments project that by the 2050s and 2080s, there will be increased thermal stress during summer, as well as more frequent droughts and floods in all four tropical ocean regions in which small island states are located. This projection implies that in the future these regions are likely to experience floods during wet seasons and droughts during dry seasons. Furthermore, warming in some regions (e.g., the Pacific Ocean) is likened to an El Niño pattern, suggesting that climate variability associated with the ENSO phenomenon will continue on a seasonal and decadal time scale. It is probable that such an association may dominate over any effects attributable to global warming. Given their high vulnerability and low adaptive capacity to climate change, communities in the small island states have legitimate concerns about their future on the basis of the past observational record and climate model projections. In this Third Assessment Report, analysis of the scientific-technical literature identifies the following key issues among the priority concerns of small island states.

Development, sustainability, and equity issues. The small island states account for less than 1% of global greenhouse gas (GHG) emissions but are among the most vulnerable of all locations to the potential adverse effects of climate change and sea-level rise. Economic development and alleviation of poverty constitute the single most critical concern of many small island states. Thus, with limited resources and low adaptive capacity, these islands face the considerable challenge of meeting the social and economic needs of their populations in a manner that is sustainable. At the same time, they are forced to implement appropriate strategies to adapt to increasing threats resulting from greenhouse gas forcing of the climate system, to which they contribute little.

Sea-level rise. Although there will be regional variation in the signal, it is projected that sea level will rise by as much as 5 mm yr^{-1} over the next 100 years as a result of GHG-induced global warming. This change in sea level will have serious consequences for the social and economic development of many small island states. For some islands, the most serious consideration will be whether they will have adequate potential to adapt to sea-level rise within their own national boundaries.

Beach and coastal changes. Most coastal changes currently experienced in the small island states are attributable to human activity. With the projected increase in sea level over the next 50–100 years superimposed on further shoreline development, however, the coastal assets of these states will be further stressed. This added stress, in turn, will increase the vulnerability of coastal environments by reducing natural resilience, while increasing the economic and social “costs” of adaptation.

Biological systems. Coral reefs, mangroves, and seagrass beds, which provide the economic foundation for many small islands, often rely on “stable” coastal environments to sustain themselves. Although it is acknowledged that human-induced stresses are contributing to their degradation, these systems will be adversely affected by rising air temperature and sea levels. In most small islands, coral reefs already are undergoing great stress from episodic warming of the sea surface, causing widespread bleaching. Mangroves—which are common on low-energy, nutrient/sediment-rich coasts and embayments in the tropics—have been altered by human activities. Changes in sea levels are likely to affect landward and longshore migration of remnants of mangrove forests, which provide some protection for the coasts and backshore infrastructure. It is projected that changes in the availability of sediment supply, coupled with increases in temperature and water depth as a consequence of sea-level rise, will adversely impact the productivity and physiological functions of seagrasses. Consequently, this would have a negative downstream effect on fish populations that feed on these communities.

Biodiversity. It is estimated that 33% of known threatened plants are island endemics, and 23% of bird species found on islands also are threatened. Although there is still some uncertainty about precisely how and to what extent biodiversity and wildlife in small islands will be affected, available projections suggest that climate change and sea-level rise will cause unfavorable shifts in biotic composition and adversely affect competition among some species.

Water resources, agriculture, and fisheries. The availability of water resources and food remain critical concerns in island communities. In many countries, water already is in short supply because islands (many of which are drought-prone) rely heavily on rainwater from small catchments or limited freshwater lenses. Arable land for crop agriculture often is in short supply; thus, the likely prospect of land loss and soil salinization as a consequence of climate change and sea-level rise will threaten the sustainability of both subsistence and commercial agriculture in these islands. Because water resources and agriculture are so climate sensitive, it is expected that these sectors also will be adversely affected by future climate and sea-level change. Although climate change is not expected to have a significant impact on world fisheries output, it is projected to have a severe impact on the abundance and distribution of reef fish population on the islands.

Human health, settlement and infrastructure, and tourism. Several human systems are likely to be affected by projected

changes in climate and sea levels in many small island states. Human health is a major concern in many tropical islands, which currently are experiencing a high incidence of vector- and water-borne diseases. This is attributable partly to changes in temperature and rainfall, which may be linked to the ENSO phenomenon, and partly to changes in the patterns of droughts and floods. Climate extremes also place a huge burden on human welfare; this burden is likely to increase in the future. Almost all settlements, socioeconomic infrastructure, and activities such as tourism in many island states are located at or near coastal areas. Their location alone renders them highly vulnerable to future climate change and sea-level rise. Tourism is a major revenue earner and generates significant employment in many small islands. Changes in temperature and rainfall regimes, as well as loss of beaches, could be devastating for the economies that rely on this sector. Because climate change and sea-level rise are inevitable in the future, it is vital that beach and coastal assets in the small island states are managed wisely. Integrated coastal management has been identified and proposed as an effective framework for accomplishing this goal.

Sociocultural and traditional assets. Other island assets, such as know-how and traditional skills (technologies), are under threat from climate change and sea-level rise. In some societies, community structures and assets such as important traditional sites of worship, ritual, and ceremony—particularly those at or near the coasts—could be adversely affected by future climate change and sea-level rise.

It is significant to note that although many vulnerability assessment methodologies have been applied to different regions of the world with varying degrees of success, global assessments have consistently identified the small island states as one of the most high-risk areas, irrespective of methodology employed. This evidently robust finding must be of considerable concern to these states. It is further established that climate change is inevitable as a result of past GHG emissions and that small islands are likely to suffer disproportionately from the enhanced effects of climate change and sea-level rise. Hence, identification and implementation of effective adaptation measures and avoidance of maladaptation (i.e., measures that increase exposure rather than decrease vulnerability) are critical for small islands, even if there is swift implementation of any global agreement to reduce future emissions.

For most small islands, the reality of climate change is just one of many serious challenges with which they are confronted. Such pressing socioeconomic concerns as poverty alleviation; high unemployment; and the improvement of housing, education, and health care facilities all compete for the slender resources available to these countries. In these circumstances, progress in adaptation to climate change almost certainly will require integration of appropriate risk reduction strategies with other sectoral policy initiatives in areas such as sustainable development planning, disaster prevention and management, integrated coastal management, and health care planning.

17.1. Regional Characteristics

17.1.1. Review of Previous Work

Almost without exception, small island states have been shown to be at great risk from projected impacts of climate change, particularly sea-level rise. The projected global rate of rise of 5 mm yr^{-1} ($\pm 2\text{--}9 \text{ mm yr}^{-1}$) is two to four times greater than the rate experienced in the previous 100 years (IPCC, 1998). Many of these islands rarely exceed 3–4 m above present mean sea level; even on the higher islands, most of the settlements, economic activity, infrastructure, and services are located at or near the coast.

Reliable instrumental records indicate that on average, Caribbean islands have experienced an increase in temperature exceeding 0.5°C since 1900. During the same period, there has been a significant increase in rainfall variability, with mean annual total rainfall declining by approximately 250 mm. For Pacific islands, the post-1900 temperature increase has been slightly lower than in the Caribbean: less than 0.5°C . In the case of rainfall, no clear trend emerges from the record, which shows decadal fluctuations of $\pm 200 \text{ mm}$ and 50–100 mm for mean annual and mean seasonal totals, respectively (IPCC, 1998).

Given the strong influence of the ocean on the climate of islands, and based on projected warming of the oceans ($1\text{--}2^\circ\text{C}$ for the Caribbean Sea and Atlantic, Pacific, and Indian Oceans) with a doubling of carbon dioxide (CO_2), small islands in these regions are expected to continue to experience moderate warming in the future. Under a similar scenario, mean rainfall intensity also is projected to increase by 20–30% over the tropical oceans, where most small island states are located. However, a decrease in mean summer precipitation over the Mediterranean Sea, where the small islands of Malta and Cyprus are located, is projected (IPCC, 1998).

Based on these projections, certain marine and coastal ecosystems are most likely to be adversely affected. Corals—many species of which currently exist near the upper limits of their tolerance to temperature—are projected to experience more frequent bleaching episodes as a result of elevated sea surface temperatures (SSTs). Bleaching therefore will pose a distinct threat to the productivity and survival of these valuable ecosystems (Wilkinson, 1996; Brown, 1997a,b; CARICOMP, 1997; Woodley *et al.*, 1997). On some islands, mangroves also are expected to be threatened by the impacts of climate change. Where the rate of sedimentation is slower than the projected rate of sea-level rise and where mangroves cannot naturally adapt and migrate landward, the vulnerability of these ecosystems will increase (IPCC, 1996, 1998). In some cases, the natural resilience of these ecosystems already has been impaired by anthropogenic stresses; thus, their capacity to cope with an additional stressor such as climate change will be further compromised.

Sea-level rise poses by far the greatest threat to small island states relative to other countries. Although the severity of the threat will vary from island to island, it is projected that beach erosion and coastal land loss, inundation, flooding, and salinization of

coastal aquifers and soils will be widespread. Moreover, protection costs for settlement, critical infrastructure, and economic activities that are at risk from sea-level rise will be burdensome for many small island states. Similarly, tourism—the leading revenue earner in many states—is projected to suffer severe disruption as a consequence of adverse impacts expected to accompany sea-level rise (Teh, 1997; IPCC, 1998).

17.1.2. Special Circumstances of Small Islands

Small island states are by no means a homogeneous group of countries. They vary by geography; physical, climatic, social, political, cultural, and ethnic character; and stage of economic development. Yet they tend to share several common characteristics that not only identify them as a distinct group but underscore their overall vulnerability in the context of sustainable development (Maul, 1996; Leatherman, 1997). These common characteristics include the following:

- Limited physical size, which effectively reduces some adaptation options to climate change and sea-level rise (e.g., retreat; in some cases entire islands could be eliminated, so abandonment would be the only option)
- Generally limited natural resources, many of which already are heavily stressed from unsustainable human activities
- High susceptibility to natural hazards such as tropical cyclones (hurricanes) and associated storm surge, droughts, tsunamis, and volcanic eruptions
- Relatively thin water lenses that are highly sensitive to sea-level changes
- In some cases, relative isolation and great distance to major markets
- Extreme openness of small economies and high sensitivity to external market shocks, over which they exert little or no control (low economic resilience)
- Generally high population densities and in some cases high population growth rates
- Frequently poorly developed infrastructure (except for major foreign exchange-earning sectors such as tourism)
- Limited funds and human resource skills, which may severely limit the capacity of small islands to mitigate and adapt to the effects of climate change.

17.1.3. Past and Present Trends

The Intergovernmental Panel on Climate Change (IPCC) in its Second Assessment Report (SAR) projected a global average temperature increase of $1.0\text{--}3.5^\circ\text{C}$, and a consequential rise in global mean sea level of 15–95 cm by the year 2100. Results from observational data show that temperatures have been increasing by as much as 0.1°C per decade and sea levels by approximately 2 mm yr^{-1} in the regions where most of the small island states are located—namely, the Pacific, Indian, and Atlantic Oceans and the Caribbean Sea (see Figure 17-1). There also is evidence that the ENSO phenomenon will continue

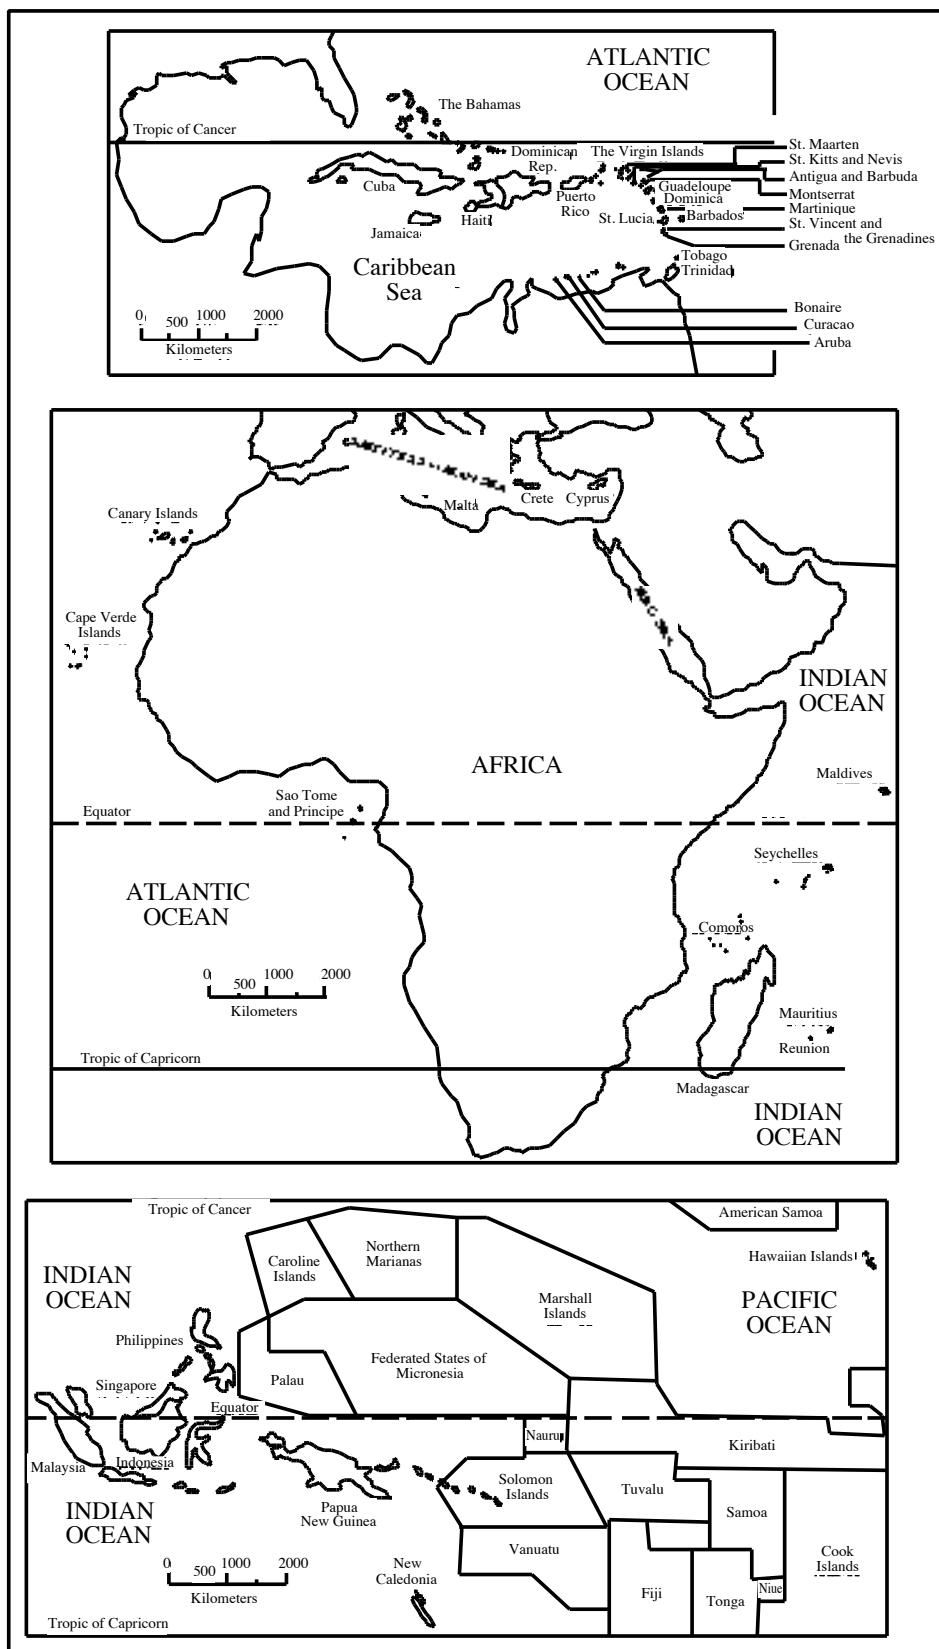

Figure 17-1: Main regions of the world in which small island states are located.

to have a major influence on climate variability in these regions.

Analyses conducted by the New Zealand Meteorological Services reveal that, since 1920, temperature has risen by 0.6–0.7°C in Noumea (New Caledonia) and Rarotonga (Cook Islands), which is greater than the mean global increase. Based on data from 34 stations in the Pacific from about 160°E and mostly south of the equator, surface air temperatures have increased by 0.3–0.8°C during the 20th century, with the greatest increase in the zone southwest of the SPCZ. This is well in excess of global rates of warming. Further recent work undertaken by the New Zealand Institute of Water and Atmospheric Research (NIWA) shows a noticeable change in aspects of the South Pacific climate since the mid-1970s. For instance, western Kiribati, the northern Cook Islands, Tokelau, and northern French Polynesia have become wetter, whereas New Caledonia, Fiji, and Tonga have become drier. Meanwhile, Samoa, eastern Kiribati, Tokelau, and northeast French Polynesia have become cloudier, with warmer nighttime temperatures; New Caledonia, Fiji, Tonga, the southern Cook islands, and southwest French Polynesia and Tuvalu have become warmer and sunnier (Salinger *et al.*, 1995). It also might be noted that in the Pacific generally, observed changes in temperature and cloudiness appear to be closely influenced by the pattern of ENSO events (Salinger, 1999).

The records also indicate that rainfall has increased in the northeast Pacific but has

decreased in the southwest Pacific region. Interannual variations in temperature and rainfall are strongly associated with ENSO, resulting in water shortages and drought in Papua New Guinea, the Marshall Islands, the Federated States of Micronesia, American Samoa, Samoa, and Fiji. Although a causal link has yet to be established, all of the foregoing changes have coincided with an eastward shift of the SPCZ since 1970. Research now suggests that some of the foregoing changes (including the shift in the SPCZ) may be closely correlated with interdecadal patterns of variability—for example, the Pacific Decadal Oscillation (PDO) (Salinger and Mullen, 1999). It should be noted, nevertheless, that the changes observed in the 20th century are considered to be consistent with patterns related to anthropogenic GHG-induced climate change (Salinger *et al.*, 1995; Hay, 2000).

The most significant and more immediate consequences for small island states are likely to be related to changes in sea levels, rainfall regimes, soil moisture budgets, and prevailing winds (speed and direction), as well as short-term variations in regional and local sea levels and patterns of wave action (Sem *et al.*, 1996). The short-term (including interannual) variations are likely to be strengthened by the ENSO phenomenon. Vulnerability assessment studies undertaken in some small islands suggest that climate change will impose diverse and significant impacts on small island states (Leatherman, 1997). In most small islands (including the high islands), the majority of the population, socioeconomic activities, and infrastructure are located within a few hundred meters of the coast; therefore, they are highly vulnerable to the impacts of climate change and sea-level rise (Hay *et al.*, 1995; Bijlsma, 1996; Nurse *et al.*, 1998; Burns, 2000). In this regard, an increase in the frequency and magnitude of tropical cyclones would be a major concern for small island states. This would increase the risk of flooding, accelerate existing rates of beach erosion, and cause displacement of settlements and infrastructure.

The key questions, therefore, are how will the impacts manifest themselves, and what are the most appropriate responses for avoiding, minimizing, or adapting to these impacts? Because small island states traditionally experience some of the greatest interannual variations in climatic and oceanic conditions, many of their natural systems are well adapted to the stresses that result. Thus, many strategies that small island states might employ to adapt to climate change usually are the same as those that constitute sound environmental management, wise use of resources, and appropriate responses to present-day climate variability.

Although the full extent of climate change impacts in the small island states is far from certain, mostly adverse consequences are projected for several systems. The combined effect of GHG-induced climate change and sea-level rise can contribute to coastal erosion and land loss, flooding, soil salinization, and intrusion of saltwater into groundwater aquifers. The quantity and quality of available water supplies can affect agricultural production and human health. Similarly, changes in SST, ocean circulation, and upwelling could affect marine organisms such

as corals, seagrasses, and fish stocks. Tourism—which is a very important economic activity in many island states—could be affected through beach erosion, loss of land, and degraded reef ecosystems, as well as changes in seasonal patterns of rainfall.

17.1.4. Scenarios of Future Climate Change and Variability

17.1.4.1. The Models Used

Projections of future climate change discussed in this chapter essentially are based on data sets available at IPCC Data Distribution Centers (DDCs) at Hamburg and Norwich and currently available numerical experiments with state-of-the-art global climate models that consider a near-identical GHG

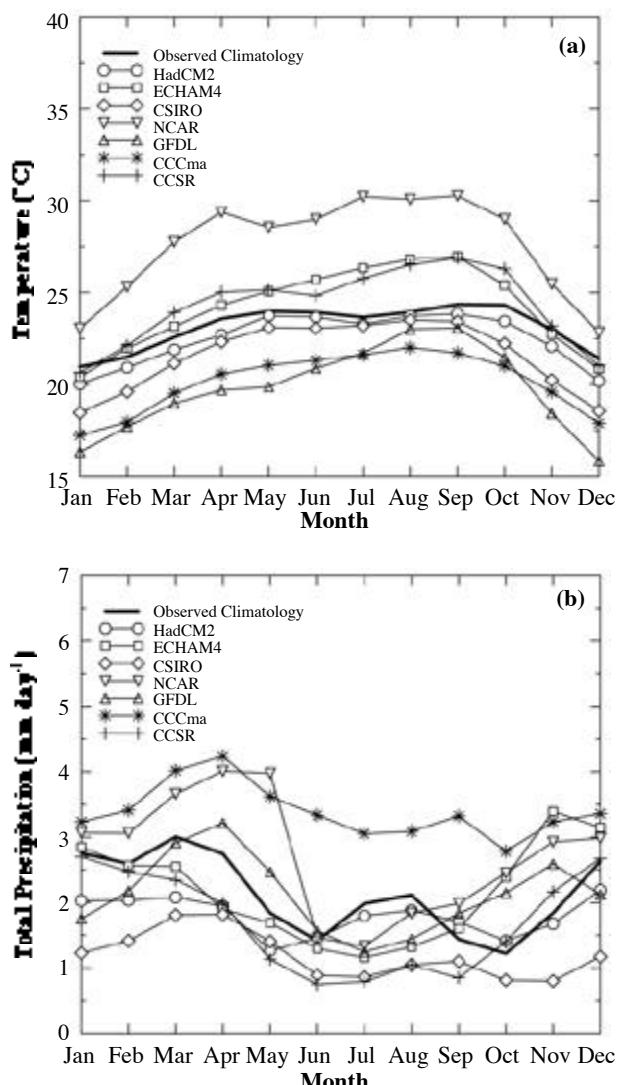

Figure 17-2: Validation of seven AOGCM-simulated and observed climatology [(a) temperature and (b) rainfall] for Mediterranean Sea islands.

forcing: 1% yr⁻¹ growth in GHG concentrations (IS92a) after 1990. Coupled AOGCMs offer the most credible tools for estimating the future response of climate to anthropogenic radiative forcings. The DDCs have compiled outputs generated in transient experiments with a set of seven recent AOGCMs that reflect the state-of-the-art of model experiments and provide a representative range of results from different AOGCMs.

17.1.4.2. Region-Specific Model Validation

A model validation exercise was undertaken for the four main regions (the Atlantic Ocean and Caribbean Sea, the Pacific Ocean, the Indian Ocean, and the Mediterranean Sea region) in which the majority of small island states are located. The results indicate that five of the seven AOGCMs [HadCM2

(UK), ECHAM4 (Germany), CSIRO (Australia), CCSR/NIES (Japan), and CCCma (Canada)] have reasonable capability in simulating the broad features of present-day climate and its variability over these regions. Comparison of the monthly mean observed and model-simulated climatology of surface air temperature and rainfall over the Mediterranean Sea and Indian Ocean regions is shown in Figures 17-2 and 17-3. The time period of 30 years (1961–1990) in baseline climatology has been used for the purpose of these model validation exercises and to generate climate change scenarios for these island regions. Two future time periods centered around the 2050s (2040–2069) and the 2080s (2070–2099) have been considered here in developing scenarios of changes in surface air temperature and precipitation.

For the four regions identified above, the HadCM2, ECHAM4, CSIRO, CCSR/NIES, and CCCma models have demonstrated good capability in simulating the present-day area-averaged monthly mean climatology in terms of surface temperature, diurnal temperature range, and rainfall (Lal *et al.*, 2001). The model projections discussed here are the scenarios arising from GHG-induced positive radiative forcings and those that take into account the negative radiative forcing of sulfate aerosols (direct effects).

17.1.4.3. Climate Change Projections for Small Island States

17.1.4.3.1. Surface air temperature

Tables 17-1, 17-2, and 17-3 provide an ensemble of climate change scenario results inferred from the five AOGCMs referred to above for four regions. These tables summarize projected seasonal mean changes in surface air temperature and precipitation during the 2050s and 2080s. The projected area-averaged annual mean warming as a consequence of increases in atmospheric concentrations of GHGs over the Atlantic Ocean and Caribbean Sea, the Pacific Ocean, the Indian Ocean, and the Mediterranean Sea is approximately 2.0, 2.0, 2.1, and 2.8°C, respectively, for the 2050s, and approximately 3.1, 3.0, 3.2, and 4.3°C, respectively, for the 2080s (see Table 17-1). Projected warming over the Mediterranean Sea area is marginally higher during Northern Hemisphere (NH) summer than during NH winter for both time periods. The increase in surface air temperature is more or less uniform in both seasons in the other three regions (Tables 17-2 and 17-3). The scatter of projected annual mean surface temperature increase over each of the regions, as simulated by each of the five GCMs, is depicted in Figures 17-4 to 17-7. The area-averaged annual increase in mean surface temperature resulting from increases in GHGs is projected to be smallest over the Pacific Ocean region and highest over the Mediterranean Sea. It is evident that even though aerosol forcing marginally reduces surface warming, the magnitude of projected warming is still considerable and could substantially impact the small island states.

With respect to diurnal changes, GCM simulations with increasing concentrations of GHGs in the atmosphere suggest relatively more

pronounced increases in minimum temperature than in maximum temperature over the regions where the small island states are located, on an annual mean basis as well as during winter, for both the 2050s and the 2080s. Hence, a marginal decrease in diurnal temperature range (between 0.3 and 0.7°C) is projected.

17.1.4.3.2. Precipitation

In general, all AOGCMs simulate only a marginal increase or decrease in annual rainfall. An area-averaged annual mean increase in precipitation of approximately 0.3% for the 2050s and 0.7% for the 2080s over the Pacific Ocean area is projected, either as a consequence of increases in atmospheric concentrations of GHGs or because of the combined influence of GHGs and sulfate aerosols. The projected increase in precipitation is at a maximum during NH summer (June-July-August) for both time periods. A marginal decline in precipitation is projected for the other three regions, particularly during NH summer—suggesting the possibility of reduced water availability (Lal *et al.*, 2001).

17.1.4.3.3. Extreme high temperature and precipitation events

An analysis of model-simulated daily temperature and precipitation data (from CSIRO and ECHAM model experiments) for the

present-day atmosphere and for the two future time slices (2050s and 2080s) projects that the frequency of extreme temperatures during the summer is likely to be higher in all four regions. This implies an increased likelihood of thermal stress conditions during the 2050s and more so during the 2080s. Similarly, although the models project a lesser number of annual rainy days, an increase in the daily intensity of precipitation also is projected (Lal *et al.*, 2001). This suggests an increase in the probability of occurrence of more frequent droughts, as well as floods, in the Atlantic Ocean and Caribbean Sea, the Mediterranean Sea, and the Indian and Pacific Oceans.

17.1.4.3.4. ENSO and precipitation variability

Although it is difficult to obtain reliable regional projections of climate change from GCMs, some consistent patterns are beginning to emerge for the Pacific with regard to ENSO and precipitation variability. Although ocean temperatures over most of the western and southern Pacific warm more slowly than the global average, the eastern central Pacific warms faster than the global average in outputs from several AOGCMs (Meehl and Washington, 1996; Timmerman *et al.*, 1997; Knutson and Manabe, 1998; Jones *et al.*, 1999). These results have been broadly interpreted as an El Niño-like pattern (e.g., Cai and Whetton, 2000) because some simulations appear

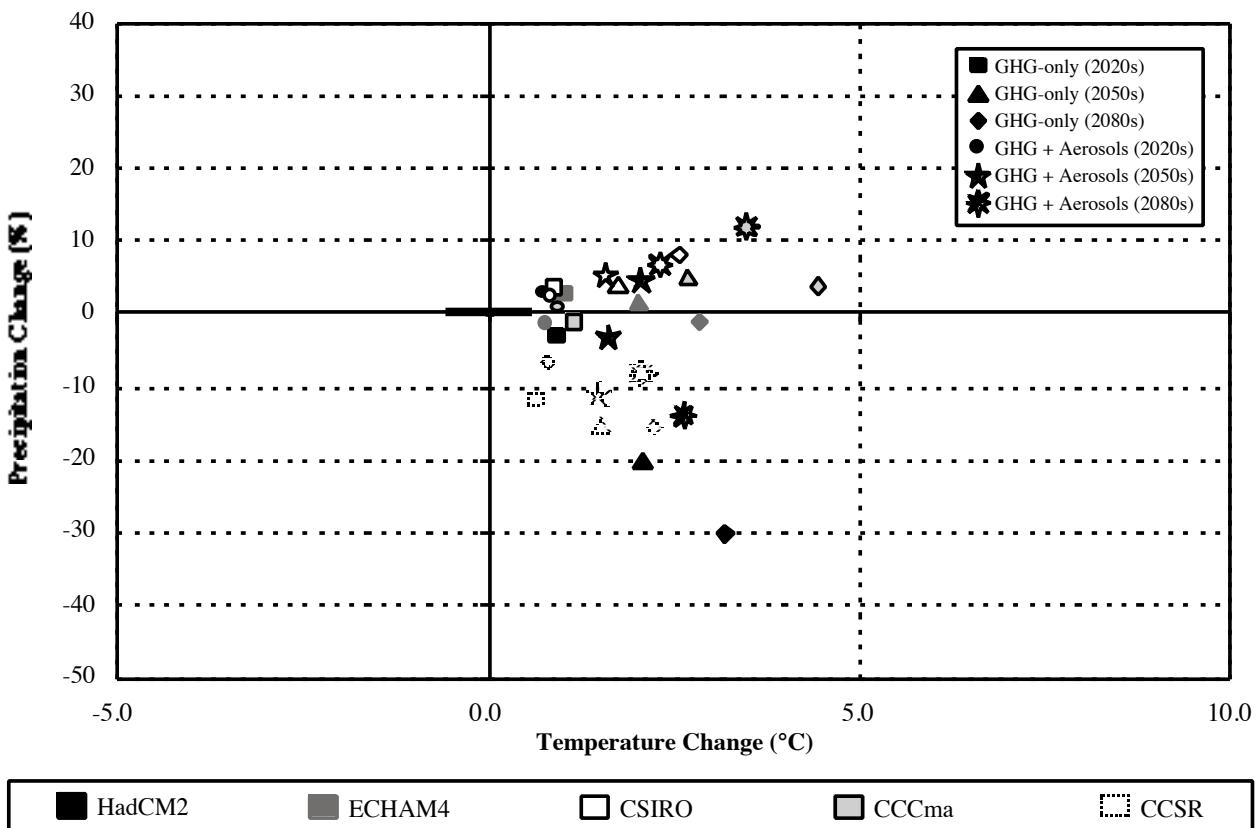

Figure 17-4: Climate change scenarios for Atlantic Ocean and Caribbean Sea islands as simulated by five AOGCMs for the 2020s, 2050s, and 2080s.

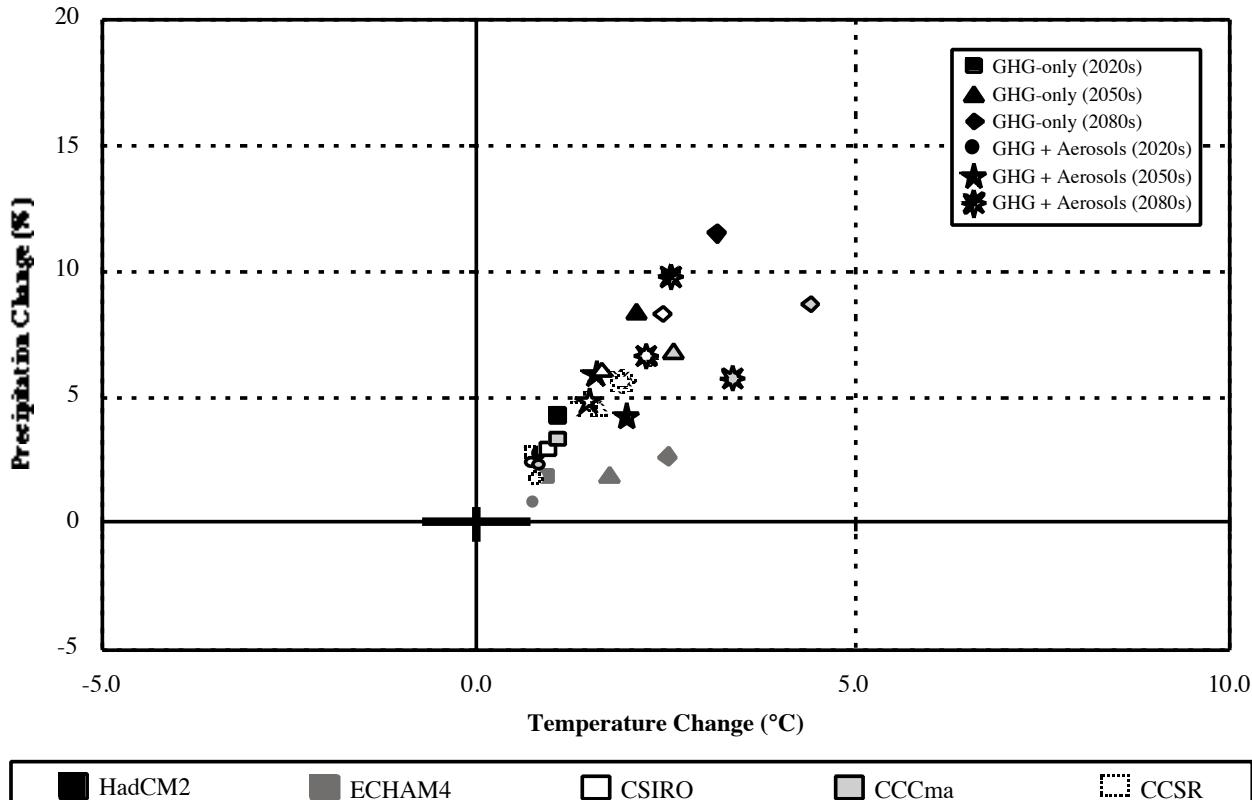

Figure 17-5: Climate change scenarios for Pacific Ocean islands as simulated by five AOGCMs for the 2020s, 2050s, and 2080s.

to project more frequent ENSO-like patterns (Timmerman *et al.*, 1997). In the Pacific, climate variability associated with the ENSO phenomenon manifests itself on a seasonal to decadal time scale. This, in turn, affects factors such as temperature, rainfall, wind speed and direction, sea level, and tropical cyclone climatology that are directly associated with numerous climate-related impacts in the region.

Jones *et al.* (1999) have produced projected ranges of change in average temperature and rainfall for the western Pacific, based on scaled patterns from three independent AOGCMs and a suite of two AOGCMs and a regional circulation model (RCM). These scaled patterns were produced by the regression method described in Hennessy *et al.* (1998) and Giorgi and Mearns (1999), in which the influences of decadal variability are significantly reduced. Jones *et al.* (1999) showed that warming in the Pacific region is projected to increase by less than the global average in most cases. Projections of rainfall are constrained by the models' ability to simulate the SPCZ and ITCZ. All models were able to produce aspects of both features, although the eastern part of the ITCZ was not well captured by any of the models; the higher resolution models were the most realistic. The models also did not produce consistent changes to these features, except for a large increase in rainfall over the central and east-central Pacific. Most of the projected changes across the western Pacific were increases, with significant increases along the equatorial belt from North Polynesia to

further east. Possible decreases were noted in some models for Melanesia and South Polynesia in both halves of the year (April–October and November–March).

Climate variability in the Pacific is a combination of seasonal, multi-annual variability associated with the ENSO phenomenon and decadal variability, the latter influencing the ENSO phenomenon itself. The major concern for impacts in the region is not with the mean climate changes described above but with the extremes that are superimposed on those mean changes. Numerous studies describe the likely intensification of rainfall when the mean change ranges from a slight decrease to an increase. For instance, mean decreases of 3.5% over South Polynesia from the mixed-layer GCM (UKHI) produced little change in intensity, whereas an increase of 7.5% over Micronesia halved the return periods of heavy rainfall events (Jones *et al.*, 1999).

GCMs currently project an increase in SSTs of approximately 1°C by the 2050s and increased rainfall intensity in the central equatorial Pacific, which would impact many small island states in that region. Recent variations over the tropical Pacific Ocean and surrounding land areas are related to the fact that since the mid-1970s, warm episodes (El Niño) have been relatively more frequent or persistent than the opposite phase (La Niña). There are indications that the ENSO phenomenon may be the primary mode of climate variability on the 2- to 5-year

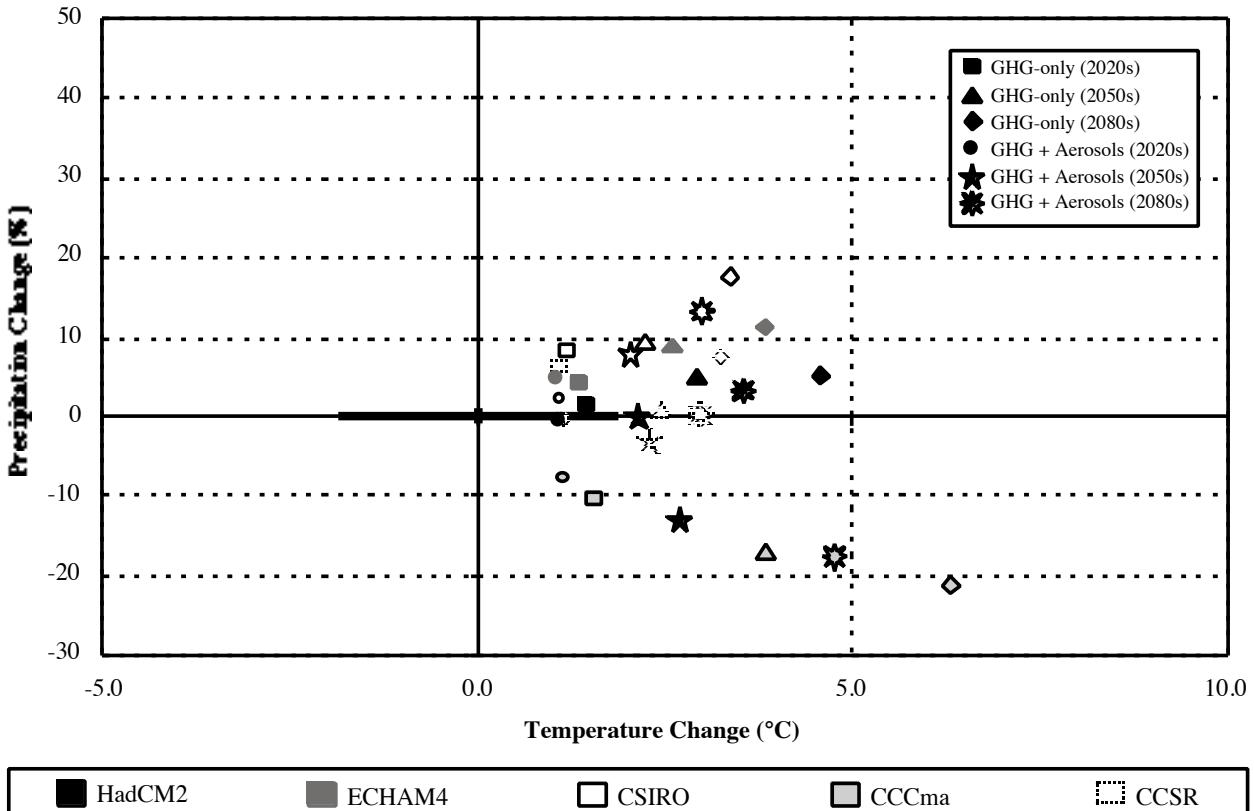

Figure 17-6: Climate change scenarios for Mediterranean Sea islands as simulated by five AOGCMs for the 2020s, 2050s, and 2080s.

time scale and that the current large interannual variability in the rainfall associated with ENSO is likely to dominate over any mean effects attributable to global warming (Jones *et al.*, 1999).

Comparisons between observations and model simulations for the Pacific region further indicate that regional warming would be mostly less than the global average because of the large expanse of ocean. However, there has been a strong indication from several model simulations that the least warming would occur in the southern ocean; the greatest warming could be expected in the far west, central, and eastern equatorial Pacific. In the case of rainfall, increases are likely to be greater where warming over the ocean is greatest, although one GCM output showed no increase in rainfall variability between 1960 and 2100. Model variability is likely to be much lower than historical variability because of the great influence of ENSO, particularly in the Pacific (Jones *et al.*, 1999).

17.1.4.3.5. Tropical cyclones

There is no consensus regarding the conclusions of studies related to the behavior of tropical cyclones in a warmer world. Working Group I concludes that current information is insufficient to assess recent trends, and confidence in understanding and models is inadequate to make firm projections (see TAR WGI). Royer *et al.* (1998), using a downscaled AOGCM coupled with

Gray's method for hurricane forecasting, found no significant change in hurricane frequency or geographical extent for the north Atlantic Ocean, the Pacific Ocean, or the Indian Ocean.

Notwithstanding the foregoing conclusions, individual studies have reported the likelihood of a possible increase of approximately 10–20% in intensity of tropical cyclones under enhanced CO₂ conditions (Holland, 1997; Tonkin *et al.* 1997). This finding is supported by Jones *et al.* (1999), who conducted an analysis of tropical cyclones from a 140-year simulation of an RCM nested in a coupled AOGCM for the Pacific region (see Box 17-1). Although the preliminary analysis implies that there might be a small decrease in cyclone formation, an increase in system intensity is projected. The pattern of cyclones during phases of ENSO was unchanged, suggesting that the relationship between cyclone distribution and ENSO may continue. The study by Jones *et al.* (1999) considers that increases in cyclone intensity (10–20%) estimated by Tonkin *et al.* (1997) and Holland (1997) are highly likely.

17.2. Key Regional Concerns

17.2.1. Development, Sustainability, and Equity Issues

The small island states account for less than 1% of global GHG emissions but are among the most vulnerable of all areas to the

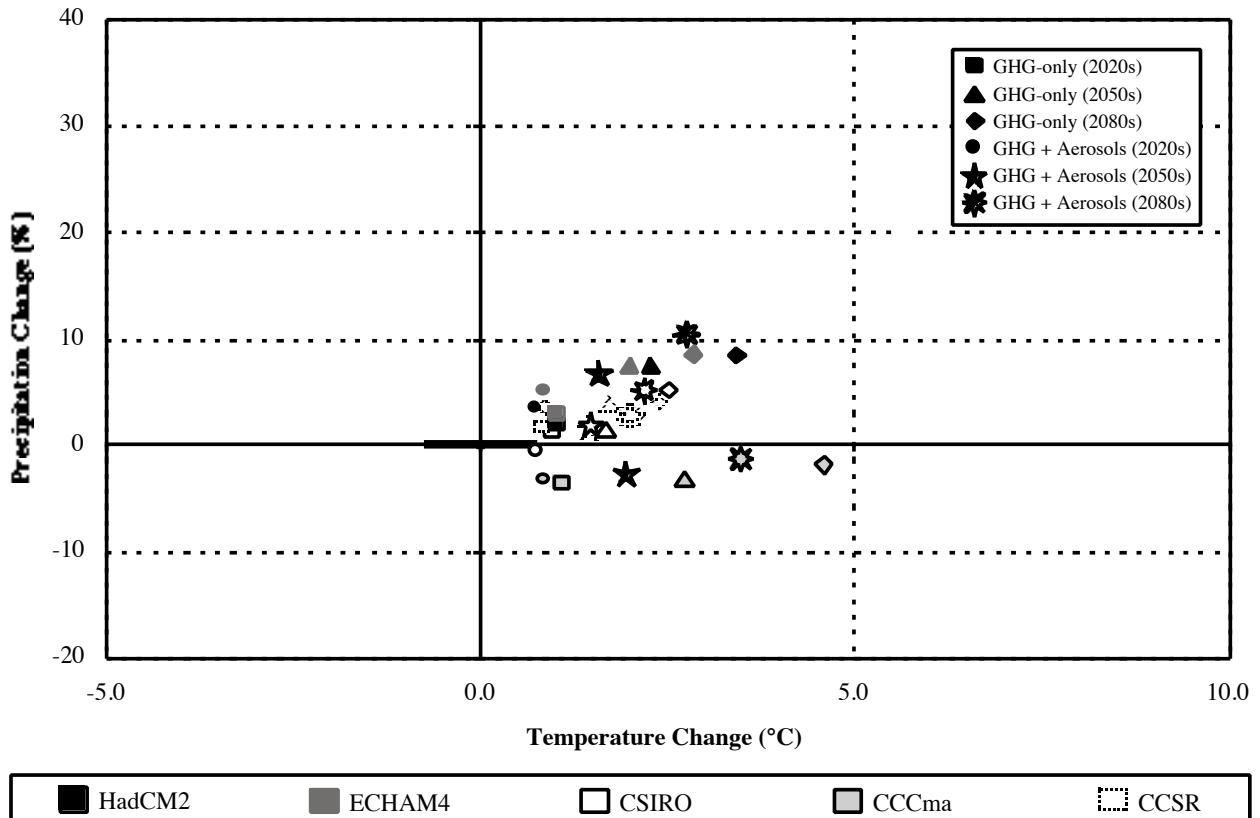

Figure 17-7: Climate change scenarios for Indian Ocean islands as simulated by five AOGCMs for the 2020s, 2050s, and 2080s.

potential adverse effects of climate change and sea-level rise (Jones, 1998; Nurse *et al.*, 1998). It has been established that there already is a global commitment to climate change and sea-level rise as a result of greenhouse forcing arising from historic emissions (Warwick *et al.*, 1996; Jones, 1998; Nicholls *et al.*, 1999; Parry *et al.*, 1999). Moreover, analysis has shown that even with a fully implemented Kyoto Protocol, by 2050 warming would be only about 1/20th of a degree less than what is projected by the IPCC (Parry *et al.*, 1999). Therefore, climate change impacts are inevitable.

Thus, owing to their high vulnerability and low adaptive capacity to climate change, communities in small island states have legitimate concerns about their future on the basis of the past observational record and present climate model projections. Economic development, quality of life, and alleviation of poverty presently constitute the most pressing concerns of many small island states. Thus, with limited resources and low adaptive capacity, these islands face the considerable challenge of charting development paths that are sustainable and controlling GHG emissions, without jeopardizing prospects for economic development and improvements in human welfare (Munasinghe, 2000; Toth, 2000). At the same time, given the inevitability of climate change and sea-level rise, they are forced to find resources to implement strategies to adapt to increasing threats resulting from GHG forcing of the climate system, to which they contribute little (Hay and Sem, 1999; Sachs, 2000). Consequently,

the already meager resources of these island states will be placed under further pressure.

17.2.2 Water-Level Changes

17.2.2.1. Sea-Level Rise

Although the severity of the threat will vary regionally, sea-level rise of the magnitude currently projected (i.e., 5 mm yr⁻¹, with a range of 2–9 mm yr⁻¹), is expected to have disproportionately great effects on the economic and social development of many small island states (Granger, 1997; IPCC, 1998). Coastal land loss already is projected to have widespread adverse consequences. Indeed, it is argued that land loss from sea-level rise, especially on atolls (e.g., those in the Pacific and Indian Oceans) and low limestone islands (e.g., those in the Caribbean), is likely to be of a magnitude that would disrupt virtually all economic and social sectors in these countries (Leatherman, 1997). Recent estimates indicate that with a 1-m rise in sea level, 10.3 km² of land in Tongatapu island, Tonga, would be lost (Mimura and Pelesikoti, 1997). This figure would increase to 37.3 km² (14%) with storm surge superimposed on a 1-m sea-level rise scenario. For some main Yap Island (Federated States of Micronesia) sites, a retreat of 9 to 96 m is projected with a 1-m rise in sea level (Richmond *et al.*, 1997). On Majuro Atoll, Marshall Islands, land loss from one area based on the Bruun rule is estimated

Box 17-1. Climate Change Scenarios for the South Pacific Region

As part of the Pacific Islands Climate Change Assistance Programme, the Commonwealth Scientific and Industrial Research Organisation (CSIRO) has prepared regional climate change scenarios for the four South Pacific regions of Micronesia, Melanesia, and north and south Polynesia (Jones *et al.*, 1999). Six coupled atmosphere-ocean climate simulations were included in the analysis of regional climate change scenarios: CSIRO Mark 2 GCM with and without sulfates, CSIRO DARLAM 125 km, DKRZ ECHAM4/OPYC3 GCM, Hadley Centre HADCM2, and the Canadian CGCM1. The regional scenarios derived can be considered as projections that represent a range of possible future climates.

Generally, the models project a temperature increase that is less than the global mean. Results show the least warming in the South Pacific; regional maximum warming is projected in the far west, central, and eastern equatorial Pacific. Four of the models show an increase in rainfall over the central and eastern Pacific over both half-years (i.e., May to October and November to April). Movements of both the ITCZ and the SPCZ were not consistent between models, but rainfall consistently increased. Increases in daily rainfall intensity are expected in regions where rainfall increases, remains the same, or decreases slightly, as derived from several models and studies. Thus, high confidence is attached to this result.

Historical sea-level rise over the Pacific from tide gauge records adjusted for postglacial rebound is consistent with global estimates of 1–2 mm yr⁻¹. ENSO is the dominant influence on climate variability in the Pacific, and model outputs show that the ENSO phenomenon is likely to continue to 2100. The results also suggest that under climate change, there is likely to be a more El Niño-like mean state over the Pacific. There is no evidence that tropical cyclone numbers may change, but a general increase in *tropical cyclone intensity*, expressed as possible increases in wind speed and central pressure of 10–20% with 2xCO₂ equivalent, now appears likely. Moderate confidence is attached to this result. No significant change in regions of formation was noted in the DARLAM 125 km resolution simulation, although this may alter in response to long-term changes to ENSO. Although there appears to be no major change in regions of origin, tropical cyclones showed a tendency to track further poleward. Low confidence is attached to this result.

to be nearly 65 ha of dry land from a 1-m rise in sea level (Holthus *et al.*, 1992).

One of the most serious considerations for some small islands is whether they will have adequate potential to adapt to sea-level rise within their own national boundaries (Nurse, 1992; IPCC, 1998). In tiny islands where physical space already is very scarce, adaptation measures such as retreat to higher ground and use of building set-backs appear to have little practical utility. In extreme circumstances, sea-level rise and its associated consequences could trigger abandonment and significant “off-island migration,” at great economic and social costs (Leatherman, 1997; Nicholls and Mimura, 1998).

17.2.2.2. Storm Surge and Flood Risks

Changes in the highest sea levels at a given locality will result from the change in mean sea level at that location and changes in storm-surge heights. If mean sea level rises, present extreme levels will be attained more frequently, all else being equal. The increase in maximum heights will be equal to the change in the mean, which implies a significant increase in the area threatened with inundation. This will be especially true in areas with a small surge envelope, which is typical in most small islands. Under such circumstances, even incrementally small elevations in sea level would have severely negative effects on atolls and low islands (Forbes and Solomon, 1997; Nicholls *et al.*, 1999).

Changes in storm-surge heights also would result from alterations in the occurrence of strong winds and low pressures, as would occur during the passage of tropical storms and cyclones. It is already known that tropical cyclones are the major cause of storm surges that impact small islands in the Atlantic, Pacific, and Indian Oceans. Changes in the frequency and intensity of tropical cyclones could result from alterations to SST, large-scale atmospheric circulation, and the characteristics of ENSO (Pittock *et al.*, 1996). Although there is no consensus yet with regard to whether there will be changes in the behavior of these systems (Royer *et al.*, 1998; Jones *et al.*, 1999), the prospect of extreme sea levels (related to storm surges and higher wave amplitudes) is a concern that small island states cannot easily ignore.

Based on global sea-level rise scenarios produced by the Hadley Centre (HADCM2 and HADCM3), Nicholls *et al.* (1999) estimate that global sea levels are expected to rise by about 38 cm between 1990 and the 2080s. They project that many coastal areas are likely to experience annual or more frequent flooding, with the islands of the Caribbean and the Indian and Pacific Oceans facing the largest relative increase in flood risk. Projected out to the 2080s, the number of people facing high flood risk from sea-level rise in these regions would be 200 times higher than in the case of no climate change (Nicholls *et al.*, 1999). Recent studies for Cuba (based on HADCM2 and IS92a scenarios) also project that 98 coastal settlements with a combined population exceeding 50,000 persons would be inundated by a 1-m rise in sea level (Perez *et al.*, 1999).

17.2.3. Beach and Coastal Changes

The morphology, characteristics, and classification of beaches are influenced by a variety of factors, including island origin, geologic structure and composition (e.g., volcanic, coral atoll, raised atoll, reef island, or emergent limestone), age, elevation, and size (Gillie, 1997; Solomon and Forbes, 1999). Thus, given their varied origins, a wide range of beach types and characteristics is represented in the small island states of the Caribbean and Mediterranean Seas and the Atlantic, Pacific, and Indian Oceans.

Coastal erosion—partly the result of anthropogenic factors such as sand mining (Gillie, 1997; Ragoonaden, 1997)—already is a problem on many islands and evidently may be exacerbated by sea-level rise (Mimura and Nunn, 1998). On many atolls (as in the Pacific) and low reef islands (as in the Caribbean), carbonate beaches are maintained by sand produced from productive reefs whose degradation already is causing accelerated beach erosion. Similarly, in the Mediterranean Sea, where the islands are periodically susceptible to flooding and scour from storm surges, an increase in storminess would further stress natural and human systems located at the coast (Nicholls and Hoozemans, 1996). The impact of the equivalent of a 1-m rise in sea level for a cumulative few hours on the coast was observed in Singapore on 7–14 February 1974. The event indicates clearly the vulnerability of the island's low-lying area to flooding and coastal erosion if sea-level rise takes place (Wong, 1992).

Beach erosion rates of approximately 2–4 m yr⁻¹, on average, have been reported for several beaches in Trinidad and Tobago, where mean relative sea-level rise of 8–10 mm yr⁻¹ has been recorded by two gauges during the past 15 years. Although beach erosion results from multiple forces, sea-level rise is considered a contributory factor (Singh, 1997a,b). Ragoonaden (1997) measured shoreline retreat of 2.7 m yr⁻¹ at Flic-en-Flac (Mauritius), and Nunn and Mimura (1997) report that the coasts of some islands in Fiji have retreated by more than 30 m in the past 70 years. In the specific case of Viti Levu and Taveuni, Fiji, beach erosion has been attributed to a combination of human-induced causes (including loss of the mangrove fringe and other natural protection) and elevated sea level, which has been rising at a rate of approximately 1–1.5 mm yr⁻¹ since 1960 (Forbes and Solomon, 1997; Nunn and Mimura, 1997).

17.2.3.1. Response, Adaptation, and Management

It is now widely accepted that strategies for adaptation to sea-level rise tend to fall into three main categories: retreat, accommodate, and protect (Bijlsma, 1996; IPCC, 1996, 1998). Hard engineering—involved the construction of groynes, seawalls, breakwaters, and bulkheads—has long been the traditional response to coastal erosion and flooding in many small island states. Unfortunately, this approach has not always been efficiently implemented and has even helped to increase coastal vulnerability in some cases (Mimura and Nunn, 1998; Solomon and Forbes, 1999). In these specific circumstances,

the term “maladaptation” (which refers to a response that does not succeed in reducing vulnerability but increases it instead; see Chapter 18) may be applied. Realistically, however, for some islands the application of hard solutions may be the only practical option along well-developed coasts, where vital infrastructure is at immediate risk.

There are other potential options available to small island states, including enhancement and preservation of natural protection (e.g., replanting of mangroves and protection of coral reefs), use of softer options such as artificial nourishment, and raising the height of the ground of coastal villages (Nunn and Mimura, 1997). Raising the height of the ground requires additional aggregate such as sand and stone and a lot of pumping, in which many small islands are seriously deficient. Removal of materials from “unimportant” islands to build up important islands via sand transfer by pipes and barges has been suggested by the IPCC (1990). Some island states may be faced with few practical options. Thus, it might be necessary for them to lose some islands so that the entire nation is not completely inundated (Nicholls and Mimura, 1998).

Similarly, beach nourishment may not be a practical or economical option for many island nations because sand often is a scarce resource (Leatherman, 1997; IPCC, 1998). Moreover, beach nourishment requires maintenance in the form of periodic sand replenishment, sometimes every 5–10 years or less (Amadore *et al.*, 1996). Such a requirement could prove to be unsustainable in small economies. In contrast, on some islands such as Singapore, where the technology and resources are more readily available, beach fill projects (used in combination with offshore breakwaters to form artificial headlands) is a feasible option (Wong, 1985). As a general strategy to respond to sea-level rise, it is likely that Singapore will focus on three main types of responses: coastal protection for developed or heavily populated areas and reclaimed land, anti-salt-intrusion measures for coastal reservoirs, and flood prevention measures (such as tidal gates) for major canals (Wong 1992).

In some islands, such as those in the Caribbean, more emphasis is being placed on the application of “precautionary” approaches, such as enforcement of building set-backs, land-use regulations, building codes, and insurance coverage. In addition, application of traditional, appropriate responses (e.g., building on stilts and use of expendable, readily available indigenous building materials), which have proven to be effective responses in many islands in the past, ought to be more widely considered (Forbes and Solomon, 1997; Mimura and Nunn, 1998).

Given the vulnerability of many small island states to various aspects of global change, integrated coastal management (ICM) is rapidly becoming an attractive paradigm for planning adaptation (Bijlsma, 1996; Cicin-Sain, 1998; Nicholls and Mimura, 1998). Furthermore, ICM can be regarded as both an anticipatory and a predictive tool, with the capability to plan for and respond to medium- and long-term concerns such as sea-level rise as well as short-term, present-day needs (Nurse, 1999; Solomon and Forbes, 1999). In addition, ICM can provide

an effective framework for resolving potential conflict among competing stakeholder interests, in a manner that is equitable to all groups. In this context, it is noteworthy that all of the small island states that recently participated in the U.S. Country Studies Program (i.e., Federated States of Micronesia, Samoa, Fiji, Kiribati, Marshall Islands, Sri Lanka, and Mauritius) concluded that ICM was the most appropriate adaptation strategy and should form an essential part of their climate change national action plans (Huang, 1997).

Enhancing the resilience of coastal systems has been suggested (e.g., Bijlsma, 1996) as an appropriate proactive adaptive response to reduce vulnerability. Klein and Nicholls (1998) agree that this could be a more cost-effective way to prepare for uncertain changes such as sea-level rise, rather than relying entirely on building traditional, more costly coastal defenses. Helmer *et al.* (1996) strongly support the notion of enhancement of coastal resilience whereby dynamic systems (e.g., dunes, lagoons, and estuaries) should be allowed to utilize their natural capacity to grow in response to rising sea levels. This philosophy could be applied through pilot studies in small islands. One of the ways in which a dynamic and resilient coast can be created is by managed retreat, based on an enforced building set-back that allows the coastline to recede to a new line of defense, thus restoring natural coastal processes and systems. An orderly plan to retreat could be a feasible option on larger islands that cannot commit the resources necessary to prevent coastal land loss in the face of rising sea levels (Leatherman, 1997).

One recommended approach to planning adaptation to sea-level rise and coastal change involves an estimation of the costs of protecting or abandoning developed properties. For developed coasts, West and Dowlatabadi (1999) propose that the real economic evaluation of sea-level rise should be regarded as the difference in utility (not just damages) with and without a sea-level rise scenario, in which it is assumed that physical conditions (e.g., erosion and storms) and human behavior remain constant. This is an improvement on past approaches, which provided the estimated costs of sea-level rise on the basis of market value of inundated land and property or the cost of structural protection.

17.2.4. Coral Reefs, Mangroves, and Seagrasses

17.2.4.1. Coral Reefs

Coral reefs represent one of the most important natural resources of many tropical islands. They are a source of food, beach sand, and building materials and function as natural breakwaters along the coasts of many tropical islands. They also provide habitats for many marine animals and reef fish and generate significant revenues for many small island economies through avenues such as tourism (e.g., snorkeling and scuba diving). On many islands, coral reefs are facing severe threats from climate- and non-climate-related stressors. The total areal extent of living coral reefs has been estimated at about 255,000–1,500,000 km² (Spalding and Grenfell, 1997),

of which 58% are considered at risk from human activities, according to a global assessment (Bryant *et al.*, 1997).

Owing to their narrow temperature tolerances, some species of corals currently live at or near their thermal limits (Goreau, 1992; IPCC, 1998). SSTprojections (based on three variants of the Max Planck Institute ECHAM and CSIRO GCMs) suggest that the thermal tolerance of reef-building corals will be exceeded within the next few decades. Moreover, the incidence of bleaching will rise rapidly, with the rate of increase highest in the Caribbean and slowest in the central Pacific region (Hoegh-Guldberg, 1999).

There is now substantial evidence that indicates that “episodic” warming of the ocean surface, as occurs in El Niño years, leads to significant coral bleaching (Brown and Ogden, 1993; Glynn, 1993; Goreau and Hayes, 1994; Wilkinson and Buddemeier, 1994; Brown, 1997a,b; CARICOMP, 1997; Goreau *et al.*, 1997). The major coral bleaching episodes in the past 20 years were found to be associated with periods when ocean temperature were about 1°C higher than the summer maximum. It also has been suggested that bleaching events could occur annually in most tropical oceans in the next 30–50 years (Hoegh-Guldberg, 1999). Bleaching was particularly severe and widespread during the period of the most recent El Niño episode of 1997–1998, which was considered to be the most intense such event on record. On some islands, more than 90% of all live reefs have been affected (Goreau and Hayes, 1994), with branching species generally most severely impacted (Wilkinson 1998, 1999). An assessment of the literature on coral bleaching is provided in Chapter 6.

The impact of increasing CO₂ concentrations in the oceans on coral reefs is now the focus of an emerging though as yet unresolved debate. Since publication of the SAR and the *Special Report on Regional Impacts of Climate Change* (IPCC, 1998), it has been suggested that the ability of reef plants and animals to make the limestone skeletons that build the reefs is being reduced by rising atmospheric CO₂ concentrations. Indeed, some authors suggest that based on projected CO₂ concentration in the atmosphere, the calcification rate of corals would decline by approximately 14–30% by 2050 (Gattuso *et al.*, 1999; Kleypas *et al.*, 1999). Again, see Chapter 6 for a full evaluation of the main issues in this debate.

Chapter 6 points out that earlier IPCC assessments have concluded that the threat of sea-level rise to reefs (as opposed to reef islands) is negligible. This conclusion was based on projected rates of global sea-level rise from Warrick *et al.* (1996) on the order of 2–9 mm yr⁻¹ over the next 100 years. It has been suggested that healthy reef flats will be able to keep pace with projected sea-level rise, given an approximate upper limit of vertical reef growth during the Holocene of 10 mm yr⁻¹ (Schlager, 1999). However, the prognosis is far less positive in many small island states (e.g., in the Caribbean Sea and the Indian Ocean), where reef structures have been weakened by a variety of anthropogenic stresses. This concern also is applicable to many island countries, where reefs in close proximity to

major settlements have been severely stressed. The ability of reefs to keep pace with sea-level rise also will be adversely affected by more frequent coral bleaching episodes and by reduced calcification rates resulting from higher CO₂ concentrations.

17.2.4.2. Mangroves

Mangroves provide important functions as protection against storms, tides, cyclones, and storm surges and are used as “filters” against the introduction of pests and exotic insects (Menendez and Priego, 1994; Suman, 1994). Mangroves have important ecological and socioeconomic functions as well, particularly in relation to animal and plant productivity, as nutrient sinks, for substrate stabilization, and as a source of wood products. These functions sometimes may be in conflict and differ in importance between riverine, basin, and coastal fringe mangroves; the latter are important primarily for shoreline protection.

Many mangrove forests are under stress from excessive exploitation, reducing resilience in the face of sea-level rise. The importance of sediment flux in determining mangrove response to rising sea levels is well established in the literature. Ellison and Stoddart (1991), Ellison (1993), and Parkinson and Delaune (1994) have suggested that mangrove accretion in low- and high-island settings with low sediment supply may not be able to keep up with future rates of sea-level rise, but Snedaker and Meeder (1994) have suggested that low-island mangroves may be able to accommodate much higher rates. These observations may not necessarily represent conflicting views because the resilience of mangroves to sea-level rise also is conditioned by the composition and status of the stands and other factors such as tidal range and sediment supply (Woodroffe, 1995; Ewel *et al.*, 1998; Farnsworth, 1998). In some protected coastal settings, inundation of low-lying coastal land actually may promote progressive expansion of mangrove forest with rising sea level (Richmond *et al.*, 1997), provided vertical accretion keeps pace.

Notwithstanding the foregoing, studies have shown that mangrove forests in some small islands will be lost as a result of elevated sea levels. For example, it is projected that with a 1-m sea-level rise in Cuba, more than 300 ha of mangroves, representing approximately 3% of that country’s forests, would be at risk (Perez *et al.*, 1999). Under similar conditions, Alleng (1998) projects a complete collapse of the Port Royal mangrove wetland in Jamaica, which has shown little capacity to migrate in the past 300 years; Suman (1994) envisages that accelerated sea-level rise would adversely affect mangroves in Puerto Rico, where 62% already has been eliminated by direct human activity.

17.2.4.3. Seagrasses

Seagrass communities provide useful habitat for many marine fish, particularly in the shallow, intertidal environments of many islands. It is postulated that an increase in SST will adversely affect seagrass communities because these ecosystems

already are sensitive to land-based pollution and runoff in coastal environments (Edwards, 1995). It is argued further that the distribution of seagrasses will shift as a result of temperature stress, which in turn can cause changes in sexual reproduction patterns (Short and Neckles, 1999). In addition, an increase in temperature will alter seagrasses’ growth rates and other physiological functions. Sea-level rise would mean increasing water depth and reduction of the amount of light reaching the seagrass beds, which would reduce plant productivity.

The effect of increased CO₂ in the water column will vary according to species and environmental circumstances but will likely alter the competition between species, as well as between seagrasses and algal populations (Beer and Koch, 1996). Laboratory experiments suggest that some seagrasses, such as *Zostera marina*, are able to respond positively to increased CO₂ levels by increasing their rate of photosynthesis (Zimmerman *et al.*, 1997), although earlier research on field-collected samples of *Thalassia testudinum* suggests that maximum photosynthesis is lower with elevated CO₂ (Durako, 1993).

As with other submerged aquatic plants, seagrasses are sensitive to ultraviolet-B (UV-B) radiation because such radiation can penetrate depths of up to 10 m (Larkum and Wood, 1993). Laboratory experiments have demonstrated that the response can vary from strong photosynthetic tolerance, in the case of *Halophila wrightii*; to moderate tolerance, as with *Syringodium filiforme*; to little photosynthetic tolerance, as exhibited by *Halophila engelmanni* (Hader, 1993; Short and Neckles, 1999).

17.2.5. Biodiversity of Islands

Small islands are highly variable with respect to their biological diversity. Some states, such as the low reef islands, have low biodiversity and low endemism. Coral reefs exhibit the highest known diversity among marine ecosystems, with 91,000 described species of reef taxa. Table 17-4 gives the diversity of mammals, birds, plants, and endemism for some select small island states. In general, small islands in absolute figures tend to have high terrestrial diversity and endemism. In Cuba, for instance, 50% of the flora and 41% of the fauna are endemic (Vales *et al.*, 1998). In the Canary Islands, 45% of all bird species are endemic. In the Hawaiian islands—the most isolated of all floristic regions—more than 90% of plant species are endemic (Biagini, 1999). When relative biodiversity and endemism are calculated in relation to area, the figures for many small island states tend to be higher than those for most other regions of the world.

Although there generally is high diversity associated with the ecosystems (marine and terrestrial) of islands, their long-term survival is threatened by anthropogenic stresses including pollution, overexploitation, and generally poor management. As in other regions, it is expected that climate change will affect the biodiversity of small islands directly and indirectly. Rising atmospheric CO₂ concentrations are projected to increase the productivity of some communities and alter competition

Table 17-4: Biodiversity status for selected small island states, 1990 (extracted from IPCC, 1998).

Country	Known Mammal Species	Known Endemic Mammal Species	Known Bird Species	Known Endemic Bird Species	Known Plant Species	Known Endemic Plant Species
Cuba	31	12	342	22	6,004	3,229
Dominican Republic	20	—	254	0	5,000	1,800
Fiji	4	1	109	26	1,307	760
Haiti	3	0	220	0	4,685	1,623
Jamaica	24	3	262	25	2,746	923
Mauritius	4	2	81	9	700	325
Palau	214	57	708	80	10,000	—
Solomon Islands	53	19	223	44	2,780	30
Trinidad and Tobago	100	1	433	1	1,982	236

among others by eliminating some species and introducing new species to take their place (McIver, 1998). In marine ecosystems such as coral reefs, incremental increases in atmospheric CO₂ would be expected to threaten the diversity of these systems by the process described in Section 17.2.4.1 (Hatcher, 1997).

The impacts of climate change and sea-level rise on biota in island states are much greater than the impacts on continental areas. For example, sea-level rise could impact the habitats of the endangered Tuamotu sandpiper (*Prosobonia cancellata*) and bristle-thighed curlew (*Numenius tahitiensis*), as well as the seabird colony of 18 species on Laysan Island (Hawaii). Other potentially vulnerable areas (not inclusive) for breeding seabirds include the Kerguelen and Crozet Islands (seabirds), the Galapagos Islands (Galapagos penguin, *Spheniscus mendiculus*), and the nesting habitat for the Bermuda petrel (*Pterodroma cahow*) (Sattersfield *et al.*, 1998). Based on outputs from HADCM2 and scenarios IS92a and Kyoto 1, Suarez *et al.* (1999) also have found that in the eastern region of Cuba, certain endemic species of flora would face extinction.

Inundation and flooding of low-lying forested islets with species such as the Manus fantail (*Rhipidura semirubra*) also might be lost. The majority of threatened bird species on islands are found in forested habitats (Sattersfield *et al.*, 1998). Impacts of climate change on these species likely would be from physiological stress and changes and loss in habitat, especially from fires and cyclones. For example, 30% of the forested area on the Santa Cruz islands was lost in one cyclone in 1993. Some vulnerable species and areas include the endangered New Caledonian lorikeet (*Charmosyna diadema*) and critically endangered New Caledonian rail (*Gallirallus lafresnayanus*) on New Caledonia, the Samoan white-eye (*Zosterops samoensis*) and critically endangered Samoan moorhen (*Gallinula pacifica*) on Savai'i (Samoa), and the Santo Mountain starling (*Aplonis santovestris*) on Espiritu Santo (Sattersfield *et al.*, 1998). In Samoa, most species of flowering plants are pollinated by a few species of animals; nearly 100% of seed dispersal in the dry season is mediated by flying foxes (*Pteropus spp.*) (Cox *et al.*, 1991). Likewise, flying foxes are the key pollinators and

seed dispersers on many islands in the South Pacific. If their habitat is threatened by climate change, the result would be the loss of many dependent plant species.

Generally on islands, one of every three known threatened plants is endemic. Among birds, approximately 23% of the species found on islands are threatened, compared with only 11% of the global bird population (McNeely *et al.*, 1993). Establishment of terrestrial, marine, or coastal reserves such as the Morne Trois Pitons Park and Forestry Reserve (Dominica, 1986), Bonaire Marine Park (Netherlands Antilles, 1979), Tobago Cays Marine Park (St. Vincent and the Grenadines), Soufriere Marine Management Area (St. Lucia, 1997), and other similar management units (“biosphere reserves”) established elsewhere is a useful management option. It has been demonstrated that the creation of such reserves helps to preserve endangered habitats and ecosystems of small islands and will contribute to maintenance of biological diversity, while increasing the resilience of these systems to cope with climate change.

17.2.6. Water Resources

Availability of water resources is a limiting factor for economic and social development in small island states. Many such countries rely almost entirely on a single source of supply, such as groundwater (Barbados, Antigua, The Bahamas, Kiribati), rainwater (Tuvalu, northern atolls of Cook Islands, and the Maldives), surface reservoirs and imports (Singapore), or rivers and other surface flows (Seychelles, Dominica).

Water supply is most vulnerable in the atoll states of the Pacific, where water supply is sensitive to precipitation patterns and changes in storm tracks (Salinger *et al.*, 1995). Captured rainwater is stored in cisterns; the only backup reserve for these islands is a thin wedge of fresh groundwater that sits on top of the saltwater lens. A reduction in precipitation coupled with sea-level rise would not only cause a diminution of the volume of potable water but would reduce the size of the narrow freshwater lens (Amadore *et al.*, 1996).

The situation is equally critical in the low limestone islands of the eastern Caribbean, where seasonality of rainfall (a marked dry and wet season regime) is pronounced. On islands such as Anguilla, Antigua and Barbuda, Grenada, and Barbados, more than 65% of total annual rainfall may be recorded in the wet season, which spans the 6-month period of June to December. Moreover, most of the rainfall is strongly associated with the genesis and passage of easterly waves, tropical depressions, and storms (Gray, 1993; Nurse *et al.*, 1998). Thus, changes in the occurrence of these heavy rainfall events will certainly impact the water supply of many Caribbean islands. The situation is further exacerbated in Barbados, where recent research has shown that groundwater recharge is restricted to the three wettest months of the year, and only 15–30 % of annual rainfall reaches the aquifer (Jones *et al.*, 1998).

Reduced availability of adequate water supply in a changing climate also poses a potential threat to the Mediterranean islands of Cyprus and Malta. Because these two countries already experience water shortages (Nicholls and Hoozemans, 1996), and given a projected decrease in mean summer precipitation over the Mediterranean Sea region (IPCC, 1998), the water resources of these states could be placed under considerable pressure in the future (Tables 17-2 and 17-3). The threat is equally strong in some parts of the eastern Caribbean. Within the past few decades in Dominica, for instance, an apparent tendency toward more extended periods of drought is well correlated with reduced flows in the Castle Comfort, Roseau, Layou, and Geneva Rivers (Government of Commonwealth of Dominica, 2000). Because rivers are the main source of potable and irrigation water on the island and are also harnessed for power generation, declining flows have become a matter of serious national concern.

Climate change can present additional water management and related challenges. Such challenges may arise from a variety of sources, including increased flood risks and impeded drainage and the presence of elevated water tables—which may pose special engineering problems. It is projected that on Andros island, the Bahamas, where the water table presently is only 30 cm below the surface, high evaporation rates and increasing brackishness will eventuate with continued sea-level rise (Martin and Bruce, 1999). Similar projections also have been made for Cuba, where underground water supplies already are stressed (Planos and Barros, 1999). For many small island states, the prospect of salinity intrusion into the freshwater lens would be a matter of great concern. In many of these islands where salinization from overpumping of aquifers is already occurring (e.g., The Bahamas and Barbados), sea-level rise would compound the risk. In some cases, higher salinity would be experienced not only in coastal aquifers but also inland at freshwater pumping plants as the salty groundwater rises. Singh (1997a,b) has reported a recent increase in salinity levels for several coastal aquifers in Trinidad and Tobago in the southern Caribbean, attributable mainly to rapid drawdown exacerbated by sea-level rise.

There now is substantial evidence to support the view that precipitation variability in various parts of the world is linked

to ENSO events. During the 1982–1983 ENSO event, rainfall in many parts of the western Pacific was a mere 10–30% of the long-term mean average (Falkland, 1992). More specifically, it is well established that ENSO has a strong influence on rainfall patterns in the tropics and low-latitude regions of the Southern Hemisphere (Shea, 1994; Whetton *et al.*, 1996). In the Caribbean islands, droughts appear to be more frequent in El Niño years, whereas conditions tend to be wetter in La Niña years. The devastating drought in the region in 1998 coincided with what is believed to be the strongest El Niño signal on record. ENSO-related droughts also are known to occur in the low-lying atolls of the tropical Pacific. Thus, in countries such as the Federated States of Micronesia and the Marshall Islands where rainwater is the main source of supply, more frequent and intense ENSO events will impose further stress on already meager water resources (Meehl and Washington, 1996); other islands in the central and eastern tropical Pacific will experience heavy rains (Jones *et al.*, 1999).

Realistically, the options available to many small islands for reducing the adverse effects of climate change on water availability are limited. This implies that greater urgency and emphasis will have to be placed on improving water resource management efforts, including inventorying of resources and rational and equitable allocation. Implementation of more efficient rainwater harvesting methods, efficient leak detection and repair, use of water-saving devices, and aggressive recycling efforts are strategies worth considering. Desalination also is becoming an increasingly attractive option, especially where the necessary technical and financial capacity is available and in cases in which more traditional strategies are inadequate or not feasible (e.g., in Singapore, Malta, Cyprus, Barbados, Antigua and Barbuda, St. Kitts and Nevis, and Grenada). As part of their long-term adaptation strategy, these water-scarce islands might wish to include “no-regrets” measures, which will promote sustainability with or without climate change. Some countries may even wish to consider application of market-based systems to allocate water supplies, which could result in less wasteful practices under current conditions and thus enable water users to more efficiently adapt to climate change (Amadore *et al.*, 1996).

17.2.7 Tourism

Tourism is a major economic sector in many small island states. Table 17-5, which expresses tourist arrivals in terms of the populations of small island states for which data were available, shows that in most small island states, the numbers of visitors substantially exceed the number of inhabitants. Table 17-5 also expresses tourism receipts in terms of gross national product (GNP) and in terms of foreign exchange inflows from exports of goods and services. Again, the ratios tend to be relatively high in most small island states; the Maldives, Antigua and Barbuda, and the Bahamas exhibit the highest ratios. In many countries, tourism also makes a significant contribution to employment. For example, the

Table 17-5: Tourist inflows and receipts, various years, for select small island states (Waters, 1998).

Country	Number of Tourists (000s) ^a	Tourists as % of Population ^a	Tourist Receipts ^b as % of GNP	Tourist Receipts ^b as % of Exports
Antigua and Barbuda	232	364.2	63.4	73.5
Bahamas	1618	586.4	42.0	75.6
Barbados	472	182.4	39.2	56.2
Cape Verde	45	11.4	11.5	37.3
Comoros	26	4.9	10.6	47.8
Cuba	1153	10.5	8.8	n/a
Cyprus	2088	280.7	24.0	49.1
Dominica	65	97.6	15.9	32.5
Dominican Republic	2211	28.1	13.6	30.2
Fiji	359	45.3	19.2	29.1
Grenada	111	116.2	27.0	60.6
Haiti	149	2.2	3.9	50.5
Jamaica	1192	45.6	31.6	39.8
Maldives	366	130.7	95.0	68.4
Malta	1111	294.7	22.9	28.7
Mauritius	536	46.4	15.7	26.8
Papua New Guinea	66	1.5	2.1	3.0
St. Kitts and Nevis	88	210.5	30.6	63.6
St. Lucia	248	164.7	41.1	66.6
St. Vincent	65	54.6	23.8	45.9
Samoa	68	31.1	19.6	48.8
Seychelles	130	166.7	34.6	52.2
Singapore	7198	209.2	6.2	4.1
Solomon Islands	16	3.7	2.8	4.2
Trinidad and Tobago	324	28.7	4.2	8.3
Vanuatu	49	27.1	19.3	40.9

^aData on tourist inflows and ratio to population pertain to 1997.

^bData for tourist receipts pertain to 1997 for the Bahamas, Cape Verde, Jamaica, the Maldives, Malta, Mauritius, Samoa, Seychelles, Singapore, and Solomon Islands; to 1996 for Antigua and Barbuda, Cuba, Dominica, Dominican Republic, Fiji, Grenada, Haiti, Papua New Guinea, St. Lucia, and St. Vincent; to 1995 for Barbados, Comoros, Cyprus, Trinidad and Tobago, and Vanuatu; and to 1994 for St. Kitts and Nevis.

industry provides jobs for 70% of the labor force in the Bahamas, 40% in Malta, and 20% in Seychelles (Waters, 1998).

It is widely acknowledged that the effects of climate change on tourism will be both direct and indirect. For instance, sea-level rise would disrupt the sector through loss of beaches, inundation, degradation of coastal ecosystems, saline intrusion, and damage to critical infrastructure (Nicholls and Hoozemans, 1996; Teh, 1997; Perez *et al.*, 1999). Because many small islands are so heavily dependent on the tourism sector for their economic survival, adverse impacts on the industry, from climate change or other causes, would be of great concern in these countries. In many small islands, the industry also would be sensitive to other climate-related impacts, such as loss of attractiveness of coral reefs as a result of bleaching.

A high proportion of tourism in small island states is motivated by the desire of visitors from developed countries of the north (their largest market) to escape cold winters. Small island states are becoming increasingly concerned that projected

milder winters in these markets could reduce the appeal of these islands as tourist destinations (Martin and Bruce, 1999). It is projected that tourism could be further harmed by increased airline fares if GHG mitigation measures (e.g., levies and emission charges) were to result in higher costs to airlines servicing routes between the main markets and small island states (Wall, 1996).

To ensure the sustainability of the tourist industry in Cyprus, it has been recommended that a strategy of protection of infrastructure combined with planned retreat would be effective and appropriate to local circumstances. The overall goal would be to maintain the limited beach area to sustain the vital tourist industry, specifically by erecting hard structures, enforcing building set-backs, and use of artificial nourishment, although the latter measure may require external sources of sand (Nicholls and Hoozemans, 1996). Although not all these strategies may be applicable to the atoll states, many other island nations—such as Barbados, Jamaica, Grenada, St. Lucia, and Singapore—already have begun to implement similar approaches as part of the ICM process.

17.2.8. Food Security

17.2.8.1. Crop Agriculture

Subsistence agricultural production is vital to the economies, nutritional status, and social well-being of small islands—particularly the small, low-lying, atoll states where food security is a major concern. The main subsistence crops include taro, sweet potato, yam, breadfruit, bananas, coconut, and a variety of vegetables. Production of cash crops such as sugarcane, copra, coffee, cocoa, rubber, and tea (grown at higher elevations on high islands) also is important because export of these products earns valuable foreign exchange. Climate change could precipitate heat stress, changes in soil moisture and temperature, evapotranspiration, and rainfall that might affect the growth of some subsistence root crops and vegetables. The consequences of such changes for agriculture are likely to be more severe in areas that already are under stress—for example, water-scarce islands. Crop agriculture also can be affected by tropical cyclones and other extreme events, such as floods and droughts. To the extent that many small islands are susceptible to these phenomena, it is highly likely that crop production in these states would be impacted by alterations in the patterns of these events as a consequence of climate change.

On low islands and atolls in the Pacific, practically all crop agriculture is concentrated at or near the coast. Thus, changes in the height of the water table and salinization as a result of sea-level rise would be stressful for most varieties of taro and other crops, which have low tolerance for salt. It has been suggested that in general, C₃ crops, which include many tropical crops, will benefit more from the effect of CO₂ fertilization than C₄ plants. However, recent findings indicate that the impact on sugarcane and maize yields would be adverse (Jones *et al.*, 1999).

Singh and El Maayar (1998), using GCM (CCC 11) outputs and high, medium, and low CO₂ emission scenarios coupled with a crop model (FAO) to simulate crop yields, found that sugarcane yields may decrease by 20–40% under a 2xCO₂ climate change scenario in Trinidad and Tobago in the southern Caribbean. The decrease in yields is attributed to increased moisture stress caused by the warmer climate. These reductions in sugarcane yields deriving from climate change are similar to those found for maize—another C₄ crop—in nearby Venezuela (Maytin *et al.*, 1995). These results are supported by similar findings in Mauritius, which are derived from the Agricultural Production Systems Simulator Model (APSIM-Sugarcane) developed by the Agricultural Production Systems Research Unit, Australia. The study projects a decline in sucrose yield by more than 50% with a doubling of CO₂ (Cheero-Nayamuth and Nayamuth, 1999).

17.2.8.2. Fisheries

Although fishing is largely artisanal or small-scale commercial, it is an important activity on most small islands and makes a significant contribution to the protein intake of island inhabitants

(Blommestein *et al.*, 1996; Mahon, 1996). The impacts of climate change on fisheries are complex and in some cases are indirect. As with other renewable resources, an assessment of climate change impacts on fisheries is complicated by the presence of anthropogenic and other non-climate-related stresses, such as habitat loss and overexploitation (Challenger, 1997).

Many breeding grounds for commercially important fish and shellfish are located in shallow waters near coasts. These areas include mangroves, coral reefs, seagrass beds, and salt ponds—all of which are likely to be affected by climate change. Generally, fisheries in the small island states are not expected to be adversely affected by sea-level rise *per se*. Higher sea level would be a critical factor for fisheries only if the rate of rise were far more rapid than the current succession of coastal ecosystems (e.g., mangroves, seagrasses, corals) on which some fish species depend (Everett, 1996). In tropical islands, these ecosystems function as nurseries and forage sites for a variety of important commercial and subsistence species. In this context, the unfavorable effects of higher CO₂ concentrations on coral reef development, coupled with widespread coral bleaching, must be considered a significant threat in many small island states (see Section 17.2.4.1). Fish production obviously would suffer if these habitats were endangered or lost (Costa *et al.*, 1994).

On a global scale, it is not expected that climate change and climate variability will lead to any significant reduction in fisheries production. However, important changes in the abundance and distribution of local stocks (which may be of direct concern to some small islands) are likely to occur (IPCC, 1996). For example, Lehodey *et al.* (1997) have shown that spatial shifts in the abundance of skipjack tuna in the Pacific are linked to the ENSO cycle. They note that catches are highest in the western equatorial Pacific warm pool, which can be displaced by as much as 50° of longitude eastward during El Niño episodes and westward in La Niña years (Lehodey *et al.*, 1997). This must be a concern to Pacific islanders whose access to the skipjack stocks now appears to be largely controlled by the periodicity of ENSO events.

Several management strategies for minimizing the adverse effects of climate change on fish stocks have been proposed. These measures—many of which already are being implemented in some island states—include conservation, restoration, and enhancement of vital habitats such as mangroves, coral reefs, and seagrass beds; establishment and management of marine reserves and protected areas for identified critical species; and implementation of bilateral and multilateral agreements and protocols for exploitation and management of shared fisheries (migratory and straddling stocks) (IPCC, 1998; Berkes *et al.*, 2001). Aquaculture also may be considered by island states as another means of reducing stress on wild stocks. However, great precaution must be taken to ensure that this measure does not exacerbate existing problems of habitat loss and competition for nutrients (Carvalho and Clarke, 1998; see also Section 6.6.4).

17.2.9. Human Welfare

17.2.9.1. Settlement and Infrastructure

In most small island states (including high islands such as Seychelles, Reunion, and Fiji), narrow coastal plains provide attractive locations for settlement and a variety of infrastructure to support economic and social needs. Most of the population, settlements, and economic activities are concentrated in areas where competition for space is acute and where fragile ecosystems, aquatic and terrestrial, coexist. In most Caribbean islands, for example, more than 50% of the population live within 2 km of the coast. On atolls, most of the important infrastructure and population clusters often are less than 100 m from the shoreline. As the shortage of coastal space becomes increasingly acute in many small islands, land reclamation often is practiced as a solution to this need. Ironically, this practice exposes these islands to greater risk by attracting more settlement and infrastructure to already highly vulnerable locations.

As elsewhere, coastal development in most small islands has been undertaken in the past without taking climate change and sea-level projections into consideration. With currently projected rates of sea-level rise and flooding, coupled with the possibility of more intense and frequent extreme events such as cyclones (hurricanes) and associated storm surge, critical infrastructure such as social services, airports, port facilities, roads, coastal protection structures, tourism facilities, and vital utilities will be at severe risk. Furthermore, the capacity of most small island states to respond effectively to these threats is limited by their low adaptive capacity, which results from a combination of factors—including physical size (little opportunity to retreat), limited access to capital and technology, and a shortage of human resource skills.

In some countries, particularly the low islands and micro-atolls, resettlement within national boundaries may have to be considered as the only viable option. However, implementation of this strategy could become extremely complicated, especially for densely populated coastal lowlands such as in the Federated States of Micronesia (950 persons km^{-2}), Majuro, Marshall Islands (2,188 persons km^{-2}) and Male, Republic of Maldives (35,000 persons km^{-2}). In extreme circumstances, it may even become necessary to abandon some atolls altogether (Nurse *et al.*, 1998). Such an option would be socially and culturally disruptive and would require access to substantial resources—which most of these countries may be unable to afford.

17.2.9.2. Human Health

Increased instability of weather patterns and large interannual variability in climate enhanced by ENSO forcing and GHG-induced climate change have catalyzed a new focus on possible health consequences in a changing climate (Epstein, 1997; Epstein *et al.*, 1997; Hales *et al.*, 1997; Woodward *et al.*, 1998). Many tropical islands are now experiencing high incidences of vector- and water-borne diseases that are attributed to changes

in temperature and rainfall regimes, which may be linked to events such as ENSO, droughts, and floods. In the Pacific, there is growing evidence that outbreaks of dengue are becoming more frequent and appear to be strongly correlated with the ENSO phenomenon (Hales *et al.*, 1997, 1999a). Many of the small island states lie in the tropical zone, where the climate is suitable for the transmission of tropical diseases such as malaria, dengue, filariasis, and schistosomiasis.

Some of the small island states, such as the Bahamas, Kiribati, the Marshall Islands, and the Maldives, are a mere 3–4 m above mean sea level, which predisposes them to inundation with seawater and, as a consequence, salinization of freshwater supplies and flooding from sea-level rise. Furthermore, low-lying islands are particularly vulnerable to storms and cyclones; these also can adversely affect public water supplies. Vector-borne diseases such as malaria and dengue are particularly sensitive to warming and flooding. Filariasis and schistosomiasis are less sensitive to short-term seasonal climatic changes, but the epidemiology of these diseases could change with long-term effects of climate change. Water-borne diseases such as shigella, cryptosporidium, giardia, and amoebiasis could increase as a result of disruption of sewage and water systems by flooding (see Chapter 9).

It is also projected that, with temperature and rainfall changes, some vectors could extend their range, so there is likely to be wider transmission of some diseases (McMichael, 1996). For example, malaria—which previously tended to be confined largely to the western and central Pacific region—now appears to be extending east as far as Fiji. It also is worth noting that the interior uplands of many islands, which now are virtually free of vectors (e.g., *Aedes aegypti* mosquito) that transmit malaria, dengue, and other tropical illnesses—could become favorable breeding sites in a changing climate (disease-specific details appear in Chapter 9).

In some regions—for example, the Pacific—it has been noted that extreme weather events appear to be occurring at a higher frequency than elsewhere (Timmerman *et al.*, 1997). As a consequence, physical injuries arising from these events can be expected to increase.

It is well-established that vulnerability to such health risks will vary according to factors such as availability of quality health care, the present health status of the population, and availability of technical and other resources (McMichael, 1993; WHO, 1996). Unfortunately, health care facilities and related infrastructure in many small island states and other developing countries often are inadequate. Hence, the resilience of such states and their capacity to respond effectively to (or mitigate) increasing health threats posed by climate change is likely to be low.

A range of adaptation strategies for reducing the severity of possible climate change-related health threats has been proposed, and many of these measures may be successfully pursued in the small island states. Such measures include, *inter alia*, implementation of effective health education programs,

preventive maintenance and improvement of health care facilities, cost-effective sewerage and solid waste management practices, and disaster preparedness plans (McMichael, 1996).

Adoption of efficient early warning systems also would be beneficial in vulnerable small islands (Stern and Easterling, 1999). This process would involve monitoring of health-risk indicators by improving the forecasting of conditions that are favorable to the outbreak of climate-sensitive diseases such as dengue, cholera, and malaria (Patz *et al.*, 1996; IPCC, 1998; Epstein, 1999). Where large populations exist, as in urban areas, simple, low-cost measures could be implemented to control the vectors of dengue and other diseases, where a risk of transmission exists. At the individual level, insecticide-treated bed nets could provide protection against vectors of malaria and filariasis. Simple technology, such as the use of sari cloth to filter drinking water, reduces the risk of cholera transmission at the household level. Although some measures for adapting to climate change can be deferred, early implementation of preventive strategies could reduce current and future health "costs."

17.2.10. Other Economic and Sociocultural Impacts

Climate change could have direct and indirect impacts on other economic and social sectors in some small islands. The insurance industry is one sector that is highly sensitive to the magnitude and frequency of various hazards, including climate-related phenomena such as tropical storms and floods. Because insurance premiums are based on assessment of risk of occurrence of a particular event, any indication of an increase in the frequency or intensity of phenomena such as tropical cyclones and floods is likely to trigger an increase in the cost of insurance. Within the past decade, insurance costs in the Caribbean have increased significantly, following the passage of a series of severe hurricanes that caused widespread socioeconomic dislocation, injury, and loss of life. Claims were so high that some reinsurance companies withdrew from the market; others imposed higher deductibles, separate conditions for windstorms, and a premium structure to minimize the risk of underinsurance (Murray, 1993; Saunders, 1993). Even in cases in which these systems did not make landfall in the insular Caribbean itself—as with Hurricane Andrew, which devastated southern Florida in the United States—an increase in insurance premiums in the islands subsequently occurred.

Certain traditional island assets (goods and services) also will be at risk from climate change and sea-level rise. These assets include subsistence and traditional technologies (skills and knowledge), community structure, and coastal villages and settlements. Sea-level rise and climate changes, coupled with environmental changes, have destroyed some very important and unique cultural and spiritual sites, coastal protected areas, and traditional heritage sites in the Federated States of Micronesia, Tuvalu, the Marshall Islands, Niue, and Kiribati and continue to threaten others (Kaluwin and Smith, 1997).

Although some of these assets fall into the category of nonmarket goods and services, they are still considered to be of vital importance in small island states. In Tuvalu, for instance (as in other Pacific atoll states), strong traditional ties to land and sea constitute a vital component of local cosmology (Sem *et al.*, 1996). Some of these values and traditions are compatible with modern conservation and environmental practices; therefore, priority action is needed in the following areas: research into traditional knowledge and practices of conservation and environment control—which have sustained these societies for generations, even in the face of hazards, risk, and uncertainty; inventorying of traditional, heritage, and other cultural sites; encouragement of practices that marry use of modern science and technology with traditional wisdom; and more effective transmission of traditional knowledge to younger generations.

17.3. Vulnerability and Adaptation Potential

17.3.1. Setting the Context

The potential impacts of climate change on small island states discussed in Section 17.2 have given rise to considerable concern. Relevant chapters in the First Assessment Report (FAR; Tsyban *et al.*, 1990) and SAR (Bijlsma, 1996) and in the *Special Report on Regional Impacts of Climate Change* (Nurse *et al.*, 1998) already concluded that low-lying small islands are among the most vulnerable countries in the world. A similar conclusion is reached in this Third Assessment Report (see Section 19.3.7). Their overall vulnerability is shown to be a function of the *degree of exposure* of these states to climate change and their *limited capacity to adapt* to projected impacts.

This section assesses the relevant literature on the vulnerability of small island states that has become available since the SAR, including an overview of available country studies. In addition, this section pays particular attention to adaptation. Whereas Bijlsma (1996) and Nurse *et al.* (1998) focus on available adaptation options, this section takes a process-oriented approach to adaptation and recognizes adaptive capacity as an important determinant of vulnerability.

17.3.2. Generic Issues

Many definitions of vulnerability and adaptation exist in the literature (see Chapter 18). However, this report defines vulnerability to climate change as "the degree to which a system is sensitive to and unable to cope with adverse impacts of climatic stimuli. Vulnerability is a function of a system's exposure and its adaptive capacity." Adaptation is the "adjustment in natural or human systems in response to actual or expected climatic stimuli, or their effects" (see Chapter 2). Vulnerability therefore is a function of potential impacts and adaptive capacity, and adaptation refers to both natural and human system responses. Whereas the previous section focused on impacts and responses of natural systems, this

section discusses the relevance of adaptation for human systems in a small islands context.

17.3.3. Vulnerability

Despite their heterogeneity, small island states share some common characteristics that help to define their high vulnerability and low adaptation potential to climate change effects (Nurse *et al.*, 1998; see also Section 17.1.2). Vulnerability assessment typically seeks to achieve three main goals: to identify the degree of future risks induced by climate change and sea-level rise; to identify the key vulnerable sectors and areas within a country; and to provide a sound basis for designing adaptation strategies and their implementation.

The IPCC Common Methodology was the first method to be widely applied to assess the vulnerability of countries to sea-level rise (IPCC, 1992). However, the methodology lacks the flexibility to consider factors of critical significance for small islands (e.g., so-called nonmarket goods and services) and requires certain quantitative data that often are not easily available in many small island states. An index-based method was developed for use in the south Pacific (Yamada *et al.*, 1995, based on Kay and Hay, 1993). In addition, alternative assessment methodologies were developed in conjunction with the various country study programs (e.g., Leatherman, 1996; Klein and Nicholls, 1998). What is significant, however, is that all available assessments confirm the high vulnerability of small island states to climate change, independent of the methodology applied. As already noted, global assessments come to the same conclusions (Nicholls *et al.*, 1999). This is

therefore a robust finding, which must be of considerable concern to these countries.

Climate change is expected to be one factor among many that affect ecological systems and economic development. Other factors that interact with climate change include overexploitation of resources, pollution, increasing nutrient fluxes, decreasing freshwater availability, sediment starvation, and urbanization (Goldberg, 1994; Viles and Spencer, 1995). Particularly relevant for small island states are rapid population growth, intra- and inter-island migration, rapid changes in social structure, and effects of economic globalization. These nonclimate stresses can decrease the resilience of natural and human systems, increasing their vulnerability to climate variability and anticipated climate change (Nicholls and Branson, 1998; Klein and Nicholls, 1999).

Most vulnerability indices developed to date have focused on economic and social systems, although studies by Ehrlich and Ehrlich (1991) and Atkins *et al.* (1998) focus on environmental vulnerability. The economic vulnerability indices include those developed by Briguglio (1995, 1997), the Commonwealth Secretariat (Wells, 1996, 1997; Atkins *et al.*, 1998), Pantin (1997), and the Caribbean Development Bank (Crowards, 1999). Another index, the Environmental Vulnerability Index, has been developed recently for small island states, particularly countries for which data availability is limited. It incorporates climate, nonclimate, and human stresses on the environment and seeks to reflect relative vulnerability as a function of these combined factors (Kaly *et al.*, 1999). All vulnerability indices consistently identify small states—sometimes more specifically small island states—as being more economically vulnerable than larger states.

Box 17-2. Tools for Vulnerability Assessment and Adaptation Policy Development

The numerous and well-developed interactions between the natural and human systems of island countries underscore the relevance of integrated assessment as a meaningful analytical tool for designing adaptation strategies. One such tool that has proven particularly beneficial is VANDACLIM, an integrated assessment model developed by the International Global Change Institute (University of Waikato, New Zealand), in collaboration with the South Pacific Regional Environment Programme (SPREP) and United Nations Institute for Training and Research (UNITAR) (Warrick *et al.*, 1999). Enhanced and country-specific versions of VANDACLIM currently are being developed.

Development of VANDACLIM involved linking a regional scenario generator with selected impact models for four key sectors: agriculture, coastal zones, human health, and water resources. The user has considerable flexibility in generating scenarios; the user can choose among a large range of projections from GHG emission scenarios; the low, mid, or high cases from each projection (which encompasses the range of uncertainty in model parameter values); several GCM patterns; and the year of interest (in 5-year increments from 1990 to 2100).

VANDACLIM integrates a variant of the “Bruun rule” with a simple inundation model that is suitable for flat, low-lying deltaic coastal plains. Health impacts projections are derived from a biophysical index that estimates potential incidence of malaria and a simple threshold index for estimating change in the risk of cholera outbreaks related to extreme flooding events. For water resources, three models are included: an atmospheric water balance model for assessing the overall water resource situation for the country; a water balance-river discharge model for estimating monthly mean discharge for estimating wet and dry season river flow; and a discharge-flood area model for defining the areal extent of flooding. For agriculture, various crop models and indices are integrated, including degree-day models, rainfall (soil moisture), a land suitability index, and temperature for a variety of tropical crops.

Most existing studies have fulfilled the first two of the three aforementioned goals of vulnerability assessment, although information on socioeconomic impacts of climate change often is limited. The third goal—to provide a basis to guide possible adaptation—usually is met only in general terms. Effective planning and design of adaptation strategies requires more detailed information on crucial vulnerable sectors and areas. Such information may be partly derived from analysis at an integrated level (see Box 17-2)—as suggested, for instance, by Klein and Nicholls (1999).

17.3.4. Adaptation and Adaptive Capacity

As Campbell (1996) notes, a key misconception is that adaptation is a task carried out by governments. Insofar as governments have property and are responsible for carrying out a variety of activities, they will be required to take adaptive action. Most adaptation, however, will be carried out by individual stakeholders and communities, urban or rural, that inhabit island countries. Therefore, the government's primary role is to facilitate and steer this process—ideally in a manner that benefits the wider community.

Small island states often are susceptible to the impacts of a wide range of natural hazards, including climatic extremes. In the south Pacific region alone, island states suffered a total of 79 tropical cyclones, 95 storm surges, 12 floods, 31 droughts, four earthquakes, five landslides, two tsunamis, and four volcanic eruptions during the 1990s (Burns, 2000; Gillespie and Burns, 2000; Hay, 2000). The World Conference on Natural Disaster Reduction and the Global Conference on Sustainable Development of Small Island States noted several issues that influence adaptation to such impacts. These issues include the limited capacity of developing small island states to respond to and recover from natural and environmental disasters, owing to their narrow resource base and small size. Another issue is the decline in traditional coping mechanisms employed by island states, such as food preservation and storage techniques and disaster-resistant housing designs.

Given their high vulnerability, it is generally accepted that a proactive approach to adaptation planning would be especially beneficial to small islands, to minimize the adverse effects of climate change and sea-level rise (Campbell and de Wet, 2000). One essential prerequisite for implementing adaptive measures is support from policymakers and the general public. Thus, raising public awareness and understanding about the threats of climate change and sea-level rise and the need for appropriate adaptation require urgent and consistent attention. Because strong social and kinship ties exist in many small island states—for example, in the Pacific—a community-based approach to adaptation could be vital if adaptation policies and options are to be successfully pursued.

It also should be noted that small island states have faced many hazards in the past; as a consequence, their inhabitants have developed some capacity to cope by resorting to a combination

of strategies, including application of traditional knowledge, locally appropriate technology (e.g., construction on stilts in flood-prone areas), use of indigenous materials, and other customary practices. Thus, for these states, it would be mandatory for any climate change adaptation policy and implementation plan to incorporate these traditional coping skills.

One of the obstacles to implementation of adaptation strategies stems from the uncertainties associated with the projection of future climate change and its impacts, at scales appropriate to small islands. Therefore, better guidance is needed for policy development in the face of uncertainties, together with more reliable climate projections at a scale that is relevant to the small island states (Edwards, 2000).

Many island states confront a range of pressing socioeconomic concerns (e.g., poverty alleviation, unemployment, health, and education), and climate change tends to be assigned a low priority on most national agendas. Thus, given the long lead time for implementing and assessing adaptation (as much as 50–100 years), progress in realizing its goals almost certainly will require integration of adaptation strategies with other sectoral and national policies, such as economic development, disaster prevention and management, integrated coastal management, and sustainable development frameworks.

17.3.5. Regional and External Factors

Small island states account for a small percentage of world energy consumption and extremely low levels of global GHG emissions and on balance are likely to be severely impacted by the effects of climate change (Yu *et al.*, 1997; see Box 17-3). In most states, the bulk of the energy requirements are met

Box 17-3. Greenhouse Gas Emissions from Small Island States in the Pacific

Based on application of the *IPCC Guidelines for National Greenhouse Gas Inventories*, Pacific island countries are responsible for a per capita equivalent emission of approximately 0.96 t of CO₂ yr⁻¹. Hence, the total Pacific island population of 7.1 million in 22 countries produces 6.816 Mt of CO₂ yr⁻¹. In contrast, based on International Energy Agency data for 1996, global CO₂ emissions arising from fossil fuel combustion alone are 22,620.46 Mt of CO₂ yr⁻¹, or 4.02 t of CO₂ yr⁻¹ per capita. Thus, on average, Pacific islanders produce approximately one-quarter of the CO₂ emissions attributable to the average person worldwide. Expressed another way, the Pacific islands region as a whole accounts for 0.03% of the global emissions of CO₂ from fuel combustion despite having approximately 0.12% of the world's population.

Box 17-4. Renewable Energy Use in Small Island States: A “Win-Win” Strategy

Most small islands are heavily dependent on imported fossil fuels for the majority of their energy requirements, particularly transport and electricity production. This is clearly demonstrated in the case of the Caribbean and Pacific islands, where petroleum imports are responsible for more than 75 and 88%, respectively, of primary energy demand. The cost of fossil fuel imports also places a considerable economic burden on small island states, accounting on average for almost 15% of all imports in these countries. In addition, the cost of electricity production (US\$0.10–0.15 and 0.20 kWh⁻¹ for the Caribbean and the Pacific, respectively) can be as much as three to four times higher than in developed countries.

In many islands, the high unit cost of conventional power production versus the increasingly competitive cost of renewable energy technologies (especially solar and wind), make the latter economically viable and environmentally friendly options. For these reasons, several small island states are making a significant contribution to global utilization of renewable energy resources. These include, *inter alia*, the following countries:

- Barbados, where approximately 33% of all households use solar water heaters
- La Desirade, Guadeloupe, where more than 75% of all electricity is generated from wind power
- Fiji and Dominica, where hydropower accounts for more than 30% of electricity production
- Tuvalu, where photovoltaics supply 45% of the electricity
- Reunion, where almost 20% of the electricity is biomass-generated (from bagasse, a by-product of sugarcane); bagasse also is becoming increasingly important as an energy source in Jamaica and Fiji.

Sources: Jensen, 1999; Ellis and Fifita, 1999.

from imported fossil fuels, which places a heavy burden on island economies (Yu *et al.*, 1997). Adaptation and mitigation strategies in these countries, as elsewhere, will necessitate more economic and efficient energy use and greater emphasis on development of renewable energy sources (see Box 17-4).

To implement these strategies, many small islands, will require external technical, financial, and other assistance (Rijsberman, 1996). Given these states' size and limited individual capacities, pooling of resources through regional cooperation has been proposed as an effective means of designing and implementing some adaptation measures (Nicholls and Mimura, 1998). Some island groupings already have begun to implement regional projects aimed at building capacity to respond to climate change. Two projects—Caribbean Planning for Adaptation to Climate Change (CPACC), which is being implemented by 12 Caribbean states, and Pacific Islands Climate Change Assistance Program (PICCAP), which is being executed by SPREP for 10 Pacific island countries—are outstanding models of regional cooperation.

17.4. Synthesis

17.4.1. Feedbacks, Interactions, and Resilience: The Relevance of these Concepts to Small Islands

Feedback mechanisms in changing systems are poorly understood. These mechanisms could produce a series of *downstream effects* as conditions within a system deviate from “normal” and can include mechanisms that bring conditions back toward “normal” (correcting) or push conditions further away from “normal” (compounding). Feedback of interactions between

humans and the environment in the face of climate change are likely to be negative and are expected to increase. As humans have to take adaptive actions to preserve their systems in the face of climate change and sea-level rise, there is a risk that impacts on the environment will increase, despite better awareness of the issues. The short-term needs of humans are likely to take precedence over longer-term needs, which are intimately tied up with the environment. This could mean greater-than-expected and unpredictable indirect impacts resulting from climate change and sea-level rise.

Small island states urgently need sensible predictive information and tools for minimizing the likely outcomes of climate change and sea-level rise because it is now generally accepted that small islands are intrinsically more vulnerable than larger countries (Briguglio, 1992, 1993, 1995, 1997; Wells, 1996, 1997; Atkins *et al.*, 1998; UNDP, 1998). The vulnerability of natural systems is still under investigation, although work is underway (Yamada *et al.*, 1995; Sem *et al.*, 1996; Kaly *et al.*, 1999). This makes the requirement for information and tools for generating such information a top priority. The outcome of climate change on human and natural systems in small island states will depend on changes induced by climate itself, feedback mechanisms, human adaptive capacity, and the resilience of biophysical and human systems.

Indicators of high resilience might include the presence of healthy, intact ecosystems; the ability of species to acclimatize to new temperature regimes; the presence of land higher than the maximum predicted transgression plus storm surges; high productivity; reproduction and recruitment of species; and high rates of natural recovery (Kaly *et al.*, 1999).

Resilience refers to the innate ability of biophysical and human systems to maintain their integrity when subjected to disturbance (Holling, 1973; Ludwig *et al.*, 1997). For most natural systems, knowledge of resilience to climate change and sea-level rise is inadequate. For example, there are insufficient data to describe the ability of a reef to withstand sea-level rise of 20–40 cm over the next 50 years (but see Hoegh-Guldberg, 1999). Predicting which ecological variables (e.g., species, processes) might be affected and what effect this would have on ecosystem diversity, function, and future resilience may be difficult or impossible (Lubchenco *et al.*, 1993). Proxy estimates have been made, most notably using recent El Niño events in the eastern Pacific; these estimates have many of the expected effects of climate change (Castilla *et al.*, 1993; Burns, 2000). For oceans, these and other proxy estimates predict the extinction of species, mass mortality and bleaching of corals, changes in the geographic range of species, increases in disease, unexpected predation, decreases in productivity, and increases in harmful algal blooms (Glynn, 1984, 1988, 1991; Bak *et al.*, 1984; Hallegraeff, 1993; Lessios, 1998; Hoegh-Guldberg, 1999).

Although earlier work suggested that systems exposed to perturbations tend to have greater capacity to recover from shock (e.g., Holling, 1973), research in a small island context challenges this conventional wisdom. Kaly *et al.* (1999) demonstrate that for many systems, the greater the number and intensity of hazards (human-induced as well as natural) that have impacted them in the past, the greater is their level of vulnerability to future stresses. Furthermore, because neither the natural resilience nor the altered resilience of any ecosystem is known—let alone the resilience that might arise as a result of summed or interactive effects—it is impossible to directly estimate overall resilience. This finding is very disturbing for most small island states, where ecosystems already are severely stressed from natural and anthropogenic forces.

17.4.2. Uncertainties and Risks

17.4.2.1. Inconsistencies and Limitations in Projected Changes

Present ability to accurately assess the effects of climate change in small island states, as in other regions, is further impeded by conflicting predictions of how natural systems may respond. For example, some studies cite the responses of ecosystems to El Niño events in the 1980s and 1990s as indicative of the likely effects of climate change, with conflicting outcomes (Salinger, 1999; Gillespie and Burns, 2000; Hay, 2000). On one hand, it is expected that primary productivity in oceans will *decrease* as a result of global warming when upwelled waters become shoaled (Roemmich and McGowan, 1995; Barber *et al.*, 1996). On the other hand, it has been predicted that harmful algal blooms will *increase* with increasing temperatures (Colwell, 1996; Nurse *et al.*, 1998; see also Hales *et al.*, 1999b). Clearly, forecasting of likely outcomes will be more complex than may have been expected initially. Thus, planning of appropriate responses in regions of low adaptive capacity, such as small island states, presents an even greater challenge.

17.4.2.2. Ecosystem Collapse

One of the likely outcomes of climate change and sea-level rise in natural systems is their collapse. Although ecosystem collapse is not presently well-defined or understood, it is a concern of island countries, which depend heavily on resources provided by these systems to sustain their economic and social well-being (Burns, 2000; Gillespie and Burns, 2000). If mangrove systems are to migrate inland, for example, what is involved is the collapse of the original mangrove system on the existing shore and its eventual replacement with another ecosystem. It is unclear whether the old mangrove area would be replaced by a viable alternative marine ecosystem or whether the new mangroves produced inland would be a viable ecosystem, with all of the same functional characteristics of the original. These and similar questions are central to understanding the ability of human and natural systems to adapt to climate change and sea-level rise.

17.5. Future Requirements, Information, and Research Needs

Although good progress has been made in understanding the vulnerability and adaptation potential of small island states to climate change, the foregoing discussion highlights critical information gaps and uncertainties that still exist. It has been established that small island states constitute a very high-risk group of countries as a consequence of their high vulnerability and low adaptive capacity. Climate change is inevitable, even if any global agreement to limit GHG emissions were swiftly implemented. Thus, the need to focus on adaptation options and requirements already is critical for small islands, given that these countries are projected to suffer disproportionately from the effects of climate change (Bijlsma, 1996; Nurse *et al.*, 1998; Nicholls *et al.*, 1999; Gillespie and Burns, 2000). The agenda set out below therefore is designed not only to fill existing knowledge gaps but also to help identify opportunities for minimizing the adverse effects of climate change (including avoidance of maladaptation), as an important component of adaptation planning in these islands:

- For most small islands, the lack of geographical detail is a critical shortcoming. Outputs from GCMs currently used to assess climate change impacts in small islands are coarse and do not provide adequate information for countries at the scale of small islands. Hence, there is an urgent need for downscaling the outputs of the GCMs to better define and understand island-scale processes and impacts.
- Research into the sensitivity of small islands to climate change, employing an integrated approach, should continue. Studies on the vulnerability of human and biophysical systems to climate change and their interaction with and response to natural and human stresses (including extreme events) need to be integrated because the more common “reductionist” approaches tend to be deficient in their treatment of interactive effects.

- Some small island states have initiated efforts to reduce the impact of natural disasters and to use seasonal to interannual climate analysis and climate forecasts to reduce the impacts of natural hazards. Because long-term climate change may result in a more El Niño-like state, with more frequent and severe extreme climate events, support to build on these past efforts could help to reduce the vulnerability of these islands to climate change.
- Although small islands have many characteristics in common, the heterogeneity factor should not be overlooked. Local conditions on widely varying island types (e.g., tectonic changes, shorelines with large sediment availability versus those with sediment deficits, highly fragmented versus single-island states) may increase or decrease climate change impacts, so the outcomes could be dramatically different in each small island setting. Climate change assessments under such varying circumstances would improve present understanding of vulnerability and adaptation requirements in small islands.
- Given their wide geographical dispersion, there is a need for a coordinated monitoring program for small islands that evaluates the long-term response of ecosystems to climate variability and change. The focus of such an effort should be on the complex interactions that may occur within human and natural systems to modify the frequency and magnitude of impacts expected and to identify ecosystems that may be in danger of collapsing, so that timely adaptive action might be taken. Such work would help to improve our understanding of the concepts of homeostasis, resilience, and feedback mechanisms, which—though frequently alluded to in the literature—are poorly understood and are critical for adaptation planning at the local and regional scale.
- Although the susceptibility of small islands to climate change impacts is high and adaptive capacity is low, the overall level of vulnerability varies within and among states. Thus, vulnerability indices being developed and refined specifically for small islands [Crowards, 1999 (Caribbean Development Bank); Kaly *et al.*, 1999 (SOPAC)] have the potential to make a significant contribution to adaptation planning and implementation in this constituency. Countries therefore might wish to consider continuation of this work among their research priorities.

Finally, there is some uneasiness in the small island states about perceived overreliance on the use of outputs from climate models as a basis for planning risk reduction and adaptation to climate change. There is a perception that insufficient resources are being allocated to relevant empirical research and observation in small islands. Climate models are simplifications of very complex natural systems; they are severely limited in their ability to project changes at small spatial scales, although they are becoming increasingly reliable for identifying general trends. In the face of these concerns, therefore, it would seem

that the needs of small island states can best be accommodated by a balanced approach that combines the outputs of downscaled models with analyses from empirical research and observation undertaken in these countries.

EXECUTIVE SUMMARY

Adaptation refers to adjustments in ecological, social, or economic systems in response to actual or expected climatic stimuli and their effects or impacts. It refers to changes in processes, practices, and structures to moderate potential damages or to benefit from opportunities associated with climate change.

Estimates of likely future adaptations are an essential ingredient in *impact and vulnerability assessments*. The extent to which ecosystems, food supplies, and sustainable development are vulnerable or “in danger” depends both on exposure to changes in climate and on the ability of the impacted system to adapt. In addition, adaptation is an important policy *response* option, along with mitigation. There is a need for the development and assessment of planned adaptation initiatives to help manage the risks of climate change.

Adaptations vary according to the system in which they occur, who undertakes them, the climatic stimuli that prompts them, and their timing, functions, forms, and effects. In unmanaged natural systems, adaptation is autonomous and reactive; it is the process by which species and ecosystems respond to changed conditions. This chapter focuses on adaptations consciously undertaken by humans, including those in economic sectors, managed ecosystems, resource use systems, settlements, communities, and regions. In human systems, adaptation is undertaken by private decisionmakers and by public agencies or governments.

Adaptation depends greatly on the *adaptive capacity* or adaptability of an affected system, region, or community to cope with the impacts and risks of climate change. The adaptive capacity of communities is determined by their socioeconomic characteristics. Enhancement of adaptive capacity represents a practical means of coping with changes and uncertainties in climate, including variability and extremes. In this way, enhancement of adaptive capacity reduces vulnerabilities and promotes sustainable development.

Adaptation to climate change has the potential to substantially reduce many of the adverse impacts of climate change and enhance beneficial impacts—though neither without cost nor without leaving residual damage.

The key features of climate change for vulnerability and adaptation are those related to variability and extremes, not simply changed average conditions. Most sectors and regions and communities are reasonably adaptable to changes in average conditions, particularly if they are gradual. However, these communities are more vulnerable and less adaptable to changes

in the frequency and/or magnitude of conditions other than average, especially extremes.

Sectors and regions will tend to adapt autonomously to changes in climate conditions. Human systems have evolved a wide range of strategies to cope with climatic risks; these strategies have potential applications to climate change vulnerabilities. However, losses from climatic variations and extremes are substantial and, in some sectors, increasing. These losses indicate that autonomous adaptation has not been sufficient to offset damages associated with temporal variations in climatic conditions. The ecological, social, and economic costs of relying on reactive, autonomous adaptation to the cumulative effects of climate change are substantial.

Planned anticipatory adaptation has the potential to reduce vulnerability and realize opportunities associated with climate change, regardless of autonomous adaptation. Implementation of adaptation policies, programs, and measures usually will have immediate benefits, as well as future benefits. Adaptation measures are likely to be implemented only if they are consistent with or integrated with decisions or programs that address nonclimatic stresses. The costs of adaptation often are marginal to other management or development costs.

The capacity to adapt varies considerably among regions, countries, and socioeconomic groups and will vary over time. The most vulnerable regions and communities are those that are highly exposed to hazardous climate change effects and have limited adaptive capacity. Countries with limited economic resources, low levels of technology, poor information and skills, poor infrastructure, unstable or weak institutions, and inequitable empowerment and access to resources have little capacity to adapt and are highly vulnerable.

Enhancement of adaptive capacity is a necessary condition for reducing vulnerability, particularly for the most vulnerable regions, nations, and socioeconomic groups. Activities required for the enhancement of adaptive capacity are essentially equivalent to those promoting sustainable development. Climate adaptation and equity goals can be jointly pursued by initiatives that promote the welfare of the poorest members of society—for example, by improving food security, facilitating access to safe water and health care, and providing shelter and access to other resources. Development decisions, activities, and programs play important roles in modifying the adaptive capacity of communities and regions, yet they tend not to take into account risks associated with climate variability and change. Inclusion of climatic risks in the design and implementation of

development initiatives is necessary to reduce vulnerability and enhance sustainability.

Current knowledge of adaptation and adaptive capacity is insufficient for reliable prediction of adaptations; it also is insufficient for rigorous evaluation of planned adaptation options, measures, and policies of governments. Climate change vulnerability studies now usually consider adaptation, but they rarely go beyond identifying adaptation options that might be possible; there is little research on the dynamics of adaptation in human systems, the processes of adaptation decisionmaking, conditions that stimulate or constrain adaptation, and the role of nonclimatic factors. There are serious limitations in existing evaluations of adaptation options:

Economic benefits and costs are important criteria but are not sufficient to adequately determine the appropriateness of adaptation measures; there also has been little research to date on the roles and responsibilities in adaptation of individuals, communities, corporations, private and public institutions, governments, and international organizations. Given the scope and variety of specific adaptation options across sectors, individuals, communities, and locations, as well as the variety of participants—private and public—involved in most adaptation initiatives, it is probably infeasible to systematically evaluate lists of particular adaptation measures; improving and applying knowledge on the constraints and opportunities for enhancing adaptive capacity is necessary to reduce vulnerabilities associated with climate change.

18.1. Introduction: Adaptation and Adaptive Capacity

Adaptation is adjustment in ecological, social, or economic systems in response to actual or expected climatic stimuli and their effects or impacts. This term refers to changes in processes, practices, or structures to moderate or offset potential damages or to take advantage of opportunities associated with changes in climate. It involves adjustments to reduce the vulnerability of communities, regions, or activities to climatic change and variability. Adaptation is important in the climate change issue in two ways—one relating to the assessment of impacts and vulnerabilities, the other to the development and evaluation of response options.

Understanding expected adaptations is essential to *impact and vulnerability assessment* and hence is fundamental to estimating the costs or risks of climate change (Fankhauser, 1996; Yohe *et al.*, 1996; Tol *et al.*, 1998; UNEP, 1998; Smit *et al.*, 1999; Pittock and Jones, 2000). Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC) refers to “dangerous” human influences on climate in terms of whether they would “allow ecosystems to adapt, ensure food production is not threatened, and enable economic development to proceed in a sustainable manner.” The extent to which ecosystems, food supplies, and sustainable development are vulnerable or “in danger” depends on their exposure to climate change effects and on the ability of impacted systems to adapt. Thus, to assess

the dangerousness of climate change, impact and vulnerability assessments must address the likelihood of autonomous adaptations (see Figure 18-1).

Adaptation also is considered an important *response option or strategy*, along with mitigation (Fankhauser, 1996; Smith, 1996; Pielke, 1998; Kane and Shogren, 2000). Even with reductions in greenhouse gas (GHG) emissions, global temperatures are expected to increase, other changes in climate—including extremes—are likely, and sea level will continue to rise (Raper *et al.*, 1996; White and Etkin, 1997; Wigley, 1999). Hence, development of planned adaptation strategies to deal with these risks is regarded as a necessary complement to mitigation actions (Burton, 1996; Smith *et al.*, 1996; Parry *et al.*, 1998; Smit *et al.*, 1999) (see Figure 18-1). Article 4.1 of the UNFCCC commits parties to formulating, cooperating on, and implementing “measures to facilitate adequate adaptation to climate change.” The Kyoto Protocol (Article 10) also commits parties to promote and facilitate adaptation and deploy adaptation technologies to address climate change.

Adaptive capacity is the potential or ability of a system, region, or community to adapt to the effects or impacts of climate change. Enhancement of adaptive capacity represents a practical means of coping with changes and uncertainties in climate, including variability and extremes. In this way, enhancement of adaptive capacity reduces vulnerabilities and promotes

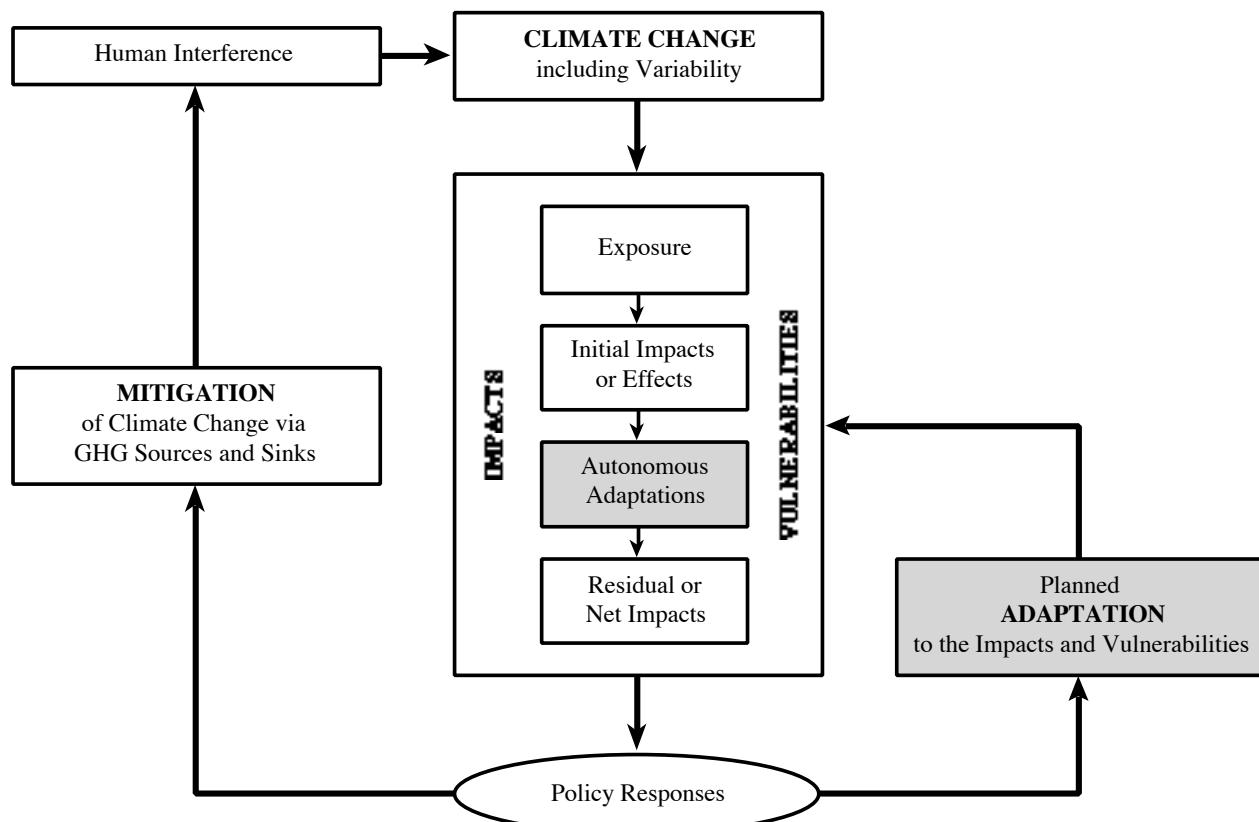

Figure 18-1: Places of adaptation in the climate change issue (Smit *et al.*, 1999).

sustainable development (Goklany, 1995; Burton, 1997; Cohen *et al.*, 1998; Klein, 1998; Rayner and Malone, 1998; Munasinghe, 2000; Smit *et al.*, 2000).

Considerable attention has been devoted to the characteristics of communities, countries, and regions that influence their propensity or ability to adapt and hence their vulnerability to risks associated with climate change. These *determinants of adaptive capacity* relate to the economic, social, institutional, and technological conditions that facilitate or constrain the development and deployment of adaptive measures (e.g., Bohle *et al.*, 1994; Rayner and Malone, 1998; Kelly and Adger, 1999).

18.2. Adaptation Characteristics and Processes

Adaptation refers both to the *process* of adapting and to the *condition* of being adapted. The term has specific interpretations in particular disciplines. In ecology, for example, adaptation refers to changes by which an organism or species becomes fitted to its environment (Lawrence, 1995; Abercrombie *et al.*, 1997); whereas in the social sciences, adaptation refers to adjustments by individuals and the collective behavior of socioeconomic systems (Denevan, 1983; Hardesty, 1983). This chapter follows Carter *et al.* (1994), IPCC (1996), UNEP (1998),

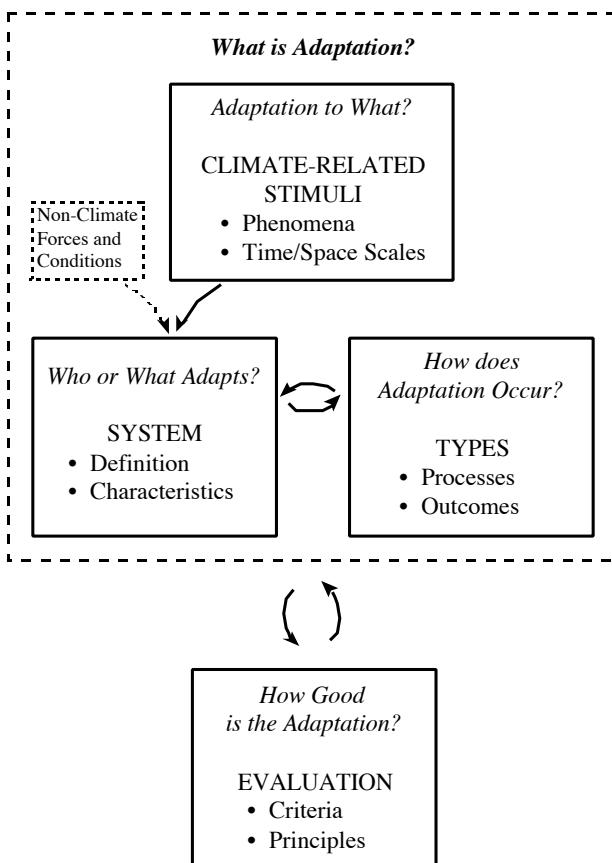

Figure 18-2: Adaptation to climate change and variability (from Smit *et al.*, 2000).

and Smit *et al.* (2000) in a broad interpretation of adaptation to include adjustment in natural or human systems in response to experienced or future climatic conditions or their effects or impacts—which may be beneficial or adverse.

18.2.1. Components and Forms of Adaptation

As both a process and a condition, adaptation is a relative term: It involves an alteration in something (the system of interest, activity, sector, community, or region) to something (the climate-related stress or stimulus). Description of an adaptation requires specification of who or what adapts, the stimulus for which the adaptation is undertaken, and the process and form it takes (Downing *et al.*, 1997; Krankina *et al.*, 1997; UNEP, 1998; Pittock *et al.*, 1999; Risbey *et al.*, 1999; Reilly and Schimmelpfennig, 2000). These elements are summarized in Figure 18-2 and addressed in turn in subsequent subsections.

18.2.2. Climate Stimuli for Adaptation

Most impact and adaptation studies to date have been based on climate change scenarios that provide a limited set of possible future climates—inevitably specified as average annual conditions, such as temperature and moisture. Yet the climate change-related stimuli for which adaptations are undertaken (i.e., adaptation to what?) are not limited to changes in average annual conditions; they include variability and associated extremes. Climatic conditions are inherently variable, from year to year and decade to decade. Variability goes along with, and is an integral part of, climate change (Mearns *et al.*, 1997; Karl and Knight, 1998; Berz, 1999; Hulme *et al.*, 1999): A change in mean conditions actually is experienced through changes in the nature and frequency of particular yearly conditions, including extremes (see Figure 18-3). Thus, adaptation to climate change necessarily includes adaptation to variability (Hewitt and Burton, 1971; Parry, 1986; Kane *et al.*, 1992b; Katz and Brown, 1992; Downing, 1996; Yohe *et al.*, 1996; Smithers and Smit, 1997; Smit *et al.*, 1999). Downing *et al.* (1996), Etkin (1998), Mileti (1999), and others use the term “climate hazards” to capture those climate stimuli, in addition to changes in annual averages, to which the system of interest is vulnerable. Climate change stimuli are described in terms of “changes in mean climate and climatic hazards,” and adaptation may be warranted when either of these changes has significant consequences (Downing *et al.*, 1997). In water resource management, changes in the recurrence interval of extreme conditions, which are associated with changes in means, are the key stimuli (Beran and Arnell, 1995; Kundzewicz and Takeuchi, 1999).

Furthermore, for most systems and communities, changes in the mean condition commonly fall within the coping range (see Figure 18-3), whereas many systems are particularly vulnerable to changes in the frequency and magnitude of extreme events or conditions outside the coping range (Baethgen, 1997; Schneider, 1997; Rayner and Malone, 1998; Kelly and Adger,

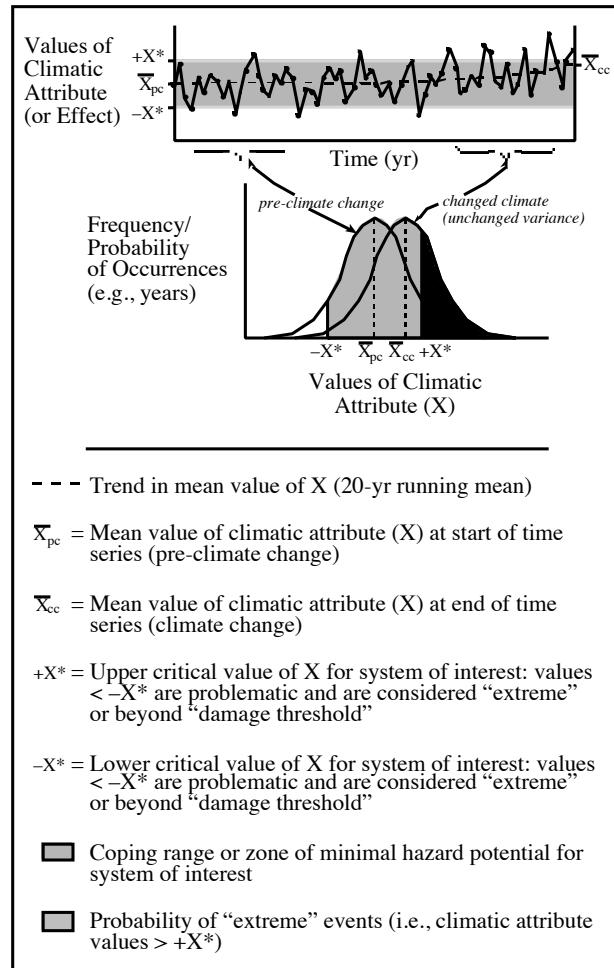

Figure 18-3: Climate change, variability, extremes, and coping range (after Hewitt and Burton, 1971; Fukui, 1979; Smit *et al.*, 1999; and others).

1999). Interannual variations are key stimuli in many sectors (Rosenzweig, 1994; Adams *et al.*, 1995; Mearns *et al.*, 1997; Bryant *et al.*, 2000).

Natural and human systems have adapted to spatial differences in climate. There also are examples of adaptation (with varying degrees of success) to temporal variations—notably, deviations from the annual average conditions on which climate change scenarios focus. Many social and economic systems—including agriculture, forestry, settlements, industry, transportation, human health, and water resource management—have evolved to accommodate some deviations from “normal” conditions, but rarely the extremes. This capacity of systems to accommodate variations in climatic conditions from year to year is captured in Figure 18-3 in the shaded “coping range.” This capacity also is referred to as the vulnerability or damage threshold (Pittock and Jones, 2000). The coping range, which varies among systems and regions, need not remain static, as depicted in Figure 18-3. The coping range itself may change (move up or down, expand

or contract), reflecting new adaptations in the system (De Vries, 1985; de Freitas, 1989; Smit *et al.*, 2000). The coping range indicated in Figure 18-3 can be regarded as the adaptive capacity of a system to deal with current variability. Adaptive capacity to climate change would refer to both the ability inherent in the coping range and the ability to move or expand the coping range with new or modified adaptations. Initiatives to enhance adaptive capacity (Section 18.6) would expand the coping range.

18.2.3. Adaptation Types and Forms

Adaptations come in a huge variety of forms. Adaptation *types* (i.e., how adaptation occurs) have been differentiated according to numerous attributes (Carter *et al.*, 1994; Stakhiv, 1994; Bijlsma *et al.*, 1996; Smithers and Smit, 1997; UNEP, 1998; Leary, 1999; Bryant *et al.*, 2000; Reilly and Schimmelpfennig, 2000). Commonly used distinctions are purposefulness and timing. Autonomous or spontaneous adaptations are considered to be those that take place—invariably in reactive response (after initial impacts are manifest) to climatic stimuli—as a matter of course, without the directed intervention of a public agency. Estimates of these autonomous adaptations are now used in impact and vulnerability assessment. Planned adaptations can be either reactive or anticipatory (undertaken before impacts are apparent). In addition, adaptations can be short or long term, localized or widespread, and they can serve various functions and take numerous forms (see Table 18-1).

Adaptations have been distinguished according to individuals’ choice options as well, including “bear losses,” “share losses,” “modify threats,” “prevent effects,” “change use,” and “change location” (Burton *et al.*, 1993; Rayner and Malone, 1998). The choice typology has been extended to include the role of community structures, institutional arrangements, and public policies (Downing *et al.*, 1997; UNEP, 1998; see Figure 18-4).

18.2.4. Systems, Scales, and Actors

Adaptations occur in something (i.e., who or what adapts?), which is called the “system of interest,” “unit of analysis,” “exposure unit,” “activity of interest,” or “sensitive system” (Carter *et al.*, 1994; Smithers and Smit, 1997; UNEP, 1998; Reilly and Schimmelpfennig, 2000). In *unmanaged natural systems*, adaptation is autonomous and reactive and is the means by which species and communities respond to changed conditions. In these situations, adaptation assessment is essentially equivalent to natural system impact assessment (addressed in other WGII chapters). This chapter focuses on adaptations consciously undertaken by *humans*, including those in economic sectors, settlements, communities, regions, and managed ecosystems.

Human system adaptation can be motivated by private or public interest (i.e., who adapts?). *Private* decisionmakers include individuals, households, businesses, and corporations; *public* interests are served by governments at all levels. The roles of

public and private participants are distinct but not unrelated. Figure 18-5 shows examples of types of adaptation differentiated according to timing, natural or human systems, and public or private decisionmakers.

Planned adaptation often is interpreted as the result of a deliberate policy decision on the part of a public agency, based on an awareness that conditions are about to change or have changed and that action is required to minimize losses or benefit from opportunities (Pittock and Jones, 2000). Autonomous adaptations are widely interpreted as initiatives by private actors rather than by governments, usually triggered by market or welfare changes induced by actual or anticipated climate change (Leary, 1999). Smith *et al.* (1996) describe autonomous adaptations as those that occur “naturally,” without interventions by public agencies, whereas planned adaptations are called “intervention strategies.” Thus defined, autonomous and planned adaptation largely correspond with private and public adaptation, respectively (see Figure 18-5).

The extent to which society can rely on autonomous, private, or market adaptation to reduce the costs of climate change impacts to an acceptable or nondangerous level is an issue of great interest. Autonomous adaptation forms a baseline against which the need for planned anticipatory adaptation can be evaluated.

Distinguishing among the various decisionmakers involved in adaptation is important. The case of African agriculture and water resources illustrates that stakeholders and potential adapters range from vulnerable consumers to international organizations charged with relief and research (Eele, 1996; Magadza, 1996; Downing *et al.*, 1997). Poor and landless households have limited resources, yet failure to adapt can lead to significant deprivation, displacement, morbidity, and mortality. Subsistence farmers do not have the same adaptation options as commercial producers. Water supply adaptations may involve landowners, private traders, local authorities, water-dependent businesses, national governments, and international organizations. Each stakeholder has distinct interests, information, risks, and resources and hence would consider distinct types of adaptive responses (Downing *et al.*, 1997).

18.2.5. Processes and Evaluation of Adaptations

In order to predict autonomous adaptations and provide input to adaptation policies, there is a need for improved knowledge about processes involved in adaptation decisions. This knowledge includes information on steps in the process, decision rationales, handling of uncertainties, choices of adaptation types and timing, conditions that stimulate or dampen adaptation, and the consequences or performance of adaptation strategies or

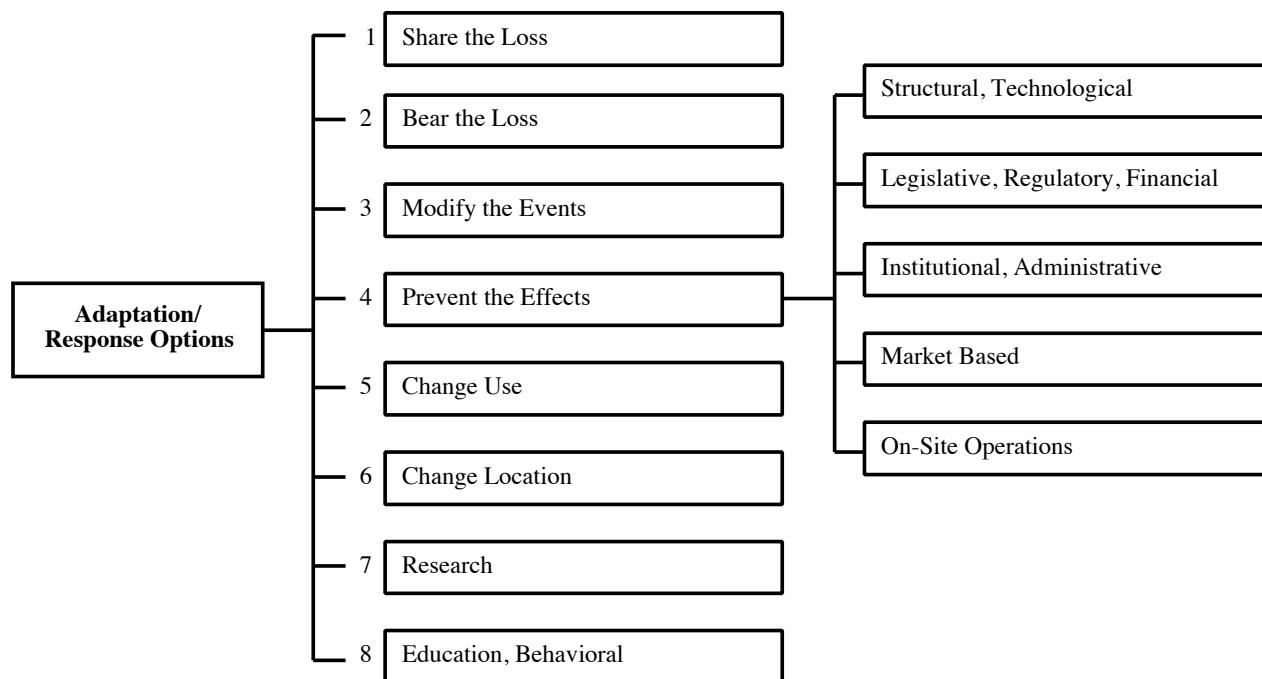

Figure 18-4: Classification of adaptation options (Burton, 1996).

measures (Burton, 1997; Rayner and Malone, 1998; Tol *et al.*, 1998; Basher, 1999; Klein *et al.*, 1999; Pittock, 1999; Smit *et al.*, 1999).

Decisions regarding adaptations can be undertaken at any of several scales, by private individuals, local communities or institutions, national governments, and international organizations. Where these adaptations are consciously planned activities, whether by public agencies or individuals, there is an interest in assessing the performance or relative merits of alternative measures and strategies (see Figure 18-4). This *evaluation* (i.e., how good is the adaptation?) can be based on criteria such as costs, benefits, equity, efficiency, and implementability (see Sections 18.3.5 and 18.4.3).

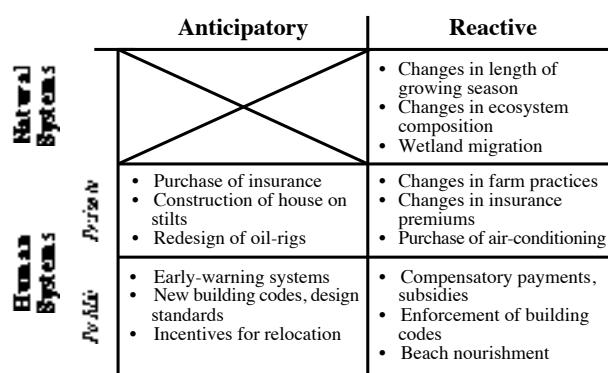

Figure 18-5: Types of adaptation to climate change, including examples (from Klein, 1999).

18.3. Future Adaptations

Predictions or estimates of likely future adaptations are an essential element of climate change impact and vulnerability assessment. The degree to which a future climate change risk is dangerous depends greatly on the likelihood and effectiveness of adaptations in that system. Studies that ignore or assume no adaptation are likely to overestimate residual or net impacts and vulnerabilities, whereas those that assume full and effective adaptation are likely to underestimate residual impacts and vulnerabilities (Reilly, 1999; Reilly and Schimmelpfennig, 1999; Risbey *et al.*, 1999; Smit *et al.*, 2000). Hence, it is important to have an improved understanding of the process of adaptation and better information on the conditions under which adaptations of various types are expected to occur. Such scholarship on the “how, when, and why” of adaptation is necessary to make informed judgments on the vulnerabilities of sectors, regions, and communities (Ausubel, 1991a; Kane *et al.*, 1992a; Reilly, 1995; Burton, 1997; Smithers and Smit, 1997; Tol *et al.*, 1998; Klein *et al.*, 1999). Insights into processes of adaptation have been gained from several types of analysis, including listing of possible adaptation measures, impact assessment models, adaptation process models, historical and spatial analogs, and empirical analysis of contemporary adaptation processes.

18.3.1. Possible Adaptation Measures

There are many arbitrary lists of possible adaptation measures, initiatives, or strategies that have a potential to moderate impacts,

Table 18-2: Examples of multilevel adaptive measures for some anticipated health outcomes of global climate change (Patz, 1996).

Adaptive Measure	Heat-Related Illness	Vector-Borne Diseases	Health and Extreme Weather Events
Administrative/legal	<ul style="list-style-type: none"> – Implement weather watch/warning systems – Plant trees in urban areas – Implement education campaigns 	<ul style="list-style-type: none"> – Implement vaccination programs – Enforce vaccination laws – Implement education campaigns to eliminate breeding sites 	<ul style="list-style-type: none"> – Create disaster preparedness programs – Employ land-use planning to reduce flash floods – Ban precarious residential placements
Engineering	<ul style="list-style-type: none"> – Insulate buildings – Install high-albedo materials for roads 	<ul style="list-style-type: none"> – Install window screens – Release sterile male vectors 	<ul style="list-style-type: none"> – Construct strong seawalls – Fortify sanitation systems
Personal behavior	<ul style="list-style-type: none"> – Maintain hydration – Schedule work breaks during peak daytime temperatures 	<ul style="list-style-type: none"> – Use topical insect repellents – Use pyrethroid-impregnated bed nets 	<ul style="list-style-type: none"> – Heed weather advisories

if they were implemented (e.g., Benioff *et al.*, 1996; Smith *et al.*, 1996; Mimura, 1999b). Such *possible* adaptations are based on experience, observation, and speculation about alternatives that might be created (Carter, 1996); they cover a wide range of types and take numerous forms (UNEP, 1998). For example, possible adaptive measures for health risks associated with climate change listed by Patz (1996) appear in Table 18-2.

Similarly, in coastal zone studies, comprehensive lists of potential adaptation measures are presented; these adaptations include a wide array of engineering measures, improvements, or changes, including agricultural practices that are more flood-resistant; negotiating regional water-sharing agreements; providing efficient mechanisms for disaster management; developing desalination techniques; planting mangrove belts to provide flood protection; planting salt-tolerant varieties of vegetation; improving drainage facilities; establishing setback policies for new developments; developing food insurance schemes; devising flood early warning systems; and so forth (Al-Farouq and Huq, 1996; Jallow, 1996; Rijsberman and van Velzen, 1996; Teves *et al.*, 1996; Mimura and Harasawa, 2000). In many other sectors and regions, arbitrary lists of possible adaptations are common (Erda, 1996; Iglesias *et al.*, 1996). In the Canadian agricultural sector alone, 96 different adaptation measures have been identified, as summarized in Table 18-3.

Such lists indicate the range of strategies and measures that represent possible adaptations to climate change risks in particular sectors and regions. They show that there is a large variety and number of possible adaptations, including many with the potential to reduce adverse climatic change impacts. Many of these adaptations—especially in agriculture, water resources, and coastal zone applications—essentially represent improved resource management, and many would have benefits in dealing with current climatic hazards as well as with future climatic risks (El Shaer *et al.*, 1996; Harrington, 1996; Huang,

1996; Stakhiv, 1996; Frederick, 1997; Hartig *et al.*, 1997; Mendelsohn and Bennett, 1997; Major, 1998). In only a few cases are such lists of possible adaptations considered according to who might undertake them, under what conditions might they be implemented, and how effective might they be (Easterling, 1996; Harrington, 1996; Frederick, 1997; Major, 1998; Moss, 1998).

18.3.2. Impact Assessment Models

Estimates of likely future adaptations are essential parts of climate change impact models. Integrated assessment models also include assumptions about adaptations in the impact

Table 18-3: Adaptation strategies for the agricultural sector (adapted from Smit, 1993; Carter, 1996).

Adaptation Strategy	Number of Measures
Change topography of land	11
Use artificial systems to improve water use/availability and protect against soil erosion	29
Change farming practices	21
Change timing of farm operations	2
Use different crop varieties	7

Research into new technologies	10

components (Leemans, 1992; Rotmans *et al.*, 1994; Dowlatabadi, 1995; Hulme and Raper, 1995; West and Dowlatabadi, 1999). Some early studies of impacts assumed no adaptation (Tol *et al.*, 1998), invoking the so-called “naïve” or “dumb farmer” assumption. The “dumb farmer” assumption—which is not unique to agriculture—is a metaphor for any impacted agent that is assumed not to anticipate or respond to changed climate conditions but continues to act as if nothing has changed (Rosenberg, 1992; Easterling *et al.*, 1993; Smit *et al.*, 1996). By ignoring autonomous and planned adaptations, such studies do not distinguish between potential and residual net impacts and are of limited utility in assessing vulnerability.

An alternative approach that is common in more recent impact modeling has been to assume levels of adaptation. Applications include Nicholls and Leatherman (1995) for coastal zones, Mendelsohn *et al.* (1994) and Rosenzweig and Parry (1994) for agriculture, Sohngen and Mendelsohn (1998) for timber, and Rosenthal *et al.* (1995) for space conditioning in buildings. These studies demonstrate that adaptive measures have the potential to significantly alleviate adverse impacts of climate change and to benefit from opportunities associated with changed climatic conditions (Helms *et al.*, 1996; Schimmelpfennig, 1996; Mendelsohn and Neumann, 1999). The models of Rosenzweig and Parry (1994) show that, with adaptations assumed, food production could be increased under climate change in many regions of the world. Stuczyński *et al.* (2000) conclude that climate change would reduce Polish agriculture production by 5–25% without adaptation; with adaptation assumed, production is estimated to change by –5 to +5% of current levels. Downing (1991) demonstrates the potential of adaptations to reduce food deficits in Africa from 50 to 20%. Mendelsohn and Dinar (1999) estimate that private adaptation could reduce potential climate damages in India’s agriculture from 25 to 15–23%. Reilly *et al.* (1994) estimate global “welfare” losses in the agri-food sector of between US\$0.1 billion and 61.2 billion without adaptation, compared to +US\$70 to –37 billion with adaptation assumed. These studies indicate *potential* rather than the *likelihood* of adaptation to alleviate damages (or benefit from opportunities) associated with changes in climatic mean conditions (rather than changing conditions that include variability and extremes of climate).

Impact models invariably are based on climate scenarios that focus on adaptation to changed average conditions, with little attention given to interannual variations and extremes. Limited research suggests that the potential of adaptation to cope with changes in average conditions is greater than its potential to cope with climate change-related variability. For example, Mendelsohn *et al.* (1999) show that, assuming adaptation, increases in average temperature would be beneficial for U.S. agriculture, but increases in interannual variation would be harmful. West and Dowlatabadi (1999) demonstrate that considering variability and extremes can lead to estimates of “optimal” adaptation and damages that differ considerably from those based on gradual changes in mean climatic conditions. The importance of considering variability, not just mean climate, when estimating adaptation is widely recognized (Robock *et*

al., 1993; Mearns *et al.*, 1997; Alderwish and Al-Eryani, 1999; Alexandrov, 1999; Luo and Lin, 1999; Murdiyarso, 2000).

In numerical impact models, assumptions about perception and adaptation are more commonly arbitrary or based on principles of efficiency and rationality and assume full information (Yohe *et al.*, 1996; Hurd *et al.*, 1997; Mendelsohn *et al.*, 1999). As Tol *et al.* (1998), Schneider *et al.* (2000), and others have noted, however, actual and assumed behavior do not necessarily match. In an analysis of global food production, Parry *et al.* (1999) assume farm-level and economic system adaptations but recognize that the “adoption of efficient adaptation techniques is far from certain.” In addition to questions relating to rationality principles, adaptation behavior is known to vary according to the amount and type of information available, as well as the ability to act. Hence, rational behavior that is based on assumed perfect information differs from rational behavior under uncertainty (Yohe *et al.*, 1996; Yohe and Neumann, 1997; West and Dowlatabadi, 1999). Replacing the “no adaptation” model with one that assumes rational, unconstrained actors with full information replaces the “dumb farmer” assumption with the “clairvoyant farmer” assumption (Smit *et al.*, 1996; Risbey *et al.*, 1999). Reilly (1998) questions the ability and hence the likelihood of agents to detect and respond efficiently to the manifestations of climate change. Tol (1998b) also questions whether perfect foresight and rational behavior are realistic assumptions for predictive models. Schneider (1997) explores further the assumptions that underlie equilibrium approaches (ergodic economics), including the equivalence of temporal and spatial variations.

Numerical impact assessment models tend to *use*, rather than *generate*, information on adaptations to estimate future impacts of climate stimuli, after the effects of adaptation have been factored in. They indicate the potential of human systems to adapt autonomously and thus to moderate climate change damages.

18.3.3. Models, Analogs, and Empirical Analysis of Autonomous Adaptation

Adaptation to rapid anthropogenic climate change may be a new challenge, but individuals, societies, and economies have adapted—in various ways and with various degrees of success—to changed and variable environmental conditions throughout history. These experiences in adaptive behavior provide information on the processes, constraints, and consequences of adaptations.

Knowledge of the processes by which individuals or communities actually adapt to changes in conditions over time comes largely from analog and other empirical analyses (Wigley *et al.*, 1981; Glantz, 1996; Meyer *et al.*, 1998; Tol *et al.*, 1998; Smit *et al.*, 1999; Yohe and Dowlatabadi, 1999; Bryant *et al.*, 2000). These studies indicate that autonomous adaptations tend to be incremental and ad hoc, to take multiple forms, to be in response to multiple stimuli (usually involving a particular catalyst and rarely climate alone), and to be constrained by

economic, social, technological, institutional, and political conditions.

Conceptual models of adaptation processes describe sequential relationships and feedback involving climatic and nonclimatic stimuli, system sensitivities and impacts, tactical and strategic adaptations, and net or residual impacts. They also indicate conditions that constrain or facilitate various kinds of adaptation (e.g., Carter, 1996; Smit *et al.*, 1996; UNEP, 1998; Schneider *et al.*, 2000). Spatial analogs have been used to gain insight into adaptation, by transferring experience from existing climatic regions to places where such climate may be found in the future. The contributions and limits of spatial analogs are known (Schneider, 1997; Rayner and Malone, 1998). Some ecological and paleoecological studies reconstruct species or community dynamics over hundreds and thousands of years (e.g., MacDonald *et al.*, 1993).

Temporal analog or case studies document adaptive responses to climatic stimuli in resource-based economic sectors and communities over periods of several decades (e.g., Glantz, 1988; Olsthoorn *et al.*, 1996; Changnon *et al.*, 1997). Other empirical analyses have examined adaptive behavior in key sectors such as agriculture in light of climatic variability and extremes over even shorter time periods (e.g., Appendi and Liverman, 1996; Smit *et al.*, 1997; Bryant *et al.*, 2000).

These direct empirical analyses of adaptation processes tend to start with the system of interest, then assess its sensitivity and adaptability to climate and other stimuli. This analytical strategy is consistent with vulnerability assessment (Downing *et al.*, 1996; Adger, 1999; Handmer *et al.*, 1999; Kelly and Adger, 1999), the “adjoint approach” (Parry, 1986), and “shift-in-risk” perspectives (Warrick *et al.*, 1986). These studies have yielded some important insights about adaptation.

For systems such as agriculture, forestry, water resources, and coastal zone settlements, the key climatic stimuli are not average conditions but variability and extremes. A direct climatic condition prompts adaptation less often than the economic and social effects or implications of the climatic stimuli that are fundamental in triggering adaptive responses. Nonclimatic conditions are important in moderating and sometimes overwhelming the influence of climate stimuli in the decisionmaking of resource users. Decisions on adaptation are rarely made in response to climate stimuli alone. These findings are important for predicting autonomous adaptations and for improving adaptation assumptions in impact models.

In estimating future adaptations and developing adaptation policies (see Section 18.4), it is helpful to understand factors and circumstances that hinder or promote adaptation. As Rayner and Malone (1998) conclude, the consequences of a climate event are not direct functions of its physical characteristics; they also are functions of “the ways in which a society has organized its relation to its resource base, its relations with other societies, and the relations among its members.” To understand vulnerability in archeological, historical, and contemporary

contexts, Rayner and Malone (1998) identify the most promising research strategy:

“...explicitly to focus attention on the process of adaptation—or, on the other hand, of failure to adapt—that partly condition the impact of the climatic stress in particular societies...cases in which societies appear to have been seriously damaged by, or even totally succumbed to, climatic stress should not be taken to demonstrate the determining influence of climate. It is essential to consider ways in which these societies might have coped better, and to focus on the political, cultural, and socioeconomic factors which inhibited them from doing so” (Ingram *et al.*, 1981).

Following this approach, McGovern’s (1991) reexamination of the extinction of Greenland settlements found that the stress imposed by climate shifts was indeed severe but was within the theoretical ability of the colonies to have coped, by means that were available to them. Why they failed to employ those adaptive means emerges as the key question, still incompletely answered, in explaining the collapse: “It did get cold and they did die out, but why?” (McGovern, 1991). Intervening between the physical events and the social consequences is the adaptive capacity and hence vulnerability of the society and its different groups and individual members.

18.3.4. Costs of Autonomous Adaptation

As assessments of climate impacts (commonly measured as “costs” that include damages and benefits) increasingly have incorporated expected adaptations, and particularly as impact models and “integrated assessment” models have shown the potential of adaptation to offset initial impact costs, interest has grown in calculating the costs of autonomous adaptations. Whether climate change or another climate stimulus is expected to have problematic or “dangerous” impacts depends on the adaptations and their costs (Leary, 1999). Climate change impact cost studies that assume adaptation also should include the “adjustment of costs” of these adaptations (Reilly, 1998).

Tol and Fankhauser (1997) provide a comprehensive summary of analyses of the costs of autonomous, mainly (but not exclusively) reactive adaptations, undertaken privately (i.e., not adaptation policies of government). A common basis for evaluating impact costs is to sum adaptation costs and residual damage costs (Fankhauser, 1996; Rothman *et al.*, 1998). Procedures for defining and calculating such adaptation costs are subject to ongoing debate. Tol and Fankhauser (1997) note that most approaches consider equilibrium adaptation costs but ignore transition costs. Hurd *et al.* (1997) include market and nonmarket adaptation in their assessment of impact costs. Most research to date on adaptation “costs” is limited to particular economic measures of well-being (Brown, 1998). Any comprehensive assessment of adaptation costs (including benefits) would consider not only economic criteria but also social welfare and equity.

Cost estimation for autonomous adaptations is not only important for impact assessment; it also is a necessary ingredient in the “base case,” “reference scenario,” or “do-nothing option” for evaluations of policy initiatives, with respect to both adaptation and mitigation (Rayner and Malone, 1998; Leary, 1999; Smit *et al.*, 2000).

18.3.5. Lessons from Adaptation Experiences

Research in many sectors and regions indicates an impressive human capacity to adapt to long-term mean climate conditions but less success in adapting to extremes and to year-to-year variations in climatic conditions. Climate change will be experienced via conditions that vary from year to year, as well as for ecosystems (Sprengers *et al.*, 1994) and human systems (Downing *et al.*, 1996); these variations are important for adaptation. Thus, although human settlements and agricultural systems, for example, have adapted to be viable in a huge variety of climatic zones around the world, those settlements and systems often are vulnerable (with limited adaptive capacity) to temporal deviations from normal conditions (particularly extremes). As a result, adaptations designed to address changed mean conditions may or may not be helpful in coping with the variability that is inherent in climate change.

All socioeconomic systems (especially climate-dependent systems such as agriculture, pastoralism, forestry, water resources, and human health) are continually in a state of flux in response to changing circumstances, including climatic conditions. The evidence shows that there is considerable potential for adaptation to reduce the impacts of climate change and to realize new opportunities. In China’s Yantze Valley, 18th-century regional expansions and contractions on the double-cropping system for rice represented adaptive responses to the frequency of production successes and failures associated with climatic variations (Smit and Cai, 1996). Adaptation options occur generally in socioeconomic sectors and systems in which the turnover of capital investment and operating costs is shorter and less often where long-term investment is required (Yohe *et al.*, 1996; Sohngen and Mendelsohn, 1998).

Although an impressive variety of adaptation initiatives have been undertaken across sectors and regions, the responses are not universally or equally available (Rayner and Malone, 1998). For example, the viability of crop insurance depends heavily on the degree of information, organization, and subsidy available to support it. Similarly, the option of changing location in the face of hazard depends on the resources and mobility of the affected part and on the availability and conditions in potential destination areas (McGregor, 1993). Many response strategies have become less available; many others have become more available. Individual cultivator response to climate risk in India has long relied on a diverse mix of strategies, from land use to outside employment (sometimes requiring temporary migration) to reciprocal obligations for support; many of these strategies have been undermined by changes such as population

pressure and government policy, without being fully replaced by others—illustrating the oft-remarked vulnerability of regions and populations in transition (Gadgil *et al.*, 1988; Johda, 1989). In areas of China, many historical adaptations in agriculture (e.g., relocating production or employing irrigation) are no longer available as population pressures increase on limited land and water resources (Fang and Liu, 1992; Cai and Smit, 1996). In Kenya, effective smallholder response to drought has shifted from traditional planting strategies to employment diversification (Downing *et al.*, 1989).

Not only is there rarely only one adaptation option available to decisionmakers (Burton and Cohen, 1993) but also “rarely do people choose the best responses—the ones among those available that would most effectively reduce losses—often because of an established preference for, or aversion to, certain options” (Rayner and Malone, 1998). In some cases there is limited knowledge of risks or alternative adaptation strategies. In other cases, adoption of adaptive measures is constrained by other priorities, limited resources, or economic or institutional barriers (Eele, 1996; Bryant *et al.*, 2000; de Loë and Kreutzwiser, 2000). Recurrent vulnerabilities, in many cases with increasing damages, illustrate less-than-perfect adaptation of systems to climatic variations and risks. There is some evidence that the costs of adaptations to climate conditions are growing (Burton, 1997; Etkin, 1998). There is strong evidence of a sharp increase in damage costs of extreme climatic or weather events (Berz, 1999; Bruce, 1999). Growing adaptation costs reflect, at least in part, increases in populations and/or improvements in standards of living, with more disposable income being used to improve levels of comfort, health, and safety in the short run. It is not clear whether the expansion in adaptations is likely to be effective and sustainable in the long run. In any event, although adaptations to changed and variable climatic conditions are undertaken, they are not necessarily effective or without costs.

Many adaptations to reduce vulnerability to climate change risks also reduce vulnerability to current climate variability, extremes, and hazards (El Shaer *et al.*, 1996; Rayner and Malone, 1998). Measures that are likely to reduce current sensitivity of climate variations in Africa also are likely to reduce the threat of adverse impacts of climate change (Ominde and Juna, 1991):

“Most analysts in the less-developed countries believe that the urgent need, in the face of both climate variation and prospective climate change, is to identify policies which reduce recurrent vulnerability and increase resilience. Prescriptions for reducing vulnerability span drought-proofing the economy, stimulating economic diversification, adjusting land and water uses, providing social support for dependent populations, and providing financial instruments that spread the risk of adverse consequences from individual to society and over longer periods. For the near term, development strategies should ensure that livelihoods are resilient to a wide range of perturbations.” (Rayner and Malone, 1998)

Examples of current adaptation strategies in agriculture with clear applications to climate change are given by Easterling (1996) and Smit *et al.* (1997), including moisture-conserving practices, hybrid selection, and crop substitution. In the water resources sector, Stakhiv (1996) shows how current management practices represent useful adaptive strategies for climate change. Some analysts go further to point out that certain adaptations to climate change not only address current hazards but may be additionally beneficial for other reasons (e.g., “no regrets” or “win-win” strategies) (Carter, 1996).

Societal responses to large environmental challenges tend to be incremental and ad hoc rather than fundamental (Rayner and Malone, 1998). In all of the climate analog cases examined by Glantz (1988), “Ad hoc responses were favored over long term planned responses. As a result, there has been a tendency to ‘muddle through.’ This has not necessarily been an inappropriate response, but it is probably more costly in the long term than putting a long-term strategy together in order to cope with climate-related environmental change.” In each case, moreover, action was not taken without a catalyst or trigger that dramatically indicated the seriousness of a threat (Glantz, 1988). Other studies also indicate the ad hoc nature of adaptations and the importance of a catalyst (Wilhite *et al.*, 1986; Glantz, 1992; Kasperson *et al.*, 1995). These findings suggest that problems that demand early or long-term attention often fail to receive it, and the most efficient responses are not taken. That the earlier action would have been more efficacious, however, presupposes that the best strategy was evident to the decisionmakers and that premature responses closing off useful options would not have been taken instead (Rayner and Malone, 1998). There is little evidence that efficient and effective adaptations to climate change risks will be undertaken autonomously.

A consistent lesson from adaptation research is that climate is not the singular driving force of human affairs that is sometimes assumed—but neither is it a trivial factor. Climate is an important resource for human activities and an important hazard. Climate change is a source of significant stresses (and perhaps significant opportunities) for societies, yet it has always been only one factor among many. The consequences of a shift in climate are not calculable from the physical dimensions of the shift alone; they require attention to human dimensions through which they are experienced (Rayner and Malone, 1998; Bryant *et al.*, 2000). The significance of climate change for regions depends fundamentally on the ability and likelihood of those regions to adapt.

To what degree are societies likely to adapt autonomously to avoid climate change damages? Some studies show faith in market mechanisms and suggest considerable capacity of human systems to adapt autonomously (Ausabel, 1991b; Mendelsohn *et al.*, 1996; Yohe *et al.*, 1996; Mendelsohn, 1998; Mendelsohn and Neumann, 1999). Other studies highlight the constraints on “optimal” autonomous adaptation, such as limited information and access to resources, adaptation costs, and residual damages; these studies emphasize the need for planned, especially anticipatory, adaptations undertaken or

facilitated by public agencies (Smith *et al.*, 1996; Reilly, 1998; Tol, 1998a; Fankhauser *et al.*, 1999; Bryant *et al.*, 2000; Schneider *et al.*, 2000)

18.4. Planned Adaptations and Evaluation of Policy Options

This section considers *planned*, mainly (but not exclusively) *anticipatory* adaptations, undertaken or directly influenced by governments or collectives as a public policy initiative. These adaptations represent conscious policy options or response strategies to concerns about climate change (Benioff *et al.*, 1996; Fankhauser, 1996; Smith, 1997; Pielke, 1998; UNEP, 1998). Public adaptation initiatives may be direct or indirect, such as when they encourage or facilitate private actions (Leary, 1999). Planned adaptation by public agencies represents an alternative or complementary response strategy to mitigation (of net GHG emissions). Analyses of such planned adaptations are essentially normative exercises involving identification of possible policy strategies and evaluation of the relative merit of alternatives, as an aid to policy development.

18.4.1. Rationale and Objectives for Planned Adaptations

Numerous reasons have been given for pursuing planned adaptations at this time (see Table 18-4). Public adaptation initiatives are regarded not as a substitute for reducing GHG emissions but as a necessary strategy to manage the impacts of climate change (Burton, 1996; Pielke, 1998). Adaptation can yield benefits regardless of the uncertainty and nature of climate change (Ali, 1999). Fankhauser *et al.* (1998) and Leary (1999) outline rationales for public adaptation policies or projects relative to relying on private actions. Leary concludes that “we

Table 18-4: Six reasons to adapt to climate change now (Burton, 1996).

-
- 1) Climate change cannot be totally avoided.
 - 2) Anticipatory and precautionary adaptation is more effective and less costly than forced, last-minute, emergency adaptation or retrofitting.
 - 3) Climate change may be more rapid and more pronounced than current estimates suggest. Unexpected events are possible.
 - 4) Immediate benefits can be gained from better adaptation to climate variability and extreme atmospheric events.
 - 5) Immediate benefits also can be gained by removing maladaptive policies and practices.
 - 6) Climate change brings opportunities as well as threats. Future benefits can result from climate change.
-

cannot rely solely or heavily on autonomous adjustments of private agents to protect public goods and should examine public policy responses to do so.” Planned anticipatory adaptation, as recognized in the UNFCCC (Article 3.3), is aimed at reducing a system’s vulnerability by diminishing risk or improving adaptive capacity.

There has been work on the process by which public agencies might or should undertake planned adaptation strategies, particularly noting the steps to be followed, relationships with other policy and management objectives, and the criteria with which options might be evaluated (Louisse and Van der Meulen, 1991; Carter *et al.*, 1994; Smith and Lenhart, 1996; Stakhiv, 1996; Major and Frederick, 1997; Smith, 1997). Klein and Tol (1997) identify five generic objectives of adaptation:

- 1) Increasing robustness of infrastructural designs and long-term investments—for example, by extending the range of temperature or precipitation a system can withstand without failure and changing the tolerance of loss or failure (e.g., by increasing economic reserves or by insurance)
- 2) Increasing the flexibility of vulnerable managed systems—for example, by allowing mid-term adjustments (including change of activities or location) and reducing economic lifetimes (including increasing depreciation)
- 3) Enhancing the adaptability of vulnerable natural systems—for example, by reducing other (nonclimatic) stresses and removing barriers to migration (including establishing eco-corridors)
- 4) Reversing trends that increase vulnerability (also termed “maladaptation”—for example, by introducing setbacks for development in vulnerable areas such as floodplains and coastal zones)
- 5) Improving societal awareness and preparedness—for example, by informing the public of the risks and possible consequences of climate change and setting up early-warning systems.

18.4.2. Identification of Adaptation Policy Options

Research addressing future adaptations to climate change tends to be normative, suggesting anticipatory adaptive strategies to be implemented through public policy. Generally, such adaptation recommendations are based on forecasts of expected (though still largely unpredictable) climate change. Recommended adaptations:

- Tend to be in response to changes in *long-term mean climate*, though more specific elements of climate change (e.g., sea-level change) gain focus when sector-specific adaptations are proposed (e.g., integrated coastal zone management) (Al-Farouq and Huq, 1996; Smith *et al.*, 1996), and some studies specifically examine potential adaptations to variability and extreme events (e.g., Appendi and Liverman, 1996; Yang, 1996; Yim, 1996).

- *Range in scope* from very broad strategies for adaptation (e.g., enhancing decisionmakers’ awareness of climatic change and variability) to recommendations of sector-specific policy. Sectors receiving particular attention include water resources, coastal resources, agriculture, and forest resources (Smith and Lenhart, 1996; Smith *et al.*, 1996; Hartig *et al.*, 1997; Mendelsohn and Bennett, 1997).
- Tend to be *regionally focused* (Smith and Lenhart, 1996), in recognition of the fact that vulnerability to the impacts of climate change is highly spatially variable. There is interest in developing countries and nations with economies in transition, given their greater reliance on natural systems-based economic activity (such as agriculture) (e.g., Magalhães, 1996; Smith *et al.*, 1996; Kelly and Adger, 1999).

Because no single set of adaptive policy recommendations can be universally appropriate, several studies suggest means by which proposed adaptations may be selected and evaluated. At a very basic level, the success of potential adaptations is seen to depend on the *flexibility* or effectiveness of the measures, such as their ability to meet stated objectives given a range of future climate scenarios (through either robustness or resilience), and their potential to produce *benefits that outweigh costs* (financial, physical, human, or otherwise) (Smith and Lenhart, 1996). Clearly, these are difficult criteria to assess, given the complexity of adaptation measures, the variable sensitivities and capacities of regions, and uncertainties associated with climate change and variability. Some research (e.g., Carter, 1996; Smith and Lenhart, 1996; Smith *et al.*, 1996; de Loë and Kreutzwiser, 2000) offers supplementary characteristics of, or criteria for, the identification of adaptations:

- The measure generates benefits to the economy, environment, or society under current conditions (i.e., independent of climate change).
- The measure addresses high-priority adaptation issues such as irreversible or catastrophic impacts of climate change (e.g., species extinction), long-term planning for adaptation (e.g., infrastructure), and unfavorable trends (e.g., deforestation, which may inhibit future adaptive flexibility).
- The measure targets current areas of opportunity (e.g., land purchases, revision of national environmental action or development plans, research and development).
- The measure is feasible—that is, its adoption is not significantly constrained by institutional, social/cultural, financial, or technological barriers.
- The measure is consistent with, or even complementary to, adaptation or mitigation efforts in other sectors.

18.4.3. Evaluation of Adaptation Options and Adaptation Costs

Some very general steps for identifying and evaluating planned adaptations are given in Carter *et al.* (1994) and UNEP(1998).

Somewhat more detailed procedures for evaluating anticipatory adaptation policies in the climate change context are outlined in Smith and Lenhart (1996) and Smith (1997). This approach addresses management of institutional processes and players and proposes net benefits and implementability as central evaluative criteria. Numerous other considerations are noted, including flexibility, benefits independent of climate change ("no regrets"), local priorities, levels of risk, and time frames of decisions. From a disaster management perspective, Tol *et al.* (1996) argue that policies must be evaluated with respect to economic viability, environmental sustainability, public acceptability, and behavioral flexibility. Tol *et al.* (1999) apply these observations in an examination of adaptation to increased risk of river floods in The Netherlands. They note several possible adaptations, but none could be accomplished without creating significant distributional and/or ecological impacts. None, therefore, would be feasible without enormous political will and institutional reform. Klein and Tol (1997) and UNEP (1998) describe methodologies for evaluation, including cost-benefit, cost-effectiveness, risk-benefit, and multi-criteria methods. Multi-criteria methods to evaluate possible adaptation options have been demonstrated for coastal zones (El-Raey *et al.*, 1999) and agriculture (Mizina *et al.*, 1999).

Fankhauser (1996) provides an economic efficiency framework in which adaptation actions are considered justified as long as the additional costs of adaptation are lower than the additional benefits from the associated reduced damages. Optimal levels of adaptation (in an economic efficiency sense) are based on minimizing the sum of adaptation costs and residual damage costs. Such studies require the definition of a base case that involves estimation of autonomous adaptations. These and other normative studies (e.g., Titus, 1990; Goklany, 1995) illustrate the range of principles and methods that have been proposed for identifying, evaluating, and recommending (planned) adaptation measures.

There are, however, few comprehensive estimates of the costs of adaptation. Mimura and Harasawa (2000) report estimates

of 11.5–20 trillion Yen as the cost of maintaining the functions of Japanese infrastructure against a 1-m rise in sea level. Yohe and Schlesinger (1998) applied a cost-benefit rule to adaptation decisions across a sample of the developed coastline of the United States. With a 3% discount rate, their national estimates of the expected discounted cost of protecting or abandoning developed coastal property in response to sea-level rise that is based on a mean greenhouse emissions scenario is US\$1.3 billion with foresight and US\$1.8 billion without. Their estimates climb to more than US\$4 billion and 5 billion, respectively, along the 1-m sea-level rise scenario that matches the Mimura and Harasawa study. Between 55 and 70% of these costs were attributed to planned adaptation. The remainder reflect estimates of residual damage associated with abandoning property with and without completely efficient autonomous adaptation. Indeed, the differences between the foresight and non-foresight estimates can be regarded as estimates of the incremental cost of incomplete autonomous adaptation in advance of planned responses.

On a more local scale, Smith *et al.* (1998) report cost estimates that are clearly sensitive to design and evaluation criteria. For example, none of the five flood protection strategies for the southernmost part of the Dutch Meuse (assuming 10% more winter precipitation and a warming of 2°C) would achieve economic benefits that exceed their costs of DGL 243–1,505 million, given a 5% discount rate. Moreover, only building quays would meet the benefit-cost standard with a 5% discount rate. Nonetheless, the government chose a wildlife renovation strategy on the basis of additional benefits for nature and recreation. Smith *et al.* (1998) also report that the cost of raising the Northumberland Bridge between Prince Edward Island and New Brunswick to accommodate a 1-m sea-level rise would be US\$1 billion or 250,000, depending on whether the entire bridge or only the portion that spanned the shipping lanes were raised.

Klein *et al.* (1999) develop a conceptual framework of the process of planned adaptations, aimed at changing existing

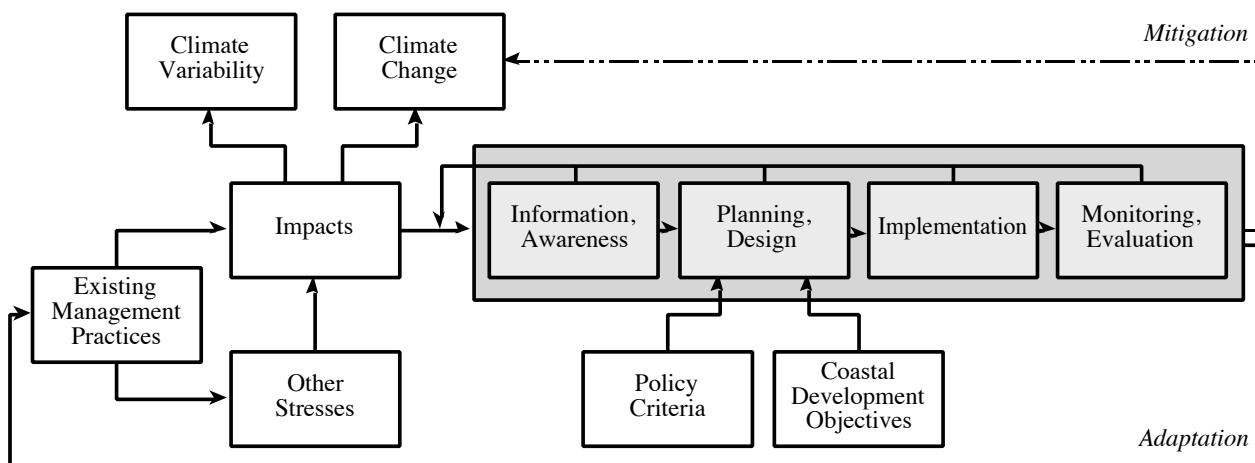

Figure 18-6: Conceptual framework showing, in shaded area, iterative steps involved in planned coastal adaptation to climate variability and change (Klein *et al.*, 1999).

management practices in coastal zones. In this model, adaptation is a continuous and iterative cycle, involving several steps: information collection and awareness raising, planning and design (incorporating policy criteria and development objectives), implementation, monitoring, and evaluation (see Figure 18-6).

18.4.4. Public Adaptation Decisions, Uncertainty, and Risk Management

Research increasingly addresses how adaptation is considered in actual policy decisionmaking. Stakhiv (1996) and Frederick (1997), dealing with the U.S. water resources sector, conclude that existing institutions and planning processes can deal with climate change; such processes essentially represent adaptive management. As in many other sectors and circumstances, adaptation to climate change hazards in the coastal zone is part of ongoing coastal zone management. Adaptation to sea-level rise and extreme climate events is being included in Japanese coastal policies (Mimura and Kawaguchi, 1997), British shoreline management (Leafe *et al.*, 1998), and Dutch law and coastal zone management (Koster and Hillen, 1995; Helmer *et al.*, 1996; Klein *et al.*, 1998).

Planning of adaptation invariably is complicated by multiple policy criteria and interests that may be in conflict (Hareau *et al.*, 1999). For example, the economically most efficient path to implement an adaptation option might not be the most effective or equitable one. Moreover, decisions have to be made in the face of uncertainty (Lempert *et al.*, 2000). Uncertainties that are pertinent to adaptation are associated with climate change itself, its associated extremes, their effects, the vulnerability of systems and regions, conditions that influence vulnerability, and many attributes of adaptations, including their costs, implementability, consequences, and effectiveness (Campos *et al.*, 1996; Lansigan *et al.*, 1997; Handmer *et al.*, 1999; Murdiyarso, 2000).

Given these uncertainties, it is not surprising that adaptation strategies frequently are described as forms of risk management. For example, adaptations to deal with climate change impacts or risks to human health can be biological (acquired immunity), individual (risk-aversion options), or social (McMichael *et al.*, 1996). Most social adaptation strategies are measures to reduce health risks via public health programs (Patz, 1996; McMichael and Kovats, 2000). Similarly, public adaptations via "disaster loss mitigation" (Bruce, 1999) are mainly risk management initiatives such as improved warning and preparedness systems, less vulnerable buildings and infrastructure, risk-averse land-use planning, and more resilient water supply systems. Nguyen *et al.* (1998), Hisschemöller and Olsthoorn (1999), and Perez *et al.* (1999) also describe adaptations to climate change and extremes as modifications to existing risk management programs. As de Loë and Kreutzwiser (2000) and others point out, it remains unclear whether practices designed for historical climatic variability will be able to cope with future variability.

To recognize these uncertainties, decision tools to help evaluate adaptation options include risk-benefit and multi-criteria analyses (Klein and Tol, 1997). Such evaluations are further complicated by the existence of secondary impacts related to the adaptation itself. For example, water development projects (adaptations to water supply risks) can have significant effects on local transmission of parasitic diseases, including malaria, lymphatic filariasis, and schistosomiasis (Hunter *et al.*, 1993; McMichael and Kovats, 2000). Improved water supply in some rural areas of Asia has resulted in a dramatic increase in Aedes mosquito breeding sites and, consequently, outbreaks of dengue (WHO, 1997). Langen and Tol (1999) provide examples of technical response options to climate hazards that are counterproductive in the longer term. Existing resource management programs do not necessarily consider changed risks or recognize local interests and inequities (Primo, 1996). Wilhite's (1996) analysis of programs in the United States, Australia, and Brazil shows the ineffectiveness of reactive crisis management approaches and the need for proactive and cooperative planning.

Nonetheless, it is widely accepted that planned adaptations to climate risks are most likely to be implemented when they are developed as components of (or as modifications to) existing resource management programs or as part of national or regional strategies for sustainable development (Campos *et al.*, 1996; Magalhães, 1996; Theu *et al.*, 1996; Mimura, 1999a; Apuuli *et al.*, 2000; Munasinghe, 2000; Osokova *et al.*, 2000).

18.5. Adaptive Capacity and its Determinants

18.5.1. Vulnerability and Adaptive Capacity

Considerable attention has been devoted to the characteristics of systems (communities or regions) that influence their propensity or ability to adapt (as part of impact and vulnerability assessment) and/or their priority for adaptation measures (as a basis for policy development). These characteristics have been called *determinants of adaptation*. Generic concepts such as sensitivity, vulnerability, susceptibility, coping range, critical levels, adaptive capacity, stability, robustness, resilience, and flexibility have been used to differentiate systems according to their likelihood, need, or ability for adaptation (Sprengers *et al.*, 1994; De Ruig, 1997; Klein and Tol, 1997; Smithers and Smit, 1997; Adger and Kelly, 1999; Kelly and Adger, 1999). These characteristics influence (promote, inhibit, stimulate, dampen, or exaggerate) the occurrence and nature of adaptations and thereby circumscribe the vulnerability of systems and their residual impacts. In the hazards literature, these characteristics are reflected in socially constructed or endogenous risks (Blaikie *et al.*, 1994; Hewitt, 1997). Together (in whole or part), they represent the adaptive capacity of a system.

Table 18-5 lists terms that are commonly used to characterize the adaptive propensity of systems to climate stimuli. There is considerable overlap in the basic concepts captured in these terms. Particular terms have been employed to distinguish

natural from socioeconomic systems or to differentiate the condition of a system before adaptation from its condition after adaptation (Klein and Nicholls, 1998). These distinctions are important and can be captured without narrowing the meaning of widely used terms. Thus, ecosystem vulnerability is different from socioeconomic vulnerability.

Adaptive capacity refers to the potential, capability, or ability of a system to adapt to climate change stimuli or their effects or impacts. Adaptive capacity greatly influences the vulnerability of communities and regions to climate change effects and hazards (Bohle *et al.*, 1994; Downing *et al.*, 1999; Kelly and Adger, 1999; Mileti, 1999; Kates, 2000). Vulnerability has been described as the “capacity to be wounded” (Kates *et al.*, 1985). Human activities and groups are considered sensitive to climate to the degree that they can be affected by it and vulnerable to the degree that they can be harmed (Rayner and Malone, 1998). Because vulnerability and its causes play essential roles in

determining impacts, understanding the dynamics of vulnerability is as important as understanding climate itself (Liverman, 1990; Handmer *et al.*, 1999).

With regard to climate change, the vulnerability of a given system or society is a function of its physical exposure to climate change effects and its ability to adapt to these conditions. Chambers (1989) distinguishes between these two aspects of differential vulnerability: physical exposure to the hazardous agent and the ability to cope with its impacts. Thus, vulnerability recognizes the role of socioeconomic systems in amplifying or moderating the impacts of climate change and “emphasizes the degree to which the risks of climate catastrophe can be cushioned or ameliorated by adaptive actions that or can be brought within the reach of populations at risk” (Downing, 1991).

The significance of climate variation or change depends on the change itself and the characteristics of the society exposed to it

Table 18-5: Terms to describe characteristics of systems that are pertinent to adaptation^a (from Smit *et al.*, 1999).

<i>Sensitivity</i>	Degree to which a system is affected by or responsive to climate stimuli (note that sensitivity includes responsiveness to both problematic stimuli and beneficial stimuli)
<i>Susceptibility</i>	Degree to which a system is open, liable, or sensitive to climate stimuli (similar to sensitivity, with some connotations toward damage)
<i>Vulnerability</i>	Degree to which a system is susceptible to injury, damage, or harm (one part—the problematic or detrimental part—of sensitivity)
<i>Impact Potential</i>	Degree to which a system is sensitive or susceptible to climate stimuli (essentially synonymous with <i>sensitivity</i>)
<i>Stability</i>	Degree to which a system is not easily moved or modified
<i>Robustness</i>	Strength; degree to which a system is not given to influence
<i>Resilience</i>	Degree to which a system rebounds, recoups, or recovers from a stimulus
<i>Resistance</i>	Degree to which a system opposes or prevents an effect of a stimulus
<i>Flexibility</i>	Degree to which a system is pliable or compliant (similar to <i>adaptability</i> , but more absolute than relative)
<i>Coping Ability</i>	Degree to which a system can successfully grapple with a stimulus (similar to <i>adaptability</i> , but includes more than adaptive means of “grappling”)
<i>Responsiveness</i>	Degree to which a system reacts to stimuli (broader than <i>coping ability</i> and <i>adaptability</i> because responses need not be “successful”)
<i>Adaptive Capacity</i>	The potential or capability of a system to adapt to (to alter to better suit) climatic stimuli or their effects or impacts
<i>Adaptability</i>	The ability, competency, or capacity of a system to adapt to (to alter to better suit) climatic stimuli (essentially synonymous with <i>adaptive capacity</i>)

^a These definitions of systems characteristics are based on widely (but not unanimously) held conventions. They focus on distinguishing generic properties and do not include factors that might influence the state of a property or the forms it might take. The terms “climate stimulus” and “system” are used as established earlier.

(Ausubel, 1991a; Rayner and Malone, 1998; Munasinghe, 2000). These characteristics of society determine its adaptive capacity and its adaptability. Adaptive capacity refers to the ability to prepare for hazards and opportunities in advance (as in anticipatory adaptation) and to respond or cope with the effects (as in reactive adaptation).

Studies of similar hazardous events recurring at different times in a given region show vastly different consequences because of societal transformations that occurred between the events. For example, rainfall and temperature fluctuations in western Europe have far milder effects on human well-being today (society generally is less vulnerable) than they did in the medieval and early modern periods, essentially as a result of enhanced adaptive capacity that reflects changes in practices, economics, and government programs (Abel, 1976; De Vries, 1977; Rayner and Malone, 1998). Similarly, particular climate events or hazards can have "vastly different consequences for those on whom they infringe because of differences in coping ability" (Rayner and Malone, 1998). An extreme climatic event will result in higher losses of life in a developing country than in a developed country because of differential adaptive capacity (Burton, *et al.*, 1993; Blaikie *et al.*, 1994; Kundzewicz and Takeuchi, 1999). Martens *et al.* (1999) describe potential adaptations to deal with increases in disease incidence associated with climate change but note that in most poor developing countries, socioeconomic, technical, and political barriers will mean that the changed health risks will not be addressed.

"In developing countries overall social, environmental, and economic vulnerability enhances the effects of droughts and other climatic events. Overpopulation (relative to current productivity, income, and natural resources), poverty, and land degradation translate into a poor capacity to face any kind of crisis. Poor people have no insurance against loss of income. Weak economic structures mean difficulties in maintaining jobs during an economic failure. Degraded marginal lands become totally unproductive when precipitation decreases. As a result, these regions have difficulty in facing climatic crises, although such crises are recurrent. Any extreme climatic event can become a social catastrophe when combined with the social-political characteristics of the region. For example, the droughts and internecine wars in Ethiopia interact to increase the adverse effects of both. Although developing regions are more vulnerable to climate changes than are developed countries, the degree of vulnerability varies in each specific region." (Magalhães, 1996)

Research on comparative adaptive capacity and vulnerability is evolving, and its difficulties are well recognized (Bohle *et al.*, 1994; Downing, 1996; Handmer *et al.*, 1999; Kelly and Adger, 1999). Estimates of adaptive capacity tend to be based on premises such as the position that highly managed systems (such as agriculture), given sufficient resources, are likely to be more adaptable (and at a lower cost) than less managed ecosystems (Strzepek and Smith, 1995; Burton, 1996; Toman and Bierbaum, 1996). It is also widely accepted that systems

with high levels of capacity to cope with historical and/or existing stresses can be expected to have high adaptive capacity for stresses associated with climatic change (Ausubel, 1991a). Such premises have formed the basis for broad assessments of sensitivity and adaptability (USNAS, 1992). Of course, sensitivity and adaptive capacity vary according to the climate change-related stress being considered. Thus, adaptive capacity to gradual changes in mean temperature may be high (or not much needed), but adaptive capacity to changes in the magnitude or frequency of extreme climatic conditions may not be so high (Appendi and Liverman, 1996).

18.5.2. Determinants of Adaptive Capacity

Adaptation to climate change and risks takes place in a dynamic social, economic, technological, biophysical, and political context that varies over time, location, and sector. This complex mix of conditions determines the capacity of systems to adapt. Although scholarship on adaptive capacity is extremely limited in the climate change field, there is considerable understanding of the conditions that influence the adaptability of societies to climate stimuli in the fields of hazards, resource management, and sustainable development. From this literature, it is possible to identify the main features of communities or regions that seem to determine their adaptive capacity: economic wealth, technology, information and skills, infrastructure, institutions, and equity.

18.5.2.1. Economic Resources

Whether it is expressed as the economic assets, capital resources, financial means, wealth, or poverty, the economic condition of nations and groups clearly is a determinant of adaptive capacity (Burton *et al.*, 1998; Kates, 2000). It is widely accepted that wealthy nations are better prepared to bear the costs of adaptation to climate change impacts and risks than poorer nations (Goklany, 1995; Burton, 1996). It is also recognized that poverty is directly related to vulnerability (Chan and Parker, 1996; Fankhauser and Tol, 1997; Rayner and Malone, 1998). Although poverty should not be considered synonymous with vulnerability, it is "a rough indicator of the ability to cope" (Dow, 1992). Holmes (1996) recognizes that Hong Kong's financial strength has contributed in the past to its ability to better manage environmental hazards through conservation and pollution control. Bohle *et al.* (1994) state that, by definition, it usually is the poor who are among the most vulnerable to famine, malnutrition, and hunger. Deschingkar (1998) describes a situation in India in which pastoralist communities are "locked into" a vulnerable situation in part because of a lack of financial power that would allow them to diversify and engage in other sources of income. At a local level, Pelling (1998) concludes that the highest levels of household vulnerability in coastal Guyana also are characterized by low household incomes in conjunction with poor housing quality and little community organization. Neighborhoods with higher levels of household income are better able to manage vulnerability

through the transfer of flood impacts from health to economic investment and loss. Kelly and Adger (1999) demonstrate the influence of poverty on a region's coping capacity; poor regions tend to have less diverse and more restricted entitlements and a lack of empowerment to adapt. There is ample evidence that poorer nations and disadvantaged groups within nations are especially vulnerable to disasters (Banuri, 1998; Munasinghe, 2000).

18.5.2.2. Technology

Lack of technology has the potential to seriously impede a nation's ability to implement adaptation options by limiting the range of possible responses (Scheraga and Grambsch, 1998). Adaptive capacity is likely to vary, depending on availability and access to technology at various levels (i.e., from local to national) and in all sectors (Burton, 1996). Many of the adaptive strategies identified as possible in the management of climate change directly or indirectly involve technology (e.g., warning systems, protective structures, crop breeding and irrigation, settlement and relocation or redesign, flood control measures). Hence, a community's current level of technology and its ability to develop technologies are important determinants of adaptive capacity. Moreover, openness to the development and utilization of new technologies for sustainable extraction, use, and development of natural resources is key to strengthening adaptive capacity (Goklany, 1995). For example, in the context of Asian agriculture and the impact of future climate change, Iglesias *et al.* (1996) note that the development of heat-resistant rice cultivars will be especially crucial. Regions with the ability to develop technology have enhanced adaptive capacity.

18.5.2.3. Information and Skills

"Successful adaptation requires a recognition of the necessity to adapt, knowledge about available options, the capacity to assess them, and the ability to implement the most suitable ones" (Fankhauser and Tol, 1997). In the context of climate variability and change, this idea may be better understood through the example of the insurance industry: As information on weather hazards becomes more available and understood, it is possible to study, discuss, and implement adaptation measures (Downing, 1996). Building adaptive capacity requires a strong, unifying vision; scientific understanding of the problems; an openness to face challenges; pragmatism in developing solutions; community involvement; and commitment at the highest political level (Holmes, 1996). Lack of trained and skilled personnel can limit a nation's ability to implement adaptation options (Scheraga and Grambsch, 1998). In general, countries with higher levels of stores of human knowledge are considered to have greater adaptive capacity than developing nations and those in transition (Smith and Lenhart, 1996). Magalhães (1996) includes illiteracy along with poverty as a key determinant of low adaptive capacity in northeast Brazil. Such findings have prompted Gupta and Hisschemöller (1997) to conclude that it is important, therefore, to ensure that systems

are in place for the dissemination of climate change and adaptation information nationally and regionally and that there are forums for discussion and innovation of adaptation strategies at various levels.

18.5.2.4. Infrastructure

Adaptive capacity is likely to vary with social infrastructure (Toman and Bierbaum, 1996). Some researchers regard the adaptive capacity of a system as a function of *availability of* and *access to* resources by decisionmakers, as well as vulnerable subsectors of a population (Kelly and Adger, 1999). For example, the Philippine island of Mindanao uses hydroelectric power to generate more than 90% of its electricity, which in turn supports local development and industry. During El Niño, drought conditions resulted in suspension of production by the hydroelectric plant and severely increased the economic vulnerability of the region (Tiglao, 1992). In the coastal area of Hong Kong, the capacity to adapt to the risk of typhoons differs for existing urban areas and for new coastal land reclamation. For existing urban areas, there is no possibility of retreat or accommodation, although during urban renewal the formation level of the ground could be raised, thereby decreasing the vulnerability of settlements (Yim, 1996). At the community level, Pelling (1997) notes that the lack of flexibility "in formal housing areas where dwelling form and drainage infrastructure were more fixed" reduced the capacity to respond to contemporary environmental conditions.

18.5.2.5. Institutions

O'Riordan and Jordan (1999) describe the role of institutions "as a means for holding society together, giving it sense and purpose and enabling it to adapt." In general, countries with well-developed social institutions are considered to have greater adaptive capacity than those with less effective institutional arrangements—commonly, developing nations and those in transition (Smith and Lenhart, 1996). The role of inadequate institutional support is frequently cited in the literature as a hindrance to adaptation. Kelly and Adger (1999) show how institutional constraints limit entitlements and access to resources for communities in coastal Vietnam and thereby increase vulnerability. Huq *et al.* (1999) demonstrate that Bangladesh is particularly vulnerable to climate change—especially in the areas of food production, settlements, and human life—reflecting serious constraints on adaptive capacity in the "existing institutional arrangements (which) is not conducive to ease the hardship of the people. Due to inherent institutional deficiencies and weaknesses in managerial capacities to cope with the anticipated natural event, it would be extremely difficult for the country to reduce vulnerability to climate change" (Ahmed *et al.*, 1999). Baethgen (1997) discusses an example in which the presence of inconsistent and unstable agricultural policies has increased the vulnerability of the food production sector in Latin America. Drastic changes in economic and policy conditions are expected to make agricultural systems

more vulnerable to changes in climate. Parrish and Funnell (1999) note that although the local agro-ecosystem in the Moroccan High Atlas region may prove resilient to climate change initially, it is possible that the need to change tenure conditions and other arrangements may create conflicts that are beyond the capacity of local institutions to resolve. Magadza (2000) shows how adaptation options in southern Africa are precluded by political and institutional inefficiencies and resulting resource inequities.

It is generally held that established institutions in developed countries not only facilitate management of contemporary climate-related risks but also provide an institutional capacity to help deal with risks associated with future climate change. Stakhiv (1994) states that in the water resource sector, present-day strategies, demand management tools, and measures (i.e., institutions) have evolved over the past 25 years and are capable of serving as a basis for adaptive response strategies to climate change: “[T]he accumulation of numerous small changes in the present range of water resources management practices and procedures increases the flexibility for adaptation to current climate uncertainty and serves as a precursor to future possible responses with an ill-defined, changing climatic regime.” However, some analyses are less sanguine about the ability of existing institutions to efficiently deal with climate change hazards. For example, Miller *et al.* (1997) note that “the time has come for innovative thinking on the question of how our water allocation institutions should function to improve our capacity to adapt to the uncertain but potentially large impacts of global climate change on regional water supplies. Given the climatic uncertainties and the very different institutional settings that have developed in this country, there is no simple prescription for adaptation.”

18.5.2.6. Equity

It is frequently argued that adaptive capacity will be greater if social institutions and arrangements governing the allocation of power and access to resources within a community, nation, or the globe assure that access to resources is equitably distributed (Ribot *et al.*, 1996; Mustafa, 1998; Adger, 1999; Handmer *et al.*, 1999; Kelly and Adger, 1999; Rayner and Malone, 1999; Toth, 1999). The extent to which nations or communities are “entitled” to draw on resources greatly influences their adaptive capacity and their ability to cope (Adger and Kelly, 1999). Some people regard the adaptive capacity of a system as a function not only of the *availability* of resources but of *access* to those resources by decisionmakers and vulnerable subsectors of a population (Kelly and Adger, 1999). In the case of technological innovation, Cyert and Kumar (1996) show that differential distribution of information within an organization can impose constraints on adaptation strategies. Differentiation in demographic variables such as age, gender, ethnicity, educational attainment, and health often are cited in the literature as being related to the ability to cope with risk (Chan and Parker, 1996; Burton *et al.*, 1998; Scheraga and Grambsch, 1998). Wisner’s (1998) study of homeless people in Tokyo

provides an example of a situation in which inequality in access to resources results in a diminished capacity to adapt to environmental risk. Homeless people generally occupy marginal areas that are more vulnerable to environmental hazards. An associated lack of financial resources and infrastructure restricts the availability of adaptation options. A study by Bolin and Stanford (1991) draws parallel conclusions about the marginalization of minority groups.

These determinants of adaptive capacity are not independent of each other, nor are they mutually exclusive. Adaptive capacity is the outcome of a combination of determinants and varies widely between countries and groups, as well as over time. “Vulnerability varies spatially because national environments, housing and social structure vary spatially. It varies temporally because people move through different life stages with varying mixes of resources and liabilities” (Uitto, 1998). Bohle *et al.* (1994) document variable vulnerability to climatic variations of groups in Zimbabwe and its association with poverty, the macro-political economy, and inequitable land distribution. Not only are conditions for adaptive capacity diverse, they also behave differently in different countries and regions, particularly depending on the level of development. These determinants represent conditions that constrain or enhance the adaptive capacity and hence the vulnerability of regions, nations, and communities.

18.5.3. Adaptive Capacity of Regions

At the global scale, there is considerable variation among countries with regard to their capacity to adapt to climate change. Given their economic affluence and stability; their institutions and infrastructures; and their access to capital, information, and technology, developed nations are broadly considered to have greater capacity to adapt than developing regions or countries in economic transition (Goklany, 1995; Burton, 1996; Magalhães, 1996; Toman and Bierbaum, 1996). In general, countries with well-developed social institutions supported by higher levels of capital and stores of human knowledge are considered to have greater adaptive capacity (Smith and Lenhart, 1996). Adaptation options—including traditional coping strategies—often are available in developing countries and countries in transition; in practice, however, those countries’ capacity to effect timely response actions may be beyond their infrastructure and economic means (IPCC, 1997). For those countries, the main barriers are (Smith, 1996; IPCC, 1998; Mizina *et al.*, 1999):

- Financial/market (uncertain pricing, availability of capital, lack of credit)
- Institutional/legal (weak institutional structure, institutional instability)
- Social/cultural (rigidity in land-use practices, social conflicts)
- Technological (existence, access)
- Informational/educational (lack of information, trained personnel).

A study by Rosenzweig and Parry (1994) found considerable disparity between developed and developing countries in terms of potential adverse effects of climate change on agricultural systems; developing countries suffer the greatest losses. In addition, poorer, developing regions presumably will face stricter constraints on technology and institutions (Fankhauser and Tol, 1997) and that measures taken in response to climate change may be very demanding financially (Dvorak *et al.*, 1997; Deschingkar, 1998). Researchers also believe that compared to industrialized countries, developing countries possess a lower adaptive capacity as a result of greater reliance on climatic resources (Schelling, 1992; Fankhauser and Tol, 1997).

There is some suggestion, however, that the complex, multi-species, low- to middle-intensity farming systems that characterize agricultural endeavors in the developing world may have greater adaptive capacity under conditions of global climate change than western monocultures (Ramakrishnan, 1998). An example is found in the village of Maatisar (India), where local institutions in the past have operated on the principle of "moral economy," or guaranteed subsistence to all households in the village. These institutions have eroded over time, however, giving way to competitive market relations that do not guarantee subsistence during times of drought. As a result, the capacity of individual households to withstand seasonal fluctuations has decreased over time (Chen, 1991). Magalhães (1996) describes how northeast Brazil has become more vulnerable to droughts as inappropriate land use overstresses natural land and water resources and as the capacity to cope is limited by poverty.

Acceptance of western economic ideals coupled with increasing and rapid development may reduce the capacity of traditional societies to adapt (Watts, 1983; Chan and Parker, 1996). In the case of traditional or indigenous societies, the pursuit of western/European-style development trajectories may modify the nature of adaptive capacity (some improved, some diminished) by introducing greater technology dependence and higher density settlement and by devaluing traditional ecological knowledge and cultural values (Newton, 1995). For example, notwithstanding remarkable adaptations to a harsh climate, the North American Inuit continue to be vulnerable to climate change as a result of their dependence on wildlife (which are climate-sensitive). This vulnerability has been reduced by technological enhancement of adaptive capacity through the acquisition of snowmobiles, motorized boats, and even sonar. Such technological advances have allowed Inuit communities to become far more "fixed" than before. Many of the most densely populated areas lie at least partially within a few meters of sea level. This lack of "semi-permanence" may actually increase the Inuits' vulnerability to potential climate-induced sea-level rise by decreasing their capacity to adapt through retreat or migration (Rayner and Malone, 1998).

Although there is considerable literature on the determinants of adaptive capacity and examples of how they influence the adaptability of particular communities, there is little scholarship (and even less agreement) on criteria or variables by which

adaptive capacity can be measured and by which the adaptive capacity of global regions can be quantitatively compared. Various studies have attempted to identify overall trends that cause increased or decreased vulnerability to environmental hazards (Torry, 1979; Lamb, 1982; Warrick and Reibsame, 1983; Ausubel, 1991b; Blaikie *et al.*, 1994); unfortunately, however, the concept of vulnerability "does not rest well on a developed theory, nor is it associated with widely accepted indicators or methods of measurement" (Bohle *et al.*, 1994).

Even less progress has been made in measuring adaptive capacity. In the context of African agriculture, Downing *et al.* (1997) attempt to quantitatively measure relative adaptive capacity of regions by using crude surrogates such as gross national product (GNP). Empirical local-level studies of vulnerability are so complex, however, that attempts to describe patterns or estimate trends at global or regional scales are extremely difficult (Liverman, 1990; Downing, 1991; Dow, 1992). These "difficulties in generalizing about levels of vulnerability even in a relatively small community" are demonstrated by Adger and Kelly's (1999) study of vulnerability to climate change in Vietnam. Because vulnerability is a composite concept, social change has the potential to make individuals or activities more vulnerable in some ways and less vulnerable in others (Rayner and Malone, 1998). The influence of changes in the determinants of adaptive capacity are not necessarily direct or clear, rendering the attempt to develop systematic indices for measurement and comparison a difficult task.

18.6. Enhancing Adaptive Capacity

The adaptive capacity of a system or nation is likely to be greater when the following requirements are met:

- 1) The nation has a stable and prosperous economy. Regardless of biophysical vulnerability to the impacts of climate change, developed and wealthy nations are better prepared to bear the costs of adaptation than developing countries (Goklany, 1995; Burton, 1996).
- 2) There is a high degree of access to technology at various levels (i.e., from local to national) and in all sectors (Burton, 1996). Moreover, openness to development and utilization of new technologies for sustainable extraction, use, and development of natural resources is key to strengthening adaptive capacity (Goklany, 1995).
- 3) The roles and responsibilities for implementation of adaptation strategies are well delineated by central governments and are clearly understood at national, regional, and local levels (Burton, 1996).
- 4) Systems are in place for the dissemination of climate change and adaptation information, nationally and regionally, and there are forums for the discussion and innovation of adaptation strategies at various levels (Gupta and Hisschemöller, 1997).
- 5) Social institutions and arrangements governing the allocation of power and access to resources within a nation, region, or community assure that access to

resources is equitably distributed because the presence of power differentials can contribute to reduced adaptive capacity (Mustafa, 1998; Handmer *et al.*, 1999; Kelly and Adger, 1999).

- 6) Existing systems with high adaptive capacity are not compromised. For example, in the case of traditional or indigenous societies, pursuit of western/European-style development trajectories may reduce adaptive capacity by introducing greater technology dependence and higher density settlement and by devaluing traditional ecological knowledge and cultural values.

18.6.1. Adaptive Capacity and Sustainable Development

Ability to adapt clearly depends on the state of development (Berke, 1995; Munasinghe, 1998). As Ribot *et al.* (1996) illustrate, underdevelopment fundamentally constrains adaptive capacity, especially because of a lack of resources to hedge against extreme but expected events. The events are not surprises: "It is not that the risk is unknown, not that the methods for coping do not exist...rather inability to cope is due to lack of—or systematic alienation from—resources needed to guard against these events" (Ribot *et al.*, 1996).

The process of enhancing adaptive capacity is not simple; it involves "spurts of growth inter-dispersed with periods of consolidation, refocusing and redirection" (Holmes, 1996). Enhancement of adaptive capacity involves similar requirements as promotion of sustainable development, including:

- Improved access to resources (Ribot *et al.*, 1996; Kelly and Adger, 1999; Kates, 2000)
- Reduction of poverty (Berke, 1995; Eele, 1996; Karim, 1996; Kates, 2000)
- Lowering of inequities in resources and wealth among groups (Berke, 1995; Torvanger, 1998)
- Improved education and information (Zhao, 1996)
- Improved infrastructure (Magalhães and Glantz, 1992; Ribot *et al.*, 1996)
- Diminished intergenerational inequities (Berke, 1995; Munasinghe, 2000)
- Respect for accumulated local experience (Primo, 1996)
- Moderate long-standing structural inequities (Magadza, 2000)
- Assurance that responses are comprehensive and integrative, not just technical (Ribot *et al.*, 1996; Cohen *et al.*, 1998; Rayner and Malone, 1998; Munasinghe and Swart, 2000)
- Active participation by concerned parties, especially to ensure that actions match local needs and resources (Berke, 1995; Ribot *et al.*, 1996; Rayner and Malone, 1998; Ramakrishnan, 1999)
- Improved institutional capacity and efficiency (Handmer *et al.*, 1999; Magadza, 2000).

Because actions taken without reference to climate have the potential to affect vulnerability to it, enhancement of adaptive

capacity to climate change can be regarded as one component of broader sustainable development initiatives (Ahmad and Ahmed, 2000; Munasinghe, 2000; Robinson and Herbert, 2000). Hazards associated with climate change have the potential to undermine progress with sustainable development (Berke, 1995; Wang'ati, 1996). Therefore, it is important for sustainable development initiatives to explicitly consider hazards and risks associated with climate change (Apuuli *et al.*, 2000).

Clearly, adaptive capacity to deal with climate risks is closely related to sustainable development and equity. Enhancement of adaptive capacity is fundamental to sustainable development. For example, in the drought-stricken region of northeastern Brazil, an assessment of past successes and failures has indicated that a comprehensive sustainable development strategy is needed to increase regional and societal capacity to face present and future climate variability (Magalhães, 1996). By assessing differences in vulnerability among regions and groups and by working to improve the adaptive capacity of those regions and groups, planned adaptation can contribute to equity considerations of sustainable development. In the context of African agriculture, Downing *et al.* (1997) conclude that enhancement of present resource management activities is necessary to prepare for potential impacts of climate change. In Malawi, as in many other places, the UNFCCC's objectives to "ensure food production is not threatened, and to enable economic development to proceed in a sustainable manner" also are central to the nation's development policies (Theu *et al.*, 1996). Thus, progress to reducing vulnerability to climate risks is consistent with Malawi's planning and development initiatives.

Notwithstanding the considerable literature on the impacts of climate change as described throughout this volume, very little attention has been devoted to the interaction of adaptation to climate change with ongoing development projects and programs. Because vulnerability to climate depends on the adaptive capacity of a wide range of attributes, it may be unrealistic to focus on development programs that deal with adaptation to climate alone (Cohen, *et al.*, 1998; Rayner and Malone, 1998). Yet there is surprisingly little recognition of climate hazards and risks associated with climate change in established development projects and programs (Berke, 1995; Burton and Van Aalst, 1999). O'Brian and Liverman (1996) show how climate change can have serious implications for development projects planned or underway in Mexico, including hydroelectric and irrigation initiatives. Torvanger (1998) shows how climate flexibility considerations that can be built into development investments at modest incremental costs are applicable regardless of the uncertainties of climate change and with immediate value because of existing risks.

18.6.2. Capacity Enhancement by Scale

The vulnerabilities and anticipated impacts of climate change will be observed at different scales and levels of society—and enhancement of adaptive capacity can be initiated at different

Table 18-6: Adaptation and adaptive capacity in sectors (key findings from Chapters 4 through 9).

Sector	Key Findings
Water Resources	<ul style="list-style-type: none"> – Water managers have experience adapting to change. Many techniques exist to assess and implement adaptive options. However, the pervasiveness of climate change may preclude some traditional adaptive strategies, and available adaptations often are not used. – Adaptation can involve management on the supply side (e.g., altering infrastructure or institutional arrangements) and on the demand side (changing demand or risk reduction). Numerous no-regret policies exist that will generate net social benefits regardless of climate change. – Climate change is just one of numerous pressures facing water managers. Nowhere are water management decisions taken solely to cope with climate change, although it is increasingly considered for future resource management. Some vulnerabilities are outside the conventional responsibility of water managers. – Estimates of the economic costs of climate change impacts on water resources depend strongly on assumptions made about adaptation. Economically optimum adaptation may be prevented by constraints associated with uncertainty, institutions, and equity. – Extreme events often are catalysts for changes in water management, by exposing vulnerabilities and raising awareness of climate risks. Climate change modifies indicators of extremes and variability, complicating adaptation decisions. – Ability to adapt is affected by institutional capacity, wealth, management philosophy, planning time scale, organizational and legal framework, technology, and population mobility. – Water managers need research and management tools aimed at adapting to uncertainty and change, rather than improving climate scenarios.
Ecosystems and Their Services	<ul style="list-style-type: none"> – Adaptation to loss of some ecosystem services may be possible, especially in managed ecosystems. However, adaptation to losses in wild ecosystems and biodiversity may be difficult or impossible. – There is considerable capacity for adaptation in agriculture, including crop changes and resource substitutions, but adaptation to evolving climate change and interannual variability is uncertain. – Adaptations in agriculture are possible, but they will not happen without considerable transition costs and equilibrium (or residual) costs. – Greater adverse impacts are expected in areas where resource endowments are poorest and the ability of farmers to adapt is most limited. – In many countries where rangelands are important, lack of infrastructure and investment in resource management limit options for adaptation. – Commercial forestry is adaptable, reflecting a history of long-term management decisions under uncertainty. Adaptations are expected in both land-use management (species-selection silviculture) and product management (processing-marketing). – Adaptation in developed countries will fare better, while developing countries and countries in transition, especially in the tropics and subtropics, will fare worse.
Coastal Zones	<ul style="list-style-type: none"> – Without adaptations, the consequences of global warming and sea-level rise would be disastrous. – Coastal adaptation entails more than just selecting one of the technical options to respond to sea-level rise (strategies can aim to protect, accommodate, or retreat). It is a complex and iterative process rather than a simple choice. – Adaptation options are more acceptable and effective when they are incorporated into coastal zone management, disaster mitigation programs, land-use planning, and sustainable development strategies. – Adaptation choices will be conditioned by existing policies and development objectives, requiring researchers and policymakers to work toward a commonly acceptable framework for adaptation. – The adaptive capacity of coastal systems to perturbations is related to coastal resilience, which has morphological, ecological, and socioeconomic components. Enhancing resilience—including the technical, institutional, economic, and cultural capability to cope with impacts—is a particularly appropriate adaptive strategy given future uncertainties and the desire to maintain development opportunities. – Coastal communities and marine-based economic sectors with either low exposure or high adaptive capacity will be least affected. Communities with less economic resources, poorer infrastructure, less developed communications and transportation systems, and weak social support systems have less access to adaptation options and are more vulnerable.

Table 18-6 (continued)

Sector	Key Findings
<i>Human Settlements, Energy, and Industry</i>	<ul style="list-style-type: none"> – The larger and more costly impacts of climate change occur through changed probability of extreme weather events that overwhelm the design resiliency of human systems. – There are many adaptation options available to reduce the vulnerability of settlements. However, urban managers, especially in developing countries, have so little capacity to deal with current problems (housing, sanitation, water, and power) that dealing with climate change risks is beyond their means. – Lack of financial resources, weak institutions, and inadequate or inappropriate planning are major barriers to adaptation in human settlements. – Successful environmental adaptation cannot occur without locally based, technically competent, and politically supported leadership. – Uncertainty with respect to capacity and the will to respond hinder the assessment of adaptations and vulnerability.
<i>Insurance and Other Financial Services</i>	<ul style="list-style-type: none"> – Adaptation in financial and insurance services in the short term is likely to be to changing frequencies and intensities of extreme weather events. – Increasing risk could lead to a greater volume of traditional business and the development of new financial risk management products, but increased variability of loss events would heighten actuarial uncertainty. – Financial services firms have adaptability to external shocks, but there is little evidence that climate change has been incorporated into investment decisions. – The adaptive capacity of the financial sector is influenced by regulatory involvement, the ability of firms to withdraw from at-risk markets, and fiscal policy regarding catastrophe reserves. – Adaptation will involve changes in the roles of private and public insurance. Changes in the timing, intensity, frequency, and/or spatial distribution of climate-related losses will generate increased demand on already overburdened government insurance and disaster assistance programs. – Developing countries seeking to adapt in a timely manner face particular difficulties, including limited availability of capital, poor access to technology, and absence of government programs. – Insurers'adaptations include raising prices, nonrenewal of policies, cessation of new policies, limiting maximum claims, and raising deductibles—actions that can seriously affect investment in developing countries. – Developed countries generally have greater adaptive capacity, including technology and economic means to bear the costs.
<i>Human Health</i>	<ul style="list-style-type: none"> – Adaptation involves changes in society, institutions, technology, or behavior to reduce potential negative impacts or to increase positive ones. There are numerous adaptation options, which may occur at the population, community, or personal levels. – The most important and cost-effective adaptation measure is to rebuild public health infrastructure—which, in much of the world, has declined in recent years. Many diseases and health problems that may be exacerbated by climate change can be effectively prevented with adequate financial and human public health resources, including training, surveillance and emergency response, and prevention and control programs. – Adaptation effectiveness will depend on timing. “Primary” prevention aims to reduce risks before cases occur, whereas “secondary” interventions are designed to prevent further cases. – Determinants of adaptive capacity to climate-related threats to health include the level of material resources, the effectiveness of governance and civil institutions, the quality of public health infrastructure, and the preexisting burden of disease. – Capacity to adapt also will depend on research to understand associations between climate, weather, extreme events, and vector-borne diseases.

social scales (Ribot *et al.*, 1996; Handmer *et al.*, 1999). In Bangladesh, Ahmed *et al.* (1999) distinguish between four scales: mega, macro, meso, and micro. Using the example of sea-level rise as a climate change impact, the authors describe adaptation options at each scale. The process of sea-level rise occurs at the mega-scale and is global in its effect. At the

macro-scale, an associated increase in surface water and groundwater has the potential to similarly effect neighboring rivers and flood plains in China, Nepal, India, Bhutan, and Pakistan. Adaptive capacity at this scale is a function of international economic and political structures, with implications for the nations'capital and technological resources and institutions. At

the meso-scale, different communities within Bangladesh are differentially vulnerable, depending on adaptive capacity and physiographic characteristics. At this scale, location-specific adaptation options would need to be considered. Finally, at a micro-scale, family units and individuals would experience vulnerabilities irrespective of the origin of the processes and would employ adaptations within their particular economic and sociocultural constraints.

Because the vulnerabilities of climate change occur at various scales, successful adaptation will depend on actions taken at a number of levels. Examples of initiatives to enhance adaptive capacity at various scales follow:

- At a *global* scale
 - Greater cooperation between industrialized and developing countries to align global and local priorities by improving policy/science interactions and working toward greater public awareness of climate change and adaptation issues (Wang'ati, 1996; Gupta and Hisschemöller, 1997)
 - Inclusion of global institutions for global-level adaptation, which would include research and facilitation of policy, funding, and monitoring at all levels (Ahmed *et al.*, 1999)
 - Removal of barriers to international trade; it is argued that improving market conditions, reducing the exploitation of marginal land, accelerating the transfer of technology, and contributing to overall economic growth will promote both sustainability and adaptive capacity (Goklany, 1995)
 - Effective global economic participation. Benefits go beyond direct financial gain and include technology transfers, technical and managerial skills transfers, and other skills transfers associated with the “learning and doing” process (Ebohon *et al.*, 1997)
- At a *national* level
 - Development of climate change policy that is specifically geared toward more vulnerable sectors in the country (Mustafa, 1998), with an emphasis on poverty reduction (Kelly and Adger, 1999)
 - Establishment of broadly based monitoring and communication systems (e.g., integrated drought monitoring and information system, as suggested in Wilhite, 1997)
 - Establishment of public policy that encourages and supports adaptation at local or community levels and in the private sector (Burton, 1996)
 - Pursuit of sustainable economic growth—which, in turn, allows for greater dedication of resources to development of adaptive technologies and innovations (Goklany, 1995)
- Via *local* means
 - Establishment of social institutions and arrangements that discourage concentration of power in a few hands and prevent marginalization of sections of the local population (Mustafa, 1998); arrangements

need to consider representativeness of decision-making bodies and maintenance of flexibility in the functioning of local institutions (Ramakrishnan, 1998)

- Encouragement of diversification of income sources (and therefore risk-spreading), particularly for poorer sectors of society (Wang'ati, 1996; Adger and Kelly, 1999)
- Encouragement of formal or informal arrangements for collective security (Kelly and Adger, 1999)
- Identification and prioritization of local adaptation measures and provision of feedback to higher levels of government. These efforts would have to be reinforced by the adequate provision of knowledge, technology, policy, and financial support (Ahmed *et al.*, 1999).

18.7. Sectoral and Regional Findings

Insights gained about adaptation and adaptive capacity from the sector chapters and the regional chapters are summarized in Tables 18-6 and 18-7, respectively.

Increasingly, adaptation and adaptive capacity are explicitly considered in impact and vulnerability assessments, and there are some consistent findings across sectors and regions (see Section 18.8). However, there is insufficient basis to rank systematically countries according to their adaptive capacity or to list the “most vulnerable” overall. Analyses to date indicate that adaptive capacity and vulnerability are multidimensional, so that one country (or, more often, a group within a country) may be extremely vulnerable economically whereas another country (or community) is extremely vulnerable in terms of life and livelihood. These different types of vulnerability reflect different types of exposures and adaptive capacities.

18.8. Conclusions

Adaptation can significantly reduce adverse impacts of climate change. Adaptation is an important part of societal response to global climate change. Planned, anticipatory adaptation has the potential to reduce vulnerability and realize opportunities associated with climate change effects and hazards. There are numerous examples of successful adaptations that would apply to climate change risks and opportunities. Substantial reductions in climate change damages can be achieved, especially in the most vulnerable regions, through timely deployment of adaptation measures.

In the absence of planned adaptation, communities will adapt autonomously to changing climatic conditions, but not without costs and residual damages. Societies and economies have been making adaptations to climate for centuries. However, losses from climate-related extreme events are substantial and, in some sectors, increasing—indicating patterns of development that remain vulnerable to temporal variations in climatic

Table 18-7: Adaptation and capacity in regions (key findings from Chapters 10 through 17).

Sector	Key Findings
Africa	<ul style="list-style-type: none"> – Adaptive measures would enhance flexibility and have net benefits in water resources (irrigation and water reuse, aquifer and groundwater management, desalination), agriculture (crop changes, technology, irrigation, husbandry), and forestry (regeneration of local species, energy-efficient cook stoves, sustainable community management). – Without adaptation, climate change will reduce the wildlife reserve network significantly by altering ecosystems and causing species emigration and extinctions. This represents an important ecological and economic vulnerability in Africa. – A risk-sharing approach between countries will strengthen adaptation strategies, including disaster management, risk communication, emergency evacuation, and cooperative water resource management. – Most countries in Africa are particularly vulnerable to climate change because of limited adaptive capacity, as a result of widespread poverty, recurrent droughts, inequitable land distribution, and dependence on rainfed agriculture. – Enhancement of adaptive capacity requires local empowerment in decisionmaking and incorporation of climate adaptation within broader sustainable development strategies.
Asia	<ul style="list-style-type: none"> – Priority areas for adaptation are land and water resources, food productivity, and disaster preparedness and planning—particularly for poorer, resource-dependent countries. – Adaptations already are required to deal with vulnerabilities associated with climate variability, in human health, coastal settlements, infrastructure, and food security. The resilience of most sectors in Asia to climate change is very poor. Expansion of irrigation will be difficult and costly in many countries. – For many developing countries in Asia, climate change is only one of a host of problems to deal with, including nearer term needs such as hunger, water supply and pollution, and energy. Resources available for adaptation to climate are limited. Adaptation responses are closely linked to development activities, which should be considered in evaluating adaptation options. – Early signs of climate change already are observed and may become more prominent over 1 or 2 decades. If this time is not used to design and implement adaptations, it may be too late to avoid upheavals. Long-term adaptation requires anticipatory actions. – A wide range of precautionary measures are available at the regional and national level to reduce economic and social impacts of disasters. These measures include awareness building and expansion of the insurance industry. – Development of effective adaptation strategies requires local involvement, inclusion of community perceptions, and recognition of multiple stresses on sustainable management of resources. – Adaptive capacities vary between countries, depending on social structure, culture, economic capacity, and level of environmental disruptions. Limiting factors include poor resource and infrastructure bases, poverty and disparities in income, weak institutions, and limited technology. – The challenge in Asia lies in identifying opportunities to facilitate sustainable development with strategies that make climate-sensitive sectors resilient to climate variability. – Adaptation strategies would benefit from taking a more systems-oriented approach, emphasizing multiple interactive stresses, with less dependence on climate scenarios.
Australia and New Zealand	<ul style="list-style-type: none"> – Adaptations are needed to manage risks from climatic variability and extremes. Pastoral economies and communities have considerable adaptability but are vulnerable to any increase in the frequency or duration of droughts. – Adaptation options include water management, land-use practices and policies, engineering standards for infrastructure, and health services. – Adaptations will be viable only if they are compatible with the broader ecological and socioeconomic environment, have net social and economic benefits, and are taken up by stakeholders. – Adaptation responses may be constrained by conflicting short- and long-term planning horizons. – Poorer communities, including many indigenous settlements, are particularly vulnerable to climate-related hazards and stresses on health because they often are in exposed areas and have less adequate housing, health care, and other resources for adaptation.

Table 18-7 (continued)

Sector	Key Findings
<i>Europe</i>	<ul style="list-style-type: none"> – Adaptation potential in socioeconomic systems is relatively high as a result of strong economic conditions; stable population (with capacity to migrate); and well-developed political, institutional, and technological support systems. – The response of human activities and the natural environment to current weather perturbations provides a guide to critical sensitivities under future climate change. – Adaptation in forests requires long-term planning; it is unlikely that adaptation measures will be put in place in a timely manner. – Farm-level analyses show that if adaptation is fully implemented large reductions in adverse impacts are possible. – Adaptation for natural systems generally is low. – More marginal and less wealthy areas will be less able to adapt, so without appropriate policies of response climate change may lead to greater inequities.
<i>Latin America</i>	<ul style="list-style-type: none"> – Adaptation measures have potential to reduce climate-related losses in agriculture and forestry. – There are opportunities for adapting to water shortages and flooding through water resource management. – Adaptation measures in the fishery sector include changing species captured and increasing prices to reduce losses.
<i>North America</i>	<ul style="list-style-type: none"> – Strain on social and economic systems from rapid climate and sea-level changes will increase the need for explicit adaptation strategies. In some cases, adaptation may yield net benefits, especially if climate change is slow. – Stakeholders in most sectors believe that technology is available to adapt, although at some social and economic cost. – Adaptation is expected to be more successful in agriculture and forestry. However, adaptations for the water, health, food, and energy sectors and the cities are likely to require substantial institutional and infrastructure changes. – In the water sector, adaptations to seasonal runoff changes include storage, conjunctive supply management, and transfer. It may not be possible to continue current high levels of reliability of water supply, especially with transfers to high-valued uses. Adaptive measures such as “water markets” may lead to concerns about accessibility and conflicts over allocation priorities. – Adaptations such as levees and dams often are successful in managing most variations in the weather but can increase vulnerability to the most extreme events. – There is moderate potential for adaptation through conservation programs that protect particularly threatened ecosystems, such as high alpines and wetlands. It may be difficult or impossible to offset adverse impacts on aquatic systems.

conditions and to climate change. The ecological, social, and economic costs of relying on reactive, autonomous adaptation to the cumulative effects of climate change are substantial and largely avoidable through planned, anticipatory adaptation.

The key features of climate change for vulnerability and adaptation are those that relate to variability and extremes, not simply changed average conditions. In addition, the speed of changes in event frequency is important. Most communities, sectors, and regions are reasonably adaptable to changes in average conditions, unless those changes are particularly sudden or not smooth. However, these communities are more vulnerable and less adaptable to changes in the frequency and/or magnitude of conditions other than average, especially extremes. Changes in the frequency and magnitude of extremes underlie changes in mean conditions and thus are inherent in climate change; adaptation initiatives to these hazards are of particular need.

Implementation of adaptation policies, programs, and measures usually will have immediate as well as future benefits. Adaptations to current climate and climate-related risks (recurring droughts, storms, floods, and other extremes) generally are consistent with adaptation to changing and changed climatic conditions.

Adaptations to changing climatic conditions are more likely to be implemented if they are consistent with or integrated with decisions or programs that address nonclimatic stresses. Vulnerabilities associated with climate change rarely are experienced independent of nonclimatic conditions. Impacts of climatic stimuli are felt via economic or social stresses, and adaptations to climate (by individuals, communities, and governments) are evaluated and undertaken in light of these conditions. The costs of adaptation often are marginal to other management or development costs. To be effective, climate change adaptation must consider nonclimatic stresses and be

Table 18-7 (continued)

Sector	Key Findings
Polar Regions	<ul style="list-style-type: none"> – Adaptation will occur in natural polar ecosystems through migration and changing mixes of species. Species such as walrus, seals, and polar bears will be threatened, although others (such as fish) may flourish. – Potential for adaptation is limited in indigenous communities that follow traditional lifestyles. – Technologically developed communities are likely to adapt quite readily, although the high capital investment required may result in costs in maintaining lifestyles. – Adaptation depends on technological advances, institutional arrangements, availability of financing, and information exchange.
Small Island States	<ul style="list-style-type: none"> – The need for adaptation has become increasingly urgent, even if swift implementation of global agreements to reduce future emissions occurs. – Most adaptation will be carried out by people and communities who inhabit island countries; support from governments is essential for implementing adaptive measures. – Progress will require integration of appropriate risk-reduction strategies with other sectoral policy initiatives in areas such as sustainable development planning, disaster prevention and management, integrated coastal zone management, and health care planning. – Strategies for adaptation to sea-level rise are retreat, accommodate, and protect. Measures such as retreat to higher ground, raising of the land, and use of building set-backs appear to have little practical utility, especially when hindered by limited physical size. – Measures for reducing the severity of health threats include health education programs, improved health care facilities, sewerage and solid waste management, and disaster preparedness plans. – Islanders have developed some capacity to adapt by application of traditional knowledge, locally appropriate technology, and customary practice. Overall, however, adaptive capacity is low because of the physical size of nations, limited access to capital and technology, shortage of human resource skills, lack of tenure security, overcrowding, and limited access to resources for construction. – Many small islands require external financial, technical, and other assistance to adapt. Adaptive capacity may be enhanced by regional cooperation and pooling of limited resources.

consistent with existing policy criteria, development objectives, and management structures.

Adaptive capacity varies considerably among regions, countries, and socioeconomic groups. The ability to adapt and cope with climate change impacts is a function of wealth, technology, information, skills, infrastructure, institutions, and equity. Groups and regions with limited adaptive capacity are more vulnerable to climate change damages.

Development decisions, activities, and programs play important roles in modifying the adaptive capacity of communities and regions, yet they tend not to take into account risks associated with climate variability and change. This omission in the design and implementation of many recent and current development initiatives results in unnecessary additional losses to life, well-being, and investments in the short and longer terms.

Enhancement of adaptive capacity is necessary to reduce vulnerability, particularly for the most vulnerable regions, nations, and socioeconomic groups. Activities required for the enhancement of adaptive capacity are essentially equivalent to those that promote sustainable development and equity.

Current knowledge about adaptation and adaptive capacity is insufficient for reliable prediction of adaptations and for

rigorous evaluation of planned adaptation options, measures, and policies of governments:

- Although climate change vulnerability studies now usually consider adaptation, they rarely go beyond identifying adaptation options that might be possible. There is little research on the dynamics of adaptation in human systems, the processes of adaptation decisionmaking, the conditions that stimulate or constrain adaptation, and the role of nonclimatic factors.
- There are serious limitations in existing evaluations of adaptation options. Economic benefits and costs are key criteria, but they are not sufficient to adequately determine the appropriateness of adaptation measures. There also has been little research to date on the roles and responsibilities of individuals, communities, corporations, private and public institutions, governments, and international organizations in adaptation.
- Given the scope and variety of specific adaptation options across sectors, individuals, communities, and locations and the variety of participants—private and public—involved in most adaptation initiatives, it is probably infeasible to systematically evaluate lists of particular adaptation measures. Improving and applying knowledge on the constraints and opportunities for enhancing adaptive capacity is necessary to reduce vulnerabilities.

EXECUTIVE SUMMARY

This chapter synthesizes the results of Work Group II of the Third Assessment Report (TAR) and assesses the state of knowledge concerning Article 2 of the United Nations Framework Convention on Climate Change (UNFCCC). The TAR's task is to define what is known about the effects of climate change: how sensitive systems are, what adaptive capacity they have, and what their vulnerability is. It is not the goal of this assessment to determine whether these effects are tolerable or are considered dangerous.

The goal of this chapter is to synthesize information on climate change impacts in a manner that will enable readers to evaluate the relationship between increases in global mean temperature and impacts. The chapter focuses on certain "reasons for concern" that may aid readers in making their own determination about what is a "dangerous" climate change. Each reason for concern is consistent with a paradigm that can be used by itself or in combination with other paradigms to help determine what level of climate change is dangerous. The reasons for concern are:

- 1) The relationship between global mean temperature increase and damage to or irreparable loss of unique and threatened systems
- 2) The relationship between global mean temperature increase and the distribution of impacts
- 3) The relationship between global mean temperature increase and global aggregate damages
- 4) The relationship between global mean temperature increase and the probability of extreme weather events
- 5) The relationship between global mean temperature increase and the probability of large-scale singular events such as the breakup of the West Antarctic Ice Sheet or the collapse of the North Atlantic thermohaline circulation.

In addition, we examine what observed effects of climate change tell us with regard to Article 2 of the UNFCCC. Increase in global mean temperature since 1900 (i.e., mean global warming) is used as the common metric against which impacts are measured. This metric is closely related to greenhouse gas (GHG) concentrations but is more relevant for impact assessments.

Some general caveats apply to all of the reasons for concern:

- In spite of many studies on climate change impacts, there still is substantial uncertainty about how effective adaptation will be (and could be) in ameliorating negative effects of climate change and taking advantage of positive effects.

- The effect of changes in baseline conditions, such as population and economic growth and development of new technologies that could change vulnerability, has not been adequately considered in most impact studies.
- Most impact studies assess the effects of a stable climate, so our understanding of what rates of change may be dangerous is limited.

It does not appear to be possible to combine the different reasons for concern into a unified reason for concern that has meaning and is credible. However, we can review the relationship between impacts and temperature for each reason for concern and draw some preliminary conclusions about the potential severity and risk of impacts for the individual reasons for concern. Note that the following findings do not incorporate the costs of limiting GHG emissions to levels that are sufficient to avoid changes that may be considered dangerous. Also note that there is substantial uncertainty regarding the impacts of climate change at the temperatures mentioned. These temperatures should be taken as approximate indications of impacts, not as absolute thresholds. In addition, change in global mean temperature does not describe all relevant aspects of climate change impacts, such as rate and pattern of change and changes in precipitation, extreme climate events, or lagged (or latent) effects such as rising sea levels. For simplification, we group different levels of temperature increase into "small," "medium," and "large." "Small" denotes a global mean temperature increase of as much as approximately 2°C; "medium" denotes a global mean temperature increase of approximately 2–3°C; and "large" denotes a global mean temperature increase of more than approximately 3°C.

Based on a review of the literature of observations of climate change impacts, as reflected in other chapters in the TAR, we conclude the following:

- *Observations:* Statistically significant associations between trends in regional climate and impacts have been documented in ~100 physical processes and ~450 biological species or communities in terrestrial and polar environments. Although the presence of multiple factors (e.g., land-use change, pollution, biotic invasion) makes attribution of observed impacts to regional climate change difficult, more than 90% (~99% physical, ~80% biophysical) of the changes documented worldwide are consistent with how physical and biological processes are known to respond to climate. Based on expert judgment, we have high confidence that the overall patterns and processes of observations reveal a widespread and

- coherent impact of 20th-century climate changes on many physical and biological systems. Signals of regional climate change impacts may be clearer in physical and biological systems than in socioeconomic systems, which also are simultaneously undergoing many complex changes that are not related to climate change, such as population growth and urbanization. Socioeconomic systems have complex and varying mechanisms for adapting to climate change. There are preliminary indications that some social and economic systems have been affected in part by 20th-century regional climate changes (e.g., increased damages from flooding and droughts in some locations). It generally is difficult to separate climate change effects from coincident or alternative explanations for such observed regional impacts.
- *Unique and Threatened Systems:* Tropical glaciers, coral reefs, mangroves, ecotones, and biodiversity “hot spots” are examples of unique and threatened entities that are confined to narrow geographical ranges and are very sensitive to climate change. However, their degradation or loss could affect regions outside their range. There is medium confidence that several of these systems will be affected by a small temperature increase; for example, coral reefs will bleach and glaciers will recede. At higher magnitudes of temperature increase, other and more numerous unique and threatened systems would be adversely affected.
 - *Distribution of Impacts:* The impacts of climate change will not be evenly distributed among the peoples of the world. There is high confidence that developing countries will be more vulnerable to climate change than developed countries, and there is medium confidence that climate change would exacerbate income inequalities between and within countries. There also is medium confidence that a small temperature increase would have net negative impacts on market sectors in many developing countries and net positive impacts on market sectors in many developed countries. However, there is high confidence that with medium to high increases in temperature, net positive impacts would start to decline and eventually would turn negative, and negative impacts would be exacerbated. Estimates of distributional effects are uncertain because of aggregation and comparison methods, assumptions about climate variability, adaptation, levels of development, and other factors.
 - *Aggregate Impacts:* With a small temperature increase, there is medium confidence that aggregate market sector impacts would amount to plus or minus a few percent of world gross domestic product (GDP), and there is low confidence that aggregate nonmarket impacts would be negative. Most people in the world would be negatively affected by a small to medium temperature increase. Most studies of aggregate impacts find that there are net damages at the global scale beyond a medium temperature increase and that damages increase from there with further temperature increases. The important qualifications raised with regard to distributional analysis (previous bullet item) also apply to aggregate analysis. By its nature, aggregate analysis masks potentially serious equity differences. Estimates of aggregate impacts are controversial because they treat gains for some as canceling out losses for others and because the weights that are used to aggregate over individuals are necessarily subjective.
 - *Extreme Climate Effects:* The frequency and magnitude of many extreme climate events increase even with a small temperature increase and will become greater at higher temperatures (high confidence). Extreme events include, for example, floods, soil moisture deficits, tropical and other storms, anomalous temperatures, and fires. The impacts of extreme events often are large locally and could strongly affect specific sectors and regions. Increases in extreme events can cause critical design or natural thresholds to be exceeded, beyond which the magnitude of impacts increases rapidly (high confidence).
 - *Large-Scale Singularities:* Large-scale singularities in the response of the climate system to external forcing, such as shutdown of the North Atlantic thermohaline circulation or collapse of the West Antarctic ice sheet, have occurred in the past as a result of complex forcings. Similar events in the future could have substantial impacts on natural and socioeconomic systems, but the implications have not been well studied. Determining the timing and probability of occurrence of large-scale singularities is difficult because these events are triggered by complex interactions between components of the climate system. The actual impact could lag the climate change cause (involving the magnitude and the rate of climate change) by decades to millennia. There is low to medium confidence that rapid and large temperature increases would exceed thresholds that would lead to large-scale singularities in the climate system.

19.1. Introduction

This chapter draws on the results of the entire TAR to assess the state of knowledge concerning Article 2 of the UNFCCC. Article 2 of the UNFCCC states that:

“...the ultimate objective of this Convention...is to achieve...stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system. Such a level should be achieved with a time frame sufficient to allow ecosystems to adapt naturally to climate change, to ensure that food production is not threatened and to enable economic development to proceed in a sustainable manner.” (UNEP/WMO, 1992).

The ultimate goal for stabilizing GHG concentrations is to avoid “dangerous anthropogenic interference with the climate system.” The question of what is dangerous is one that the authors of this chapter cannot answer. Danger is a function of the degree to which effects are negative and the degree to which those effects are unacceptable. The latter is a value judgment. The TAR’s task is to define what is known about the effects of climate change—to identify their character and their implications and whether they are negative or positive. It is not about determining whether these effects are acceptable.

The preceding chapters review the literature about vulnerability to climate change in regions and sectors. The goal of this chapter is to draw on very disparate reasons for concern regarding climate change impacts in a manner that will enable readers to evaluate the relationship between increases in global mean temperature and impacts (for an explanation of why change in global mean temperature is used as an indicator, see Section 19.1.2). It attempts to enable readers to understand the risks of higher magnitudes of increased global mean temperature.

19.1.1. Reasons for Concern

To provide information to readers in a manner that will enable them to make judgments about what level of climate change may be dangerous, this chapter addresses “reasons for concern,” which represent a way for readers to think about the seriousness of climate change impacts. These reasons for concern are taken from debates and literature about the risks of climate change. The authors of this chapter make no judgment regarding whether one or several reasons for concern are more important than others. Nor do we attempt to combine the reasons for concern to produce a single “bottom line.”

The reasons for concern are as follows:

- 1) *The relationship between global mean temperature increase and damage to or irreparable loss of unique and threatened systems:* Some unique and threatened systems may be irreparably harmed by changes in climate beyond certain thresholds.

- 2) *The relationship between global mean temperature increase and the distribution of impacts:* Some regions, countries, islands, and cultures may be adversely affected by climate change, whereas others could benefit, at least up to a point. For example, in some sectors, adverse effects may be experienced in some parts of the world while other parts may have net gains. Within countries, some regions or groups of people could be harmed while others benefit or experience less harm.
- 3) *The relationship between global mean temperature increase and global aggregated impacts:* Using a consistent method of measurement and aggregation of climate change impacts, we address how aggregate impacts change as global mean temperature increases, whether aggregate impacts are positive at some levels of temperature increase and negative at others, whether change will occur smoothly or in a more complex dynamic pattern, and whether aggregate impacts mask unequal distribution of impacts.
- 4) *The relationship between global mean temperature increase and the probability of extreme weather events:* As mean climate changes, so too will the probability of extreme weather events such as days with very high or very low temperatures, extreme floods, droughts, tropical cyclones, and storms. This chapter addresses how the probability and consequences of such events may change as global mean temperature increases.
- 5) *The relationship between global mean temperature increase and the probability of large-scale singular events, such as collapse of the West Antarctic ice sheet (WAIS) or shutdown of the North Atlantic thermohaline circulation (THC):* This chapter addresses what is known about how the probabilities of such events change as the magnitude of climate change increases.

In addition, this chapter addresses whether changes in climate during the 20th century have resulted in observed impacts. The IPCC has documented these changes, and an important question is whether these changes have resulted in measurable impacts on nature or society. Important questions include the following:

- Are the observed effects of climate change consistent with model predictions, particularly those that estimate more serious impacts at larger GHG concentrations?
- Even if it is not clear whether observed effects are caused primarily by climate change, do these effects give us information about the potential vulnerability of systems to climate change?

Observations are not a reason for concern. Instead, they help us determine whether impacts that are relevant to any of the five reasons for concern have occurred.

19.1.2. Choice of Indicator

A critical issue is the indicator of climate change against which we measure impacts. A common measure allows consistent

discussion about the relationship between climate change and impacts. Several indicators could be used:

- 1) GHG emission levels
- 2) Atmospheric GHG concentration levels
- 3) Changes in global mean temperature and sea-level rise
- 4) Changes in regional climate variables
- 5) Changes in the intensity or frequency of extreme events.

Several considerations must be taken into account in selecting an indicator. Using GHG emission levels (1) or even concentration levels (2) implies examining impacts beyond the 21st century. Published estimates of time frames for stabilizing GHG atmospheric concentration levels tend to assume such levels will not be stabilized until after the end of the 21st century (Enting *et al.*, 1994; Wigley *et al.*, 1996; Schimel *et al.*, 1997).

The problem with using such levels as an indicator is that most of the impact literature examines potential impacts only as far as 2100. In addition, most studies are based on scenarios of specific changes in global mean or, more typically, regional climate variables such as temperature or precipitation.¹ It is difficult to relate a specific level of GHG concentration to a specific change in global average climate or regional climate. For each GHG concentration level, there is a range of potential changes in global mean temperature (see Box 19-1). And for each change in global mean temperature, there is a range of potential changes in average regional temperature, precipitation, and extreme events.

The problem with indicators 3, 4, and 5 is the inverse of the foregoing problem. For each change in global or regional climate or extreme events, there is a range of levels of GHG concentrations that could cause such a change in climate. Thus, using these indicators makes it more difficult to work back to defining atmospheric concentrations of GHGs, as required by Article 2 of the UNFCCC. In addition, as one gets to finer levels of spatial and temporal resolution, such as changes in regional climates and extreme events, it becomes more difficult to attribute such changes to changes in GHG concentrations.

Thus, whatever the indicator selected, there will be problems in using it to relate impacts to the level of GHG concentrations. The choice of indicator depends on two factors:

- 1) What does the literature on climate change impacts allow us to consider?
- 2) What indicator can be most directly related to GHG concentrations?

We selected change in global mean temperature as our indicator for two reasons. The first is that the impact literature can be directly related to a change in global mean temperature. Many studies are based on specific results from general circulation

models (GCMs), which estimate a change in global mean temperature. Other studies can be related to a change in global mean temperature by inversely using the scaling method from Chapter 4. The second reason is that, as discussed in Box 19-1, it is most feasible to relate changes in global mean temperature to GHG concentrations. It is harder to relate the other indicators directly to GHG concentrations. Thus, global mean temperature increase is the indicator that can be used most readily to relate GHG emissions (and emissions control) to changes in climate and impacts.

For any change in global mean temperature, there are many possible changes in regional climate and climate variability, which could have quite different results. Thus, a 2°C increase in global mean temperature may result in a particular region being much wetter or drier or having more or fewer extreme climate events. Whether the region gets wetter or drier or has more severe climate is likely to have much greater bearing on impacts than a change in mean temperature. Hence, although the use of global mean temperature as an indicator is preferable to the other options because it has fewer problems in implementation, it has its own limitations.

This chapter does not address the effect of different rates of change in climate on vulnerability. There is no doubt that a 3°C increase in global mean temperature realized in 50 years could be far worse than the same amount of warming realized in 100 or 200 years. In addition, changes in extreme events such as more intense El Niño-Southern Oscillation (ENSO) events (see, e.g., Timmermann *et al.*, 1999) could lead to more adverse impacts than a monotonic and gradual change in climate. Thus, rate of change is an important factor affecting what climate change is considered to be dangerous. Unfortunately, most of the impact literature has addressed only static or equilibrium changes in climate. These studies have not examined what rates of change various sensitive systems can adapt to. Future research should address this matter.

19.1.3. Role of Adaptation

Successful adaptation reduces vulnerability to an extent that depends greatly on adaptive capacity—the ability of an affected system, region, or community to cope with the impacts and risks of climate change (see Chapter 18). Enhancement of adaptive capacity can reduce vulnerability and promote sustainable development across many dimensions.

Adaptive capacity in human systems varies considerably among regions, countries, and socioeconomic groups. The ability to adapt to and cope with climate change impacts is a function of wealth, technology, information, skills, infrastructure, institutions, equity, empowerment, and ability to spread risk. Groups and regions with adaptive capacity that is limited along any of these dimensions are more vulnerable to climate change damages, just as they are more vulnerable to other stresses. Enhancement of adaptive capacity is a necessary condition for reducing vulnerability, particularly for the most vulnerable regions, nations,

¹One recent exception is DETR (1999), which examines changes in global impacts at different CO₂ stabilization levels.

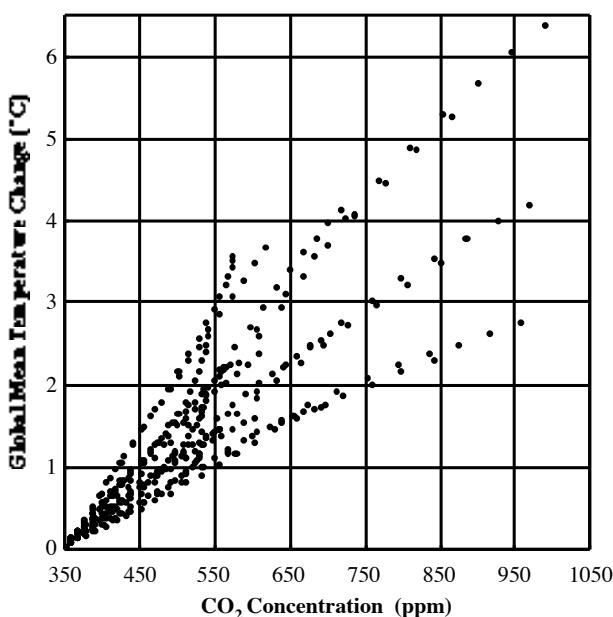

Box 19-1. Uncertainties in Future Warming

Does a given atmospheric concentration of GHGs cause a specific change in global mean temperature (or other climate variables, for that matter)? To answer this question, we quantify uncertainties in the change in global mean temperature for a given CO₂ concentration level. This is accomplished by using the same simple models that are used in the TAR Working Group I report (TAR WGI Chapter 9). These models are updated versions of models used previously by the IPCC in the Second Assessment Report (SAR) (Kattenberg *et al.*, 1996; see also Raper *et al.*, 1996). We consider the effects of uncertainties in future emissions of *all* radiatively important gases (particularly the relative importance of CO₂ to other forcing factors) and climate sensitivity, but not uncertainties in translating emissions to concentrations.

These uncertainty issues are addressed by comparing CO₂ concentrations (not other GHGs) and the corresponding temperature projections for 5-year time steps from 1990 to 2100 (i.e., using results for 1995, 2000, 2005, etc.) for the six illustrative emissions scenarios from the IPCC *Special Report on Emissions Scenarios* (SRES) (Nakicenovic *et al.*, 2000) under a range of climate sensitivity assumptions. The six emissions scenarios provide a sampling of the space of the relative effects of CO₂ compared with other GHGs and sulfur dioxide (SO₂)-derived sulfate aerosols. Climate sensitivity (ΔT_{2x}) values of 1.5, 2.5, and 4.5°C are used.

The results are plotted as a simple scatter diagram of temperature change against CO₂ concentration (see Figure 19-1). The scatter plot has 22 5-year values (1990 values are zero in each case) by six scenarios by three sensitivities (396 points). The diagram is meant only to illustrate a range of possibilities. One cannot associate any specific confidence intervals with the ranges shown; however, simultaneous use of realistic values in several input parameters with the judgment that the climate sensitivity range of 1.5–4.5°C represents approximately the 90% confidence interval (see, e.g., Morgan and Keith, 1995) suggests that the probability of a result *outside* the ranges shown, during the interval 1990–2100, is less than 10%.

The results are shown in Figure 19-1. For example, for a future CO₂ level of 550 ppmv, the global mean warming range is 1–3°C relative to 1990. Thus, a specific CO₂ concentration could lead to a range of increases in global mean temperature. Note that this is a transient result; in other words, *if CO₂ concentrations were stabilized at 550 ppmv, substantial additional warming would occur beyond this range* as the climate system slowly relaxed toward a new equilibrium state. The levels of increase in global mean temperature displayed in the diagram are less than what would eventually happen if CO₂ concentrations were stabilized at a particular level. Note also that there is no time (or date) associated with any particular concentration level. For, example, in the SRES scenarios, 550 ppmv is reached at a range of dates from about 2050 onward.

◀ **Figure 19-1:** Global mean temperature change (from 1990) as a function of CO₂ concentration for SRES scenarios. For any given CO₂ level, uncertainties in temperature arise through several factors. The three most important are accounted for here: First, different temperatures for a given future CO₂ level may arise because each emissions scenario has different levels of other GHGs and different levels of SO₂ emissions—factors that lead to a range of possible non-CO₂ forcings (results here consider all six SRES illustrative scenarios); second, different temperatures arise because of uncertainties in climate sensitivity (three values—1.5, 2.5, and 4.5°C equilibrium warming for a CO₂ doubling—are used here); and third, different temperatures arise because different rates of radiative forcing change and different climate sensitivities lead to different levels of damping of the instantaneous equilibrium response.

and socioeconomic groups. To be sure, some development paths can increase some types of vulnerabilities, whereas others can reduce those vulnerabilities.

Adaptive capacity in natural systems tends to be more limited than adaptive capacity in human systems. Many species have limited ability to migrate or change behavior in response to climate change. What may be of greater concern is the harm that already has been done to natural systems by societal development. Habitat fragmentation and destruction, as well as creation of barriers to migration, will make it much more difficult for species to cope with climate change than if natural systems were undisturbed.

We do not address adaptation explicitly in this chapter, except to the extent that the literature cited here considers adaptation. Adaptation may have the potential to reduce vulnerability and, in many cases, shift the threshold for negative impacts to higher magnitudes of climate change. The degree to which adaptation can do so is not addressed here; it should be the subject of future research.

19.1.4. Chapter Organization

The chapter is organized into the following sections:

- Section 19.2 addresses the insights we can gain by examining observed effects of climate change. Are we seeing impacts of climate change on nature and society?
- Section 19.3 addresses what changes in global mean temperature may cause harm to threatened and unique systems. For example, are threatened and unique systems at risk from even low levels of increase in global mean temperature? Are some societies at particular risk at low levels of temperature increase?
- Section 19.4 addresses the evidence regarding the relationship between change in global mean temperature and distribution of impacts. Are adverse or positive impacts from climate change distributed equally around the world and within countries? Are some regions harmed at certain levels of climate change while others benefit? Are some subgroups or cultures at greater risk than the population as a whole?
- Section 19.5 addresses what insights we gain from aggregate or comprehensive approaches to measuring impacts. What do approaches such as monetization or looking at the number of people who are harmed or benefited tell us about the relationship between aggregate impacts and higher temperatures? This section also addresses insights gained from integrated assessment models (IAMs).
- Section 19.6 addresses the potential for increases in extreme climate events and large-scale singular effects. As temperatures increase or the rate of temperature rise increases, does the potential for extreme climate events and singular effects such as a change in ocean circulation patterns or the collapse of ice sheets increase? Can

thresholds of change in terms of magnitudes or rates of change be identified?

- Section 19.7 addresses the limitations of the information used in this chapter to address observations and the reasons for concern. It also addresses future research that is needed to narrow these uncertainties.
- Section 19.8 summarizes the findings on observations and the reasons for concern.

Sections 19.2 and 19.3 draw most heavily on the TAR. Examples can be found in the region and sector chapters of this report; the sections in this chapter do not introduce new information. Instead, they synthesize that information in ways that the other chapters are unable to because they do not examine all regions and sectors. Sections 19.4, 19.5, and 19.6 draw on information that is not found in the regional and sectoral chapters. They do so because they address issues that those chapters cannot:

- Comparison of impacts across regions (Section 19.4). The sectoral chapters do this for each sector, but this can be done comprehensively only in this chapter.
- Aggregation of impacts (Section 19.5). This requires use of common metrics to aggregate impacts across sectors and regions. None of the other chapters can do this.
- Examination of changes in extreme events and large-scale discontinuities (Section 19.6). This generally is not addressed in the region and sector chapters because the climate change scenarios that are used most commonly in impacts studies examine only changes in average conditions, not changes in extreme events or large-scale discontinuities (see Chapter 4).

Thus, this chapter contains much new information in a framework that can help readers judge what may be considered to be a dangerous level of climate change.

19.2. Observations of Climate Change Impacts

It is well established from physical, ecological, and physiological studies that climate strongly influences physical and biological systems. This section addresses whether changes in regional climate during the 20th century, documented by WGI, have resulted in measurable impacts on physical and biological systems. We also consider the potential for detecting observed impacts of regional climate change in socioeconomic systems. The objective here is to evaluate the accumulating body of evidence with regard to the following questions:

- 1) Is there a coherent signal in patterns of observed impacts?
- 2) Are observed effects of regional climate changes consistent with functional understanding and modeled predictions of impacts?
- 3) Do observed effects provide information about the potential vulnerability of systems to climate change?
- 4) How do impacts observed over the past century relate to the five reasons for concern brought forward by this chapter?

In relation to the five reasons for concern, the accumulating body of studies documenting observed impacts of regional climate changes may contribute to understanding of:

- Actual and potential climate change effects on *unique and threatened systems*
- Relationships of impacts to changes in *extreme events*
- Functional and geographical *distribution* of current and future climate change effects
- *Aggregation of impacts*
- Potential effects of *large-scale singularities*.

In this section, we focus on observed impacts that have been associated with regional climate changes over the past 100 years. We examine evidence in physical and biological systems in terrestrial, coastal and marine, and freshwater environments, as well as in socioeconomic systems, including agriculture, commercial fisheries, human settlements, insurance and financial services, and human health (see also other chapters in this report).

The studies reviewed document an observed impact in a physical, biological, or socioeconomic system associated with changes in one or more regional climate variables (most often temperature rise). The effects are examined with regard to the range and geographical extent of processes and species involved, their consistency with functional understanding of mechanisms or processes involved in climate-impact relationships, and the possibility of alternative explanations and confounding factors. Expected directions of change relating to regional climate warming for physical systems include shrinkage of glaciers, decrease in snow cover, shortening of duration of lake and river ice cover, declines in sea-ice extent and thickness, lengthening of frost-free seasons, and intensification of the hydrological cycle. Expected directions of change relating to regional climate warming for biological systems include poleward and elevational shifts in distribution and earlier phenology (i.e., earlier breeding, emergence, flowering) in plant and animal species.

We follow the WGI definition of climate change as a statistically significant variation in the mean state of the climate or its variability, persisting for an extended period (typically decades or longer). Climate change, as defined here, may be caused by natural internal processes or external forcings or by persistent anthropogenic changes in the composition of the atmosphere or land use.

Since 1860, the global mean temperature has warmed $0.6 \pm 0.2^\circ\text{C}$; regional temperature changes have varied, ranging from greater than 0.6°C to cooling in some regions (TAR WGI Chapter 2). Annual land-surface precipitation has increased (0.5–1% per decade) in most middle and high latitudes of the northern hemisphere, except over eastern Asia. In contrast, over much of the subtropical land areas, rainfall has decreased during the 20th century (0.3% per decade), although it has been recovering in recent years (TAR WGI Chapter 2). The recent warming period began in 1976, with pronounced warming observed in northwestern North America, central northern Asia, and the

southern Pacific Ocean. Detection of climate change and attribution of causes are discussed in TAR WGI Chapter 12.

19.2.1. Methods of Analysis

Accumulation of evidence over time and space, based on numerous individual studies, is needed to detect and characterize patterns and processes of observed climate change impacts on a global basis (see Chapter 2). In many studies, changes in impact systems are compared with trends in climate variables over the same period and location. Many studies establish statistically significant trends in the observed impact and the climate variable, as well as a statistically significant association between the two (e.g., Beebee, 1995; Brown *et al.*, 1999; Barber *et al.*, 2000). Others refer to trends in climate documented elsewhere (e.g., Menzel and Fabian, 1999; Thomas and Lennon, 1999). When multiple species or locations are examined, cases are reported that exhibit no change, change that is consistent with understanding of climate-impact relationships, and change that is inconsistent with understanding of climate-impact relationships. This allows for assessment of whether observed changes are significantly different from random chance and are consistent with functional understanding of climate responses (e.g., Ellis, 1997; Ellis *et al.*, 1997; Bradley *et al.*, 1999; Pounds *et al.*, 1999).

Individual studies that link observed impacts to regional climate change may be hampered by methodological problems such as length of time-series data of observed impacts; number of replications of populations, census sites, or species; availability of climate data to which to compare observed changes; and uncertainty about whether observed impacts and regional climate variables are measured at appropriate spatial scales (Chapter 2). In some regions, several individual studies have focused on differing aspects of a common ecosystem, providing evidence for associations between climate change and multiple responses in a given geographical area (e.g., Smith *et al.*, 1999); in other regions, however, studies examine more isolated responses.

Because changing climate and ecological responses are linked over a range of temporal scales, long periods of study allow more accurate conclusions regarding the significance of observed ecosystem changes. Large-amplitude temporal changes usually involve large spatial dimensions, so broad-scale spatial/temporal ecosystem studies tend to be more robust. The majority of studies document trends for periods of more than 20 years (e.g., Post *et al.*, 1997; Winkel and Hudde, 1997; Post and Stenseth, 1999); a few studies document trends for 10–19 years (e.g., Jarvinen, 1994; Forchhammer *et al.*, 1998); and several studies analyze data from two periods with a gap between them (Bradley *et al.*, 1999; Sagarin *et al.*, 1999).

Climate Trends: The various studies of observed impacts of recorded regional temperature change over the past century, which include the recent warm decades of the 1980s and 1990s, often differentiate responses to mean, minimum, and maximum temperatures. Regional precipitation changes and periods of

droughts and floods are much more variable in observed records and more uncertain with regard to future predictions and are not the primary focus here. Studies also have considered possible observed responses to the rising atmospheric concentrations of CO₂ over the past century, but these studies are not included in this review.

To the extent that periodicities or trends are found in the climate record, nonzero autocorrelations are to be expected on the interannual time scale. Their importance depends on the percentage of variance associated with the periodicities and the magnitude of the trend relative to interannual noise. Often the periodicities represent only a small proportion of the total variance; this is especially true on a local level, where the noise is likely to be higher than at broader spatial scales. A nonzero autocorrelation does not automatically mean the year-to-year ecological impact is not meaningful because if year-to-year climate variability is associated with a periodic or steadily increasing climate forcing, so too would be the ecological response.

Processes and Mechanisms: Beyond statistical association, an important aspect of many studies is comparison of documented changes to known relationships between climate and impact systems. For example, under regional warming, retreat of glaciers is expected because of shifts in the energy balance of glaciers, as is poleward expansion of species' ranges when temperatures exceed physiological thresholds. If documented changes are consistent with known processes that link climate and the impact system, confidence in the associations between changes in regional climate and observed changes is enhanced.

Multiple Causal Factors: The presence of multiple causal factors (e.g., land-use change, pollution, biotic invasion) makes attribution of many observed impacts to regional climate change a complex challenge at the individual study and meta-analysis levels (e.g., Prop *et al.*, 1998; Körner, 1999). Some of the competing explanations for observed impacts themselves could have a common driver that would make them strongly correlated; identifying these drivers is a methodological challenge. Studies seek to document observed climate change impacts by ruling out other possible contributing causative factors, ecological or anthropogenic, through study design and sampling techniques (e.g., Parmesan, 1996; Menzel and Fabian, 1999; Parmesan *et al.*, 1999), statistical analyses (e.g., Prop *et al.*, 1998; Reading, 1998), or expert judgment (De Jong and Brakefield, 1998; Brown *et al.*, 1999). Sometimes, different studies offer alternative explanations for observed impacts (e.g., Körner, 1999).

Signals of regional climate change impacts may be clearer in physical systems than in biological systems, which are simultaneously undergoing many complex changes that are not related to climate, including land-use change and pollution processes such as eutrophication and acidification. Observed impacts in high-latitude and high-altitude physical systems, such as melting of glaciers, may be more straightforward to detect, whereas biological responses to climate tend to be more complex and may be masked by the presence of the

aforementioned multiple causal factors. To deal with these ecological complexities, confounding factors often are minimized by conducting studies away from large urban or agricultural areas, in large natural areas (e.g., northern Canada, Australia), or in preserved areas.

Signals of regional climate change impacts probably are most difficult to detect in socioeconomic systems because such systems are strongly affected by simultaneous trends in population and income growth and urbanization and because of the presence of adaptive capacity (see Chapter 18). Observed climate change impacts in socioecosystems may be adaptations in many cases, such as farmers sowing crops earlier in response to warmer spring temperatures.

An example of these methodological complexities in climate change impact detection may be drawn from the human health sector. Although climate is known to influence many disease vectors (such as the range of anopheline mosquitos that carry malaria), the presence or absence of sanitation systems, vaccination programs, adequate nutritional conditions, animal husbandry, irrigation, and land-use management also influences whether the presence of a disease in wild vectors leads to disease outbreaks in human populations (see Chapter 9).

Evaluating Patterns of Change: Grouping individual studies to evaluate patterns and processes of change on larger spatial scales reduces the influences of study-specific biases and local nonclimatic factors. Comparing expected geographical patterns of responses to regional climate changes and to changes that are not related to climate helps distinguish among multiple possible causations. For example, regional warming would be expected to skew the distribution of insect extinctions to be greater at the southern boundaries rather than at the northern boundaries; land-use change, in contrast, would be expected to cause approximately equal extinctions at both range boundaries (Parmesan, 1996; Parmesan *et al.*, 1999). Care must be taken to ensure that the sample of studies is representative across time and space, is not biased in reporting, and uses appropriate statistical tests. Spottiness of evidence in other regions may indicate that observed impacts of regional climate change are not occurring, have not yet been detected, or are being masked by other changes, such as urbanization.

Some studies of observed impacts have used a "fingerprint" approach, based on the definition of expected biological changes arising from regional climate change (e.g., Epstein *et al.*, 1998). This approach is similar to that used in detection of climate changes (see TAR WGI Chapter 12) but differs in that fingerprint studies of ecosystem impacts use selected data and that long-term monitoring of changes in ecosystems generally is lacking at regional or global scales.

19.2.2. Synthesis of Observed Impacts

There is an accumulating body of evidence of observed impacts relating to regional climate changes—primarily rising

temperature across a broad range of affected physical processes and biological taxa—and widespread geographical distribution of reported effects (see Figure 19-2 and accompanying notes). In many cases, reported changes are consistent with functional

understanding of the climate-impact processes involved. Cases of no change or change in unexpected direction are noted, as are possible alternative explanations and confounding factors, where available.

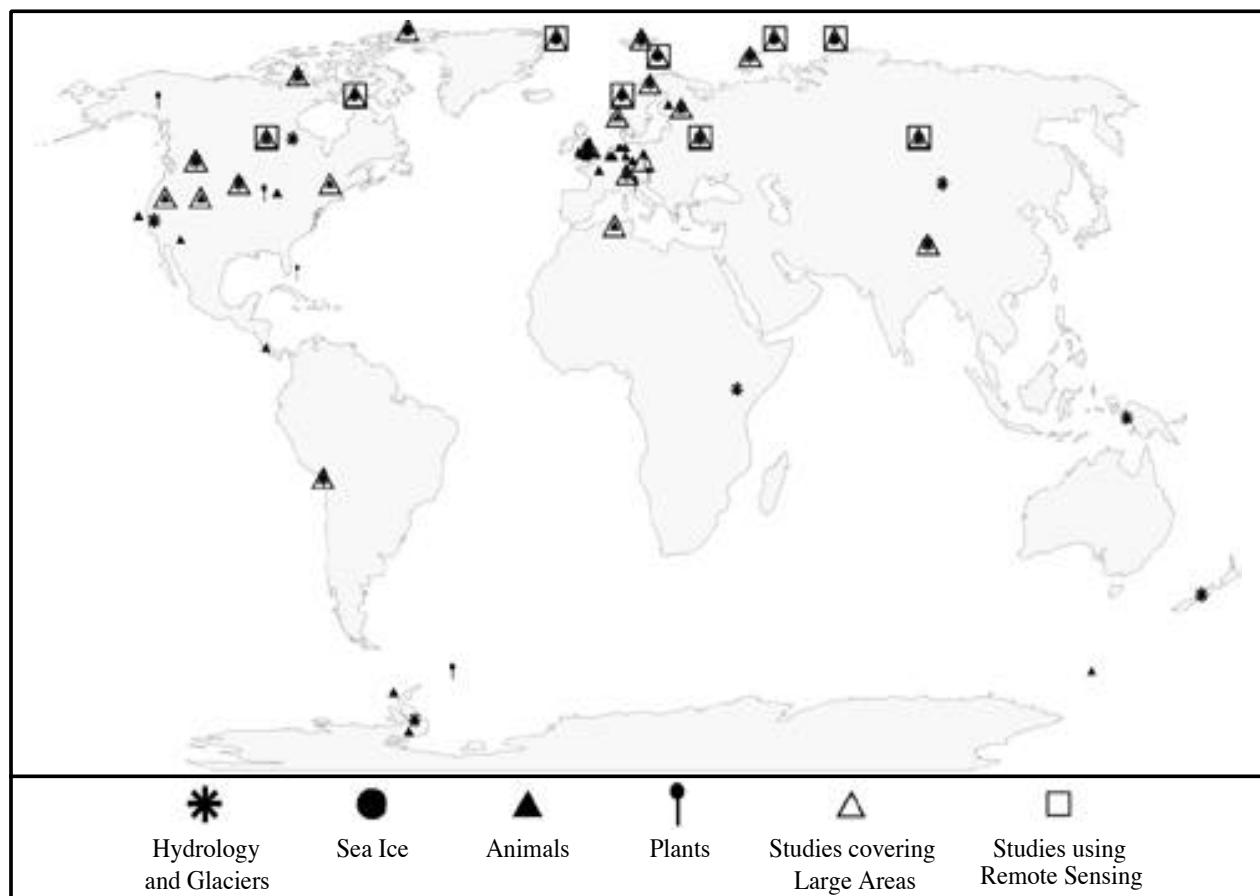

Figure 19-2: Observed impacts of temperature-related regional climate change in the 20th century:

- *Hydrology and Glaciers*—Glacier retreat, decrease in snow-cover extent/earlier snowmelt, reduction in annual duration of lake and river ice
- *Sea Ice*—Decline in sea-ice extent and thickness
- *Animals*—Poleward and elevational shifts in range, alteration in species abundance, changes in phenology (including earlier reproduction and migration), physiological and morphological adaptation
- *Plants*—Change in abundance and diversity, change in phenology (including earlier flowering), change in growth.

Studies that cover large areas and use remote-sensing methods are indicated. About 50 studies were selected, according to the following criteria: (1) hydrology/sea-ice studies that report long-term trends in observed variables (time periods of studies range from ~20 to 150 years), and (2) terrestrial and marine ecosystem studies that associate trends in observed change(s) with trends in regional climate data for ≥20 years (time periods of studies range from ~20 to 50 years). Of the ~100 physical processes and ~450 biophysical species that exhibited change, more than 90% (~99% physical, ~80% biophysical) are consistent with well-known mechanisms of system responses to climate.

Sources: *Hydrology and Glaciers, and Sea Ice*—Ames and Hastenrath (1996), Cavalieri *et al.* (1997), Dettinger and Cayan (1995), Dowdeswell *et al.* (1997), Dyurgerov and Meier (1997), Greene *et al.* (1999), Groisman *et al.* (1994), Haeberli and Beniston (1998), Hastenrath (1995), Johannessen *et al.* (1999), Kaser (1999), Kratz *et al.* (2001), Magnuson *et al.* (2000), Maslanik *et al.* (1996), Rothrock *et al.* (1999), Schindler *et al.* (1990), and Vinnikov *et al.* (1999); *Animals and Plants*—Barber *et al.* (2000), Bergmann (1999), Bezzel and Jetz (1995), Bradley *et al.* (1999), Brown *et al.* (1999), Crick and Sparks (1999), Crick *et al.* (1997), Cunningham and Moors (1994), Dunn and Winkler (1999), Ellis (1997), Ellis *et al.* (1997), Fleming and Tatchell (1995), Forchhammer *et al.* (1998), Fraser *et al.* (1992), Gatter (1992), Grabherr *et al.* (1994), Hasenauer *et al.* (1999), Jarvinen (1994), Loeb *et al.* (1997), Ludwichowski (1997), Mason (1995), McCleery and Perrins (1998), Menzel and Fabian (1999), Pauli *et al.* (1996), Parmesan (1996, 2001), Parmesan *et al.* (1999), Post and Stenseth (1999), Post *et al.* (1997), Pounds *et al.* (1999), Ross *et al.* (1994), Sagarin *et al.* (1999), Slater (1999), Smith (1994), Smith *et al.* (1999), Sparks (1999), Thomas and Lennon (1999), Visser *et al.* (1998), Winkel and Hudde (1996, 1997), Zhou *et al.* (1995).

19.2.2.1. Hydrology

The hydrological cycle is expected to respond to regional climate warming through changes in the energy balance of glaciers and the depth and extent of snow cover, earlier snowmelt runoff, seasonal changes in freezing and thawing of lakes and rivers, and intensification of precipitation and evaporative processes. For the most part, evidence of regional climate change impacts on elements of the hydrological cycle is consistent with expected responses to warming temperatures and intensification of hydrological regimes (see Chapters 4 and 5, and TAR WGI).

Evidence for such changes in the 20th century includes recession of glaciers on all continents (e.g., Hastenrath, 1995; Ames and Hastenrath, 1996; Dowdeswell *et al.*, 1997; Dyurgerov and Meier, 1997; Haeberli and Beniston, 1998; Greene *et al.*, 1999; Kaser, 1999; Krabill *et al.*, 1999; Serreze *et al.*, 2001). There have been decreases in the extent of snow cover (10% since the late 1960s and 1970s) in the northern hemisphere (e.g., Groisman *et al.*, 1994; Serreze *et al.*, 2001). Since the late 1940s, snowmelt and runoff have occurred increasingly earlier in northern and central California (Dettinger and Cayan, 1995). Annual duration of lake- and river-ice cover in the middle and high latitudes of the northern hemisphere has been reduced by about 2 weeks and is more variable (Schindler *et al.*, 1990; Magnuson *et al.*, 2000; Kratz *et al.*, 2001).

Also reported is increased frequency of extreme rainfall in the middle and high latitudes of the northern hemisphere, including the United States (Karl and Knight, 1998), the UK (Osborn *et al.*, 2000), and most extratropical land areas except China (Groisman *et al.*, 1999).

19.2.2.2. Terrestrial Ecosystems

Ecological theory predicts several types of species and community responses to changing regional climate in plants and animals: changes in ecosystem structure and dynamics, including shifts in ranges and distributions; altered phenology; effects on physiology; and genetic evolutionary responses (see Chapters 2 and 5). Changes in disturbance (e.g., fires, wind damage) also may be occurring but are not included in this review (see Chapters 5 and 6). Evidence from plants and animals documents all of these types of ecological responses to regional warming, especially poleward and elevational shifts in species ranges and earlier timing of reproduction. Reviews of recent changes in biological systems also have documented examples of these different types of responses, consistent with process-level understanding (Hughes, 2000).

19.2.2.2.1. Vegetation

Much of the evidence of vegetation change relating to regional climate change comes from responses to warming at high-latitude and high-altitude environments, where confounding factors such as land-use change may be minimized and where

climate signals may be strongest (see TAR WGI Chapter 12). Increases in species richness were found at 21 of 30 high summits in the Alps; remaining summits exhibited stagnation or a slight decrease (Grabherr *et al.*, 1994; Pauli *et al.*, 1996). However, Körner (1999) suggests that grazing, tourism, and nitrogen deposition may be contributing to such observed migrations. Hasenauer *et al.* (1999) found significant increases in diameter increments of Norway spruce across Austria related to increased temperatures from 1961 to 1990. In North America, Barber *et al.* (2000) linked reduced growth of Alaskan white spruce to temperature-induced drought stress, and Hamburg and Cogbill (1988) propose that historical declines in red spruce in the northeastern United States are related to climatic warming, possibly aggravated by pollution and pathogen factors.

In more temperate ecosystems, Bradley *et al.* (1999) documented phenological advances in flowering date in 10 herbaceous and tree species and no change in 26 such species related to local warming in southern Wisconsin over the periods 1936–1947 and 1976–1998. Menzel and Fabian (1999) document extension of the growing season for 12 tree and shrub species at a network of sites throughout Europe, which they attribute to warming temperature. Alward and Detling (1999) found reorganization of a shortgrass steppe ecosystem in a semi-arid site in Colorado related to increased spring minimum temperatures, although the responses of C₃ and C₄ species did not occur as expected.

Regarding regional changes in precipitation—which are much more uncertain with regard to future climate—reorganization of a semi-arid ecosystem in Arizona, including increases in woody shrubs, has been associated with increases in winter precipitation (Brown *et al.*, 1997); retraction of mesic species to areas of higher rainfall and lower temperature has been attributed to a long-term decline in rainfall in the West African Sahel (Gonzalez, 2001).

19.2.2.2.2. Animals

Temperature change-related effects in animals have been documented within all major taxonomic groups (amphibians, birds, insects, mammals, reptiles, and invertebrates) and on all continents (see Chapter 5). Terrestrial evidence in animals that follows process-level understanding of responses to warming includes poleward and elevational changes in spatial distribution, alterations in species abundance and diversity, earlier phenology (including advances in timing of reproduction), and physiological and genetic adaptations.

Poleward and elevational shifts associated with regional warming have been documented in the ranges of North American, British, and European butterfly species (Parmesan, 1996; Ellis, 1997; Ellis *et al.*, 1997; Parmesan *et al.*, 1999), birds (Thomas and Lennon, 1999), and insects (Fleming and Tatchell, 1995). Prop *et al.* (1998) found that increasing spring temperatures and changes in agricultural practices in Norway have allowed barnacle geese (*Branta leucopsis*) to move northward and

invade active agricultural areas. Changes in species distribution and abundance of amphibians, birds, and reptiles in Costa Rica have been associated with changing patterns of dry-season mist frequency and Pacific sea-surface temperatures (SST) (Pounds *et al.*, 1999; Still *et al.*, 1999).

Earlier timing of reproduction has been found for many bird species (Mason, 1995; Crick *et al.*, 1997; McCleery and Perrins, 1998; Crick and Sparks, 1999; Slater, 1999) and amphibians (Beebee, 1995; Reading, 1998) in the UK and Europe (Winkel and Hudde, 1996, 1997; Ludwichowski, 1997; Forchhammer *et al.*, 1998; Visser *et al.*, 1998; Bergmann, 1999). Zhou *et al.* (1995) found a warming trend in the spring to be associated with earlier aphid flights in the UK. Also in the UK, Sparks (1999) has associated arrival times of bird migration to warmer spring temperature. Bezzel and Jetz (1995) and Gatter (1992) document delays in the autumn migratory period in the Alps and Germany, respectively.

In North America, Brown *et al.* (1999) document earlier egg-laying in Mexican jays (*Aphelocoma ultramarina*) associated with significant trends toward increased monthly minimum temperatures in Arizona. Dunn and Winkler (1999) found that the egg-laying date of North American tree swallows advanced by as much as 9 days, associated with increasing air temperatures at the time of breeding. Bradley *et al.* (1999) document phenological advances in arrival dates for migratory birds in southern Wisconsin, associated with earlier icemelt of a local lake and higher spring temperature.

Post *et al.* (1997) and Post and Stenseth (1999) document differential selection of body size in red deer throughout Norway from 1965 to 1995. Male red deer have been getting larger and females smaller, correlated with warming trends and variations in the North Atlantic Oscillation (NAO). Post and Stenseth (1999) also report on the interactions of plant phenology, northern ungulates (red deer, reindeer, moose, white-tailed deer, musk oxen, caribou, and Soay sheep), and the NAO. Jarvinen (1994) found that increased mean spring temperatures in Finnish Lapland are associated with mean egg volume of the pied flycatcher. De Jong and Brakefield (1998) found shifts in color patterns (black with red spots versus red with black spots), most likely related to thermal budgets of ladybird beetles (*Adalia bipunctata*) in The Netherlands, coinciding with an increase in local ambient spring temperatures. The potential for rapid adaptive responses and their genetic costs to populations has been studied by Rodriguez-Trelles and Rodriguez (1998), who found microevolution and loss of chromosomal diversity in *Drosophila* in northwestern Spain as the local climate warmed.

19.2.2.3. Coastal Zones and Marine Ecosystems

In coastal zones and marine ecosystems, there is evidence of changes in physical and biological systems associated with regional trends in climate, especially warming of air temperatures and SST (see Chapters 4, 5, and 6). However, separating out responses of marine ecosystems to variability caused by

large-scale ocean-atmosphere phenomena, such as ENSO and NAO, from regional climate changes is a challenge (e.g., Southward *et al.*, 1995; McGowan *et al.*, 1998, 1999; Sagarin *et al.*, 1999). Variations caused by ENSO and NAO *per se* are not considered climate change, but multi-decadal trends of change in ENSO or NAO frequency and intensity are climate changes, according to the IPCC definition.

19.2.2.3.1. Physical processes

Changes in the physical systems of coastal zones related to regional warming trends include trends in sea ice and coastal erosion. Since the 1950s, Arctic sea-ice extent has declined by about 10–15%; in recent decades, there has been about a 40% decline in Arctic sea-ice thickness during late summer to early autumn and a considerably slower decline in winter (e.g., Maslanik *et al.*, 1996; Cavalieri *et al.*, 1997; Johannessen *et al.*, 1999; Rothrock *et al.*, 1999; Vinnikov *et al.*, 1999; Serreze *et al.*, 2001). No significant trends in Antarctic sea-ice extent are apparent (see TAR WGI).

19.2.2.3.2. Marine ecosystems

Evidence from marine ecosystems documents changes in species abundance and diversity and spatial distributions associated with air and ocean temperature rises (Chapters 5 and 6). Several studies document changes from the Antarctic region: Increases in chinstrap (*Pygoscelis antarctica*) penguins, stability or slow declines in Adelie (*Pygoscelis adeliae*) penguins, and declines in rockhopper penguins in recent decades are attributed in part to differential responses to warming climate conditions that are altering bird habitats (Fraser *et al.*, 1992; Cunningham and Moors, 1994; Smith *et al.*, 1999). Loeb *et al.* (1997) report effects on the Antarctic food web resulting from decreased frequency of winters with extensive sea-ice development; krill abundance is positively correlated with sea-ice extent, and salp abundance is negatively correlated. Smith (1994) reports a significant and relatively rapid increase in the numbers of individuals and populations of the only two native Antarctic vascular plant species at two widely separated localities in the maritime Antarctic.

Increases in abundance of southern macroinvertebrate species and declines in northern species in a rocky intertidal community on the California coast are consistent with recent climate warming (Sagarin *et al.*, 1999). Warming annual temperature has been suggested as a possible cause of increases in abundance of plankton in the German Bight, but numerous factors, including regional eutrophication, also have been noted (Greve *et al.*, 1996). Lehman (2000) found that the distribution of phytoplankton biomass in northern San Francisco Bay Estuary was influenced by environmental conditions resulting from an interdecadal climate regime shift between 1975 and 1993; precipitation regimes were primarily implicated, with water temperatures also playing an important role. Ross *et al.* (1994) document the loss of low-elevation pine forests in the Florida Keys because of rising sea level.

19.2.2.4. Socioeconomic Systems

Evidence of observed impacts of regional climate changes from socioeconomic systems is much sparser than from physical and biological systems, and methodologically it is much more difficult to separate climate effects from other factors such as technological change and economic development, given the complexities of these systems. Vulnerability to climate change and climate variability is a function of exposure and adaptive capacity (see Chapter 18). Exposure varies from region to region, sector to sector, and community to community, and adaptive capacity may be even more variable. The adaptive capacity of socioeconomic systems also contributes to the difficulty of documenting effects of regional climate changes; observable effects may be adaptations to a climate change rather than direct impacts. Evidence of observed adaptation of many of these systems to multiple stresses, including climate variability, suggests that complexities inherent in socioeconomic systems could be a source of resilience, with potential for beneficial adaptations in some cases. Studies that have explored some of these complex relationships are briefly reviewed in the following subsections, but they are not included in the summary tabulation or figure.

19.2.2.4.1. Agriculture and commercial fisheries

It has been proposed that observed impacts of changes in regional climate warming that are relevant to agriculture are related to increasing yield trends in Australia, lengthening growing seasons at high latitudes, improved wine quality in California, and expansion and advanced phenologies of agricultural pests. However, links between changes in regional climate variables and such changes are hard to prove because agriculture is a multifactored biophysical and socioeconomic system (see Chapter 5).

Nicholls (1997) analyzed Australian wheat yields from 1952 to 1992 and concluded that climate trends appear to be responsible for 30–50% of observed increases, with increases in minimum temperatures (decreases in frosts) the dominant influence (Nicholls, 1997); this conclusion has been questioned, however, by Godden *et al.* (1998) and Gifford *et al.* (1998). Possible confounding socioeconomic factors in identifying the effects of climate change on crop yields are responses of farmers to growing conditions (e.g., farmers may increase fertilizer application in good years, thereby exaggerating the impact of climate variables on yield), technological progress, changes in market structure, and changes in agricultural subsidies. Crop responses to increasing atmospheric CO₂ concentrations also may affect yield trends.

Carter (1998) found that the growing season in the Nordic region (Iceland, Denmark, Norway, Sweden, and Finland) lengthened between 1890 and 1995 at all sites except Iceland, with likely but undocumented impacts on crop phenologies and timing of farm operations.

Nemani *et al.* (2001) relate warming at night and during spring in California over the period 1951–1997 (especially since 1976) to improved vintage quantity and quality.

Recent expansion and advances in insect phenologies may be associated with regional increases in mean or minimum temperatures (e.g., advances in flight phenology of aphid species in Britain) (Fleming and Tatchell, 1995; Zhou *et al.*, 1995). Such increases in insect pests may be contributing to agricultural losses at least partially related to recent climate trends, but these effects have not been examined analytically.

Some changes in marine and coastal ecosystems have links to commercial fisheries, but it is difficult to separate regional climate effects from human use of fish stocks (see Chapter 6). Recent warming trends and coincident overfishing and eutrophication have been noted in the English Channel and North Sea, with potential future consequences for fish of high mass-market value (e.g., haddock, cod, plaice, lemon-sole cod—Southward *et al.*, 1995; O'Brien *et al.*, 2000). Diminished krill supplies in the Antarctic associated with decreases in annual sea-ice cover and warmer air temperature documented by Loeb *et al.* (1997) between 1976 and 1996 may have long-term negative effects on upper trophic levels, affecting commercial harvests. These observations, in part, have prompted the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) to request updated krill data currently used in krill management. CCAMLR manages and sets limits on the international harvest of Antarctic krill (Loeb *et al.*, 1997).

19.2.2.4.2. Energy, industry, human settlements, and financial and insurance services

Associations between regional climate trends and impacts related to energy, industry, and human settlements are sparse. One documented example is rapid coastal retreat along ice-rich coasts of the Beaufort Sea in northwestern Canada (Dallimore *et al.*, 1996). Where communities are located in ice-rich terrain along the shore, warmer temperatures combined with increased shoreline erosion can have a very severe impact (see Chapter 6).

Determining the relationship between regional climate trends and impacts relating to financial and insurance services is difficult because of concurrent changes in population growth, economic development, and urbanization. Trends have been analyzed regarding increased damages by flooding and droughts in some locations. Global direct losses resulting from large weather-related disasters have increased in recent decades (see Chapter 8). Socioeconomic factors such as increased coverage against losses account for part of these trends; in some regions, increases in floods, hailstorms, droughts, subsidence, and wind-related events also may be partly responsible (see Chapter 8). Attribution is still unclear, however, and there are regional differences in the balance of these two causes. Hurricane and flood damages in the United States have been studied by Changnon *et al.* (1997), Changnon (1998), and Pielke and Downton (2001). Pielke and Downton (2001) found

that increases in recent decades in total flooding damage in the United States are related to climate factors and societal factors: increased precipitation and increasing population and wealth. Hurricane damages, on the other hand, are unaffected by observed climate change (Changnon *et al.*, 1997; Changnon, 1998).

19.2.2.4.3. Human health

There is little evidence that recent trends in regional climates have affected health outcomes in human populations (see Chapter 9). This could reflect a lack of such effects to date or difficulty in detecting them against a noisy background containing other more potent influences on health (Kovats *et al.*, 1999). The causation of most human health disorders is multifactorial, and the socioeconomic, demographic, and environmental context varies constantly. With respect to infectious diseases, for example, no single epidemiological study has clearly related recent climate trends to a particular disease.

Various studies of the correlation between interannual fluctuations in climatic conditions and the occurrence of malaria, dengue, cholera, and several other infectious diseases have been reported. Pascual *et al.* (2000) report a relationship between cholera and El Niño events. Such studies confirm the climate sensitivity of many infectious diseases, but they do not provide quantitative information about the impact of decadal-level climate change. Fingerprint studies examine the patterns of collocated change in infectious diseases and their vectors (if applicable) in simpler physical and ecological systems. This is an exercise in pattern recognition across qualitatively different systems.

One example is the set of competing explanations for recent increases in malaria in the highlands (see Chapter 9). A fingerprint study has hypothesized possible connections of plant and insect data, glacier observations, and temperature records to global climate change in high-altitude locations, with implications for patterns of mosquito-borne diseases (Epstein *et al.*, 1998). Loevinsohn (1994) notes a connection between climate warming and increased rainfall with increased malaria incidence in Rwanda, whereas Mouchet *et al.* (1998) emphasizes the importance of nonwarming factors (e.g., land-use change in response to population growth, climate variability related to ENSO) in explaining variations in malaria in Africa.

Changes in disease vectors (e.g., mosquitoes, ticks) are likely to be detected before changes in human disease outcomes. Furthermore, a change in vector does not necessarily entail an increase in health impacts because of simultaneous processes related to the disease itself and the human population at risk. For example, the presence or absence of sanitation systems, vaccination programs, adequate nutritional conditions, animal husbandry, irrigation, and land-use management influences whether the presence of a disease in wild vectors leads to disease outbreaks in human populations. The effects of changes in frequency of extreme events may entail changes in health impacts, but these have not been documented to date.

19.2.3. Conclusions

Statistically significant associations between trends in regional climate and impacts have been documented in ~100 physical processes and ~450 biological species or communities in terrestrial and polar environments. More than 90% of the changes (~99% physical, ~80% biophysical) documented worldwide are consistent with how physical and biological processes are known to respond to climate. There are systematic trends of ecological change across major taxonomic groups (amphibians, birds, insects, mammals, reptiles, and invertebrates) inhabiting diverse climatic zones and habitats. The overall processes and patterns of observations reveal a widespread and coherent impact of 20th-century climate changes on many physical and biological systems (see Figure 19-2).

Expected directions of change relating to regional climate warming for physical systems have been reported in studies documenting shrinkage of glaciers, decreases in snow cover, shortening of duration of lake- and river-ice cover, declines in sea-ice extent and thickness, lengthening of frost-free seasons, and intensification of the hydrological cycle. Expected directions of change relating to regional climate warming for biological systems have been reported in studies documenting poleward and elevational shifts in distribution and earlier phenology (i.e., earlier breeding, emergence, flowering) in plant and animal species.

In general, geographic patterns of responses also conform to expectations relating to regional climate change, as opposed to alternative explanations. Reported cases of observed impacts are concentrated in high-latitude and high-altitude physical and biological systems and tend to be in regions where observed regional warming has been greatest and confounding factors often are at least partially minimized. Although land-use change, pollution, and biotic invasions are widespread anthropogenic influences, they are unlikely to cause the spatial patterns (e.g., skewed poleward and elevational range shifts) and temporal patterns (e.g., earlier breeding and flowering) that are documented over the set of reported studies.

The sample of studies shown in Figure 19-2 was drawn from a literature survey with keywords relating to climate trends and observed trends in impacts. The time period of most of the studies includes the recent warm period beginning in the late 1970s. The geographical distribution of studies to date is biased toward Europe and North America but does include evidence of observed impacts of regional climate change relating to physical processes from all continents. The spottiness of biological evidence in other regions may indicate that observed impacts of regional climate change are not occurring, have not yet been detected, or are being masked by other changes, such as urbanization. Many studies include multiple species and report on the number of species that responded to regional climate changes as expected, not as expected, or exhibited no change. Most of the biophysical studies included in Figure 19-2 report on statistical tests of trends in climate variable, trends in observed impacts, and relationships between the two (see Chapter 5).

In Figure 19-2, ~16 studies examining glaciers, sea ice, snow-cover extent/snowmelt, or ice on lakes or streams at more than 150 sites were selected. Of these ~150 sites, 67% (~100) show change in one or more variable(s) over time. Of these ~100 sites, about 99% exhibit trends in a direction that is expected, given scientific understanding of known mechanisms that relate temperatures to physical processes that affect change in that variable. The probability that this proportion of sites would show directional changes by chance is much less than 0.00001.

There are preliminary indications that some social and economic systems have been affected in part by 20th-century regional climate changes (e.g., increased damages from flooding and droughts in some locations). It generally is difficult to separate climate change effects from coincident or alternative explanations for such observed regional impacts. Evidence from studies relating regional climate change impacts on socioeconomic systems has been reviewed but is not included in the summary figure because of the complexities inherent in those systems.

The effects of regional climate change observed to date provide information about the potential vulnerability of physical, biological, and socioeconomic systems to climate change in terms of exposure, sensitivity, and adaptive capacity. Some of the observed effects are adaptations. In some cases, observed impacts are large relative to the levels of regional climate changes (e.g., large changes in ecosystem dynamics with small changes in regional climate). In general, observations of impacts agree with predictions that estimate more serious impacts at higher GHG concentrations because the greater regional climate changes are associated with stronger impacts.

Relating the observed impacts summarized here to the reasons for concern analyzed in this chapter, we find the following:

- 1) There is preliminary evidence that *unique and threatened systems* are beginning to be affected by regional climate change (e.g., glaciers, polar environments, rare species).
- 2) With regard to the *distributional effects* of observed impacts relating to regional climate changes, most evidence to date comes from high-latitude and high-altitude environments, where regional warming has been and is expected to be more pronounced.
- 3) *Aggregate impacts* of regional climate changes at the global level are difficult to define, except in sectors in which there is a common metric, as in market sectors. The many simultaneous factors and varying adaptive capacities make extracting aggregate effects attributable to observed climate change difficult. What can be stated in summary regarding the diverse set of impacts reported to date is that there are cases of observed impacts in many diverse environments; that they occur in a wide array of processes, species, and ecosystems; and that the overall patterns and processes reveal a coherent impact of 20th-century climate changes on many physical and biological systems.
- 4) Impacts of *extreme events* have been implicated in many of the observations summarized in this section,

including increases in extreme precipitation events in some locations.

- 5) There is no current evidence in observed impacts that *large-scale abrupt changes* already are occurring. Yet, paleoclimate evidence (see TAR WGI Chapter 2) shows that such changes have occurred in physical and biological systems in the past and therefore may occur with a continuation of the current warming trend.

19.3. Impacts on Unique and Threatened Systems

19.3.1. What are Unique and Threatened Systems?

Unique systems are restricted to a relatively narrow geographical range but can affect other entities beyond their range. Indeed, many unique systems have global significance. The fact that these unique entities are restricted geographically points to their sensitivity to environmental variables, including climate, and therefore attests to their potential vulnerability to climate change.

Identification of these unique entities provides the first reason for concern regarding vulnerability to climate change. In this section, we provide examples of unique entities that are likely to be threatened by future changes in climate. From those treated by WGII, we address physical, biological, and human systems. We offer a few examples in each system: tropical glaciers, coral reefs, mangrove ecosystems, biodiversity “hot spots,” ecotones, and indigenous communities. These are meant only as illustrative examples; there are many unique and threatened entities. Table 19-1 lists some unique and potentially threatened systems in relation to climate change thresholds that may cause adverse effects. Table 19-2 lists some of the unique and threatened systems that are discussed elsewhere in the TAR.

19.3.2. Physical Systems

A number of physical systems are threatened by climate change. Among the most prominent are those in regions dominated by cold temperatures, such as glaciers. Many glaciers already are receding, and many are threatened by climate change. Other physical systems, such as small lakes in areas that will become drier (see Chapter 4), also are threatened by climate change. Changes in unique physical systems can have serious consequences for unique biological and human systems.

19.3.2.1. Tropical Glaciers

Tropical glaciers are present on several mountains in Asia, Africa, and Latin America. These glaciers are valuable because, among other reasons, they are a major source of water for people living below them. For example, through a network of mountain streams, meltwater of the Himalayan glaciers contributes a sizeable portion of river flows to the Ganges, Brahmaputra, Indus, and other river systems in south Asia.

Table 19-1: Vulnerability of wildlife to climate change (compiled from Chapter 5).

Geographic Area	Impact	Vulnerable to
Most continents, marine, polar regions	– Poleward/elevational shifts in ranges	– Already observed in many species in response to regional climate change
Most continents, marine, polar regions	– Shifts in phenology (e.g., breeding, arrival dates, flowering)	– Already observed in response to regional climate change
Sunderbans, Bangladesh	– Loss of only remaining habitat of Royal Bengal tiger	– Sea-level rise
Caribbean, South Pacific Islands	– Habitat loss, direct mortality of birds	– Hurricanes
Marine	– Reproductive failure in seabirds	– Increased sea-surface temperature (ENSO)
Galapagos, Ecuador, Latin America	– Reduced survival of iguanas	– ENSO
Africa	– Reduced overwinter survival of palearctic migratory birds	– Extreme drought in the Sahel
Monteverde Reserve, Costa Rica	– Extirpation of some cloud forest reptiles and amphibians (already has occurred), elevational shift in some birds	– ENSO, warming, increased frequency of dry season mist
Norway	– Poleward shift of spring range of barnacles geese	– Increase in number of April and May days with temperatures above 6°C
Australia	– Susceptibility of quokka to salmonella infections	– Environmental conditions
United Kingdom	– Earlier hatching of spittlebugs	– Winter-warmed (3°C) grassland plots (experimental)
Scotland	– Faster growth in juvenile red deer, leading to increased body size	– Warmer springs
Isle Royale National Park, United States	– Increased wolf pack size, increased moose mortality, greater growth of understory balsam fir	– Reduction in winter snow cover
Western Antarctic Peninsula	– Reductions in Adelie penguin populations, increases in chinstrap penguin populations	– Increased midwinter surface air temperature, reductions in pack ice, increased snowfall
Northern Hemisphere	– Increased winter survival of some boreal insect pests	– Increased nighttime winter temperatures
Great Plains, USA, and Canada	– Reductions in waterfowl breeding populations as a result of wetland loss	– Increased drought
Africa and Australia	– Wetland loss	– Increased drought
Africa and Australia	– Reduced populations of some mammals	– Increased drought

Table 19-1 (continued)

Geographic Area	Impact	Vulnerable to
Canada	– Loss of 60% of available habitat (habitat migration blocked by Arctic Ocean)	– Climate change
USA and Canada	– Reductions in populations of caribou	– Increased temperatures, snowfall, shifts in precipitation timing
Mexico	– Loss of wintering habitat for eastern population of monarch butterfly	– Climate change leading to habitat change
USA	– Loss of migratory shorebird habitat	– Sea-level rise tied to 2°C temperature increase
Arctic	– Reduced habitat availability and accessibility hampering migration and survival of polar bears, muskox, caribou, and some birds	– Increased temperatures, changing sea-ice regimes
United Kingdom	– Loss of habitat in 10% of designated nature reserves within 30–40 years	– Climate change

Similarly, snow accumulates in winter in the high parts of the cordillera in Peru and melts during summer, becoming the main source of water for many rivers in Latin America (see Section 14.1.3.1.1). In addition, glaciers act as buffers that regulate runoff water supply from mountains to plains during dry and wet spells. Thus, tropical glaciers are instrumental in securing agricultural productivity and livelihoods and provide cultural inspiration for millions of people who live remote from their sources.

Because of the narrow range of ambient temperatures in the tropics, tropical glaciers are more sensitive to climate change than glaciers elsewhere (see Section 4.3.11). Indeed, records spanning several decades show accelerated retreat of several Himalayan and other tropical glaciers (see Section 11.2.1.2).

In the transient phase of melting, increasing discharge will generate floods in the mountains and immediate vicinity, increased siltation of rivers, and larger sediment load in dams and reservoirs. Riparian mountain ecosystems will be impacted during their dry seasons—in the transient phase by a significant increment of downstream flow, as well as following the transient phase—by significant reduction of this flow. These changes will have tangible economic and cultural implications (see Section 11.2.1.2). This example of a tropical unique entity provides an “early warning” for nontropical glaciers and their potential impacts.

19.3.3. Biological Systems

As discussed in Section 19.2, change in climate already appears to be affecting many biological systems. Continued climate changes can threaten a large number of unique biological systems.

This section identifies specific characteristics of some of the most unique and threatened systems, which explain why many are at risk from climate change. In addition, some specific examples of unique and threatened biological systems are presented. Many others also are threatened by climate change; these are discussed in detail in other chapters of this report. Examples of natural systems that may be threatened include montane ecosystems that are restricted to upper 200–300 m of mountainous areas, prairie wetlands, remnant native grasslands, coldwater and some coolwater fish habitat, ecosystems that overlie permafrost, and ice-edge ecosystems that provide habitat for polar bears and penguins. Examples of species that may be threatened by changes in climate include forest birds in Tanzania, the resplendent quetzal in Central America, the mountain gorilla in Africa, amphibians that are endemic to the cloud forests of the neotropics, and the spectacled bear of the Andes.

19.3.3.1. Risks to Species and Ecosystems

Laboratory and field studies have demonstrated that climate plays a strong role in limiting the ranges of species and ecosystems. Species already are responding to changes in regional climate, with altered population sizes and breeding times or flowering dates that occur earlier in the season (see Chapter 5). These responses suggest that many unique species will undergo complex changes with a few degrees of warming, which could lead to extinction in many locations. Such species can be found across various regions (see Table 19-1). Other chapters in this report list many examples (see Table 19-2). However, projecting possible responses of wild animal and plant species is extremely difficult for most species because there are many possible biological interactions and confounding factors, such as habitat destruction and invasive species.

Table 19-2: Threatened and unique entities identified in WGII TAR.

Chapter	Entity
4. Water Resources	<ul style="list-style-type: none"> – Endorheic lakes: Caspian and Aral Seas, Lake Balkash, Lake Chad, Lake Titicaca, Great Salt Lake – Glaciers (in general, no particular reference)
5. Ecosystems and Their Services	<ul style="list-style-type: none"> – Some butterfly species in United States and Europe – Leadbetters's possum in Australia – Cape Floral Kingdom, South Africa
6. Coastal Zones and Marine Ecosystems	<ul style="list-style-type: none"> – Coral reefs
7. Human Settlements	<ul style="list-style-type: none"> – Coastal settlements along North Sea coast in northwest Europe, the Seychelles, parts of Micronesia, Gulf Coast of United States and Mexico, Nile delta, and Bay of Bengal
10. Africa	<ul style="list-style-type: none"> – Cape Floral Kingdom and Succulent Karoo
11. Asia	<ul style="list-style-type: none"> – Biodiversity of Lake Baikal – Glaciers in the Tianshan, Hindukush Himalayas; permafrost in Tibet – Mangroves
12. Australasia	<ul style="list-style-type: none"> – Alpine ecosystems, snow and glaciers in New Zealand, wetlands in Kakadu National Park, Queensland fruit fly – Indigenous communities
13. Europe	<ul style="list-style-type: none"> – Snowpack and permafrost in the mountains
14. Latin America	<ul style="list-style-type: none"> – Mountain glaciers
15. North America	<ul style="list-style-type: none"> – Mountain glaciers – Sardine population – Indigenous communities
16. Polar Regions (Arctic and Antarctic)	<ul style="list-style-type: none"> – Indigenous communities
17. Small Island States	<ul style="list-style-type: none"> – Mangroves and seagrass beds – Coral reefs

Species that make up a natural community, however, most likely will not shift together (Davis, 1986; Overpeck *et al.*, 1994; Root, 2000). This could break apart established natural communities and create newly evolving assemblages. Depending on the magnitude and duration of the environmental disturbance, some or all individuals of a given species may shift out of an area. This, in turn, can cause a local (or even the overall) population size to decline. Superimposed on these potential changes are those caused by land-use change, which frequently fragments populations into patches throughout their ranges.

Species with wide nonpatchy ranges, rapid dispersal mechanisms, and a large population normally are not in danger of extinction [e.g., European house sparrow (*Passer domesticus*) and many weedy plant species]. Those with narrow patchy ranges and

small populations frequently are endangered and may require management for survival [e.g., most crane species (*Gruidea spp.*)]. In summary, species tend to become rarer when ranges shift from wide to narrow, available habitat becomes patchier, and population size declines (Huntley *et al.*, 1997). Indeed, a species is likely to become extinct if it is forced into a narrow patchy range and its population declines—a probability that is enhanced when environmental disturbances such as climate change, along with companion transient changes, occur.

Even when conservation management of rare species is effective, survival still may be problematic because in a small population, genetically similar individuals may breed, which decreases genetic variability. This, in turn, may reduce adaptability to stresses, thereby further lowering population size and decreasing

the types of habitat within which the species could survive. Environmental catastrophes such as hurricanes, oil spills, extreme temperatures, and drought can trigger the extinction of even well-managed rare species. The only way to reduce the risk of extinction brought about by catastrophes is to increase population sizes and maintain corridors between isolated populations.

19.3.3.2. Biodiversity Hot Spots

Biodiversity “hot spots” are areas that feature exceptional concentrations of species, including many endemic species. Unfortunately, many such hot spots also experience large habitat losses. In addition to a hot spot’s economic, social, and cultural significance to local people, the uniqueness of its biodiversity and its high share of global biodiversity give the hot spot a global value. Thus, biodiversity hot spots qualify as unique and threatened entities.

Myers *et al.* (2000) define a hot spot as an area featuring a biogeographic unit that contains at least 0.5% of the world’s 300,000 vascular plant species as endemics and has lost 70% or more of its primary vegetation. Table 19-3 shows that two-thirds of the hot spots listed in Myers *et al.* (2000) are in the tropics, some of which have the highest percentage of global plants (6.7%) and as much as 28% of area of habitat with primary vegetation. Arctic and boreal biomes, however—which are devoid of hot spots—will have the greatest changes in temperature and precipitation by 2100, whereas the exposure of nearly all hot spots to a global change of 4°C and/or 30% of precipitation is ranked only 3 (on a 1 to 5 scale proposed by Sala *et al.*, 2000). With respect to biome-specific exposure, climate is expected to warm most dramatically at high latitudes, change least in the tropics, and show intermediate changes in other biomes. Indeed, Table 19-3 shows that the tropical hot spots are least vulnerable to climate change and elevated CO₂ (0.12 and 0.10, respectively, on a scale of 0 to 1), whereas the eight Mediterranean and savanna hot spots are at least twice as vulnerable (0.24 and 0.30 for climate change and elevated CO₂, respectively—Sala *et al.*, 2000).

The Cape Floral Kingdom (also called the Cape Floristic Province) and the adjacent succulent Karoo in South Africa are examples of Mediterranean and savanna biodiversity hot spots that very much qualify as unique and threatened entities. The Cape Floral Kingdom is sixth in the world in plant richness of species (5,682 endemic species—Cowling and Hilton-Taylor, 1997). These hotspots are vulnerable for the following reasons:

- Their mountains have no permanent snow cover to which high montane species can retreat as climate warms.
- Montane endemic plants already are concentrated near the peaks, with little or no possibility for altitudinal expansion.
- Endemics are concentrated in the southwestern corner of Africa, with no possibility for latitudinal shifts farther south (except for the extreme southern tip of the continent, which is intensively farmed).
- Increased frequency of fires and drought will affect many short-lived and fire-sensitive species; seedlings that germinate after fires will be exposed to successively more extreme climate conditions.

The succulent Karoo flora may be effectively lost with a mean annual temperature increase of 3–4°C (Rutherford *et al.*, 1999), owing to changing fire regimes, loss of specialist pollinators, and increased frequency of drought. Tropic hot spots that are not as sensitive as the Cape Floral Kingdom also will be seriously affected if other anthropogenic drivers act synergistically (Sala *et al.*, 2000). Thus, although the hot spot analysis (Myers *et al.*, 2000) indicates that much of the problem of current and projected mass extinction could be countered by protection of the 25 hot spots, the ability of these hot spots to be sources of biodiversity is threatened by climate change.

19.3.3.3. Ecotones

Ecotones are transition areas between adjacent but different environments: habitats, ecosystems, landscapes, biomes, or ecoclimatic regions (Risser, 1993). Ecotones that are unique

Table 19-3: Sensitivity of biodiversity hot spots (Myers *et al.*, 2000; Sala *et al.*, 2000).

Biome	Number of Hotspots Biome	% of Global Plants (range)	Remaining Habitats with Primary Vegetation (range)	Impact by 2100 (of a large change in driver, scale 1–5)		Effect by 2100 (expected change in driver x impact, scale 0–1)	
				of climate change	of elevated CO ₂	of climate change	of elevated CO ₂
Tropical forests	15	0.5–6.7	3–28	3	1	0.12	0.10
Mediterranean	5	0.7–4.3	5–30	3	2	0.24	0.20
Savanna, grassland	3	0.6–1.5	20–27	3	3	0.23	0.30
North temperate forest	2	0.5–1.2	8–10	2	1.5	0.17	0.15

entities in the context of climate change are transition zones between ecoclimatic regions. Ecotones have narrow spatial extent, a steep ecological gradient and hence high species richness (Risser, 1993), a unique species combination, genetically unique populations (Lesica and Allendorf, 1994), and high intra-species genetic diversity (Safriel *et al.*, 1994).

Ecotones affect distant and larger areas: They regulate interactions between biomes by modifying flows between them (Johnston, 1993; Risser, 1993); they generate evolutionary diversity (Lesica and Allendorf, 1994); and they serve as repositories of genetic diversity to be used for rehabilitation of ecosystems in adjacent ecoclimatic regions if and when these ecosystems lose species because of climate change (see Section 11.3.2.2; Volis *et al.*, 1998; Kark *et al.*, 1999). Conservation of ecotone biodiversity therefore is an adaptation. Finally, although ecological changes in response to climate change will occur everywhere, the signals will be detectable first in ecotones (Neilson, 1993). This sensitivity makes them indicators that provide early warning for other regions (Risser, 1993).

Although ecotones are unique in provision of climate change-related services, they are threatened. Conservation traditionally is aimed at “prime” core areas of biomes rather than ecotones. Even conservation efforts that are directed at ecotones may not suffice, however: 47–77% of the areas of biosphere reserves are predicted to experience change in ecosystem types, compared to only 39–55% of the total global terrestrial area that will undergo such changes (Leemans and Halpin, 1992; Halpin, 1997).

An example of a threatened ecotone is the desert/nondesert ecoclimatic transition zone—the semi-arid drylands sandwiched between arid and the dry subhumid drylands (Middleton and Thomas, 1997). Semi-arid drylands are prone to desertification, expressed as irreversible loss of soil productivity because of topsoil erosion (see Section 11.2.1.4). Already affected by extreme soil degradation are 67 Mha of semi-arid drylands (2.9% of global semi-arid area)—nearly as much as affected dry-subhumid drylands (28 Mha, 2.2%) and arid drylands (43 Mha, 2.7%—Middleton and Thomas, 1997). This degradation is destroying the habitats of the biodiversity assets of these ecotones, including those to be conserved as an adaptation to climate change (Safriel, 1999a,b).

Climate change is expected to exacerbate desertification (see Section 11.2.1.4; Schlesinger *et al.*, 1990; Middleton and Thomas, 1997). Reduced precipitation and increased evapotranspiration will change ecotones’ spatial features (e.g., coalescence of patches at one side and increased fragmentation at the other—Neilson, 1993). Furthermore, overexploitation of vegetation that is typical in semi-arid drylands (UNDP, 1998; ICCD, 1999), in synergy with climate change, will further increase habitat loss and hence loss of biodiversity, ecosystem services, and the potential for adaptation. Similar synergies between climate change effects and other anthropogenic impacts are projected for alpine ecotones (Rusek, 1993). To conclude, ecotones between biomes and within climatic transition areas are unique entities; they are important for monitoring climate

change and for adapting to climate change, yet they are highly threatened by climate change interacting with other anthropogenic stresses.

19.3.3.4. Coral Reefs

Coral reefs are restricted to narrow latitudinal, horizontal, and vertical ranges along the tropical continental shelves. Their contribution to global coastal biodiversity is disproportionate to their spatial extent: Although they cover less than 1% of the world’s oceans, they are inhabited by one-third of globally known marine species (Reaka-Kudla, 1996). Coral reefs have far-reaching effects; they are nurseries for many ocean fish species, and they protect coastlines from wave impact and erosion (see Section 11.2.4.3). Thus, fisheries, tourism, infrastructures, societies, and cultures depend on the well-being of this unique entity that is impacted by increased temperature, atmospheric CO₂, and sea level, synergistically combined with anthropogenic stresses that are independent of climate change.

Many reef-building coral species already live close to their upper thermal limit (see Section 6.4.5). If they are exposed to moderate increases (1–2°C) in water temperature, they become stressed and experience bleaching (Goreau *et al.*, 1998; Hoegh-Guldberg, 1999). The increasing frequency of coral bleaching events during the past decade provides a reason for concern for this warming-induced impact (see Section 12.4.2.3). For example, 50–90% bleaching-induced mortality in the Indian Ocean reefs was associated with a 2–6°C above-normal sea-surface maximum triggered by El Niño during 1997–1998; several other severe bleaching events occurred in the 1982–1983 and 1987 El Niño years (Glynn, 1991; Wilkinson *et al.*, 1999; see Figure 19-3).

Defining the upper thermal thresholds of corals and using global warming scenarios, Hoegh-Guldberg (1999) found that the frequency of bleaching is expected to rise until they become annual events in most oceans (at about a 1°C warming). In some areas, bleaching events would happen more frequently as early as 2020 (with less than 0.5°C warming); within the next 30–50 years, bleaching could be triggered by normal seasonal changes in seawater temperature, and most regions may experience severe bleaching conditions every year. This trend exceeds the frequency at which corals can effectively recover from bleaching-related mortality (Hoegh-Guldberg, 1999).

Besides the detrimental effect of temperature rise, increased atmospheric CO₂ concentrations reduce coral calcification rates (Gattuso *et al.*, 1999; Kleypas *et al.*, 1999; see Sections 6.4.5 and 12.4.1.6), which already might have decreased and could decrease an additional 10–30% by 2100 (see Chapter 6). A 10–20% decrease in calcium carbonate production may impair expansion of coral reefs into higher latitudes as a response to predicted increasing SST (Kleypas *et al.*, 1999). Healthy reef flats may benefit from projected increased sea level because they would be able to keep up with the projected rise in sea level. However, any increase in the frequency of El Niño and

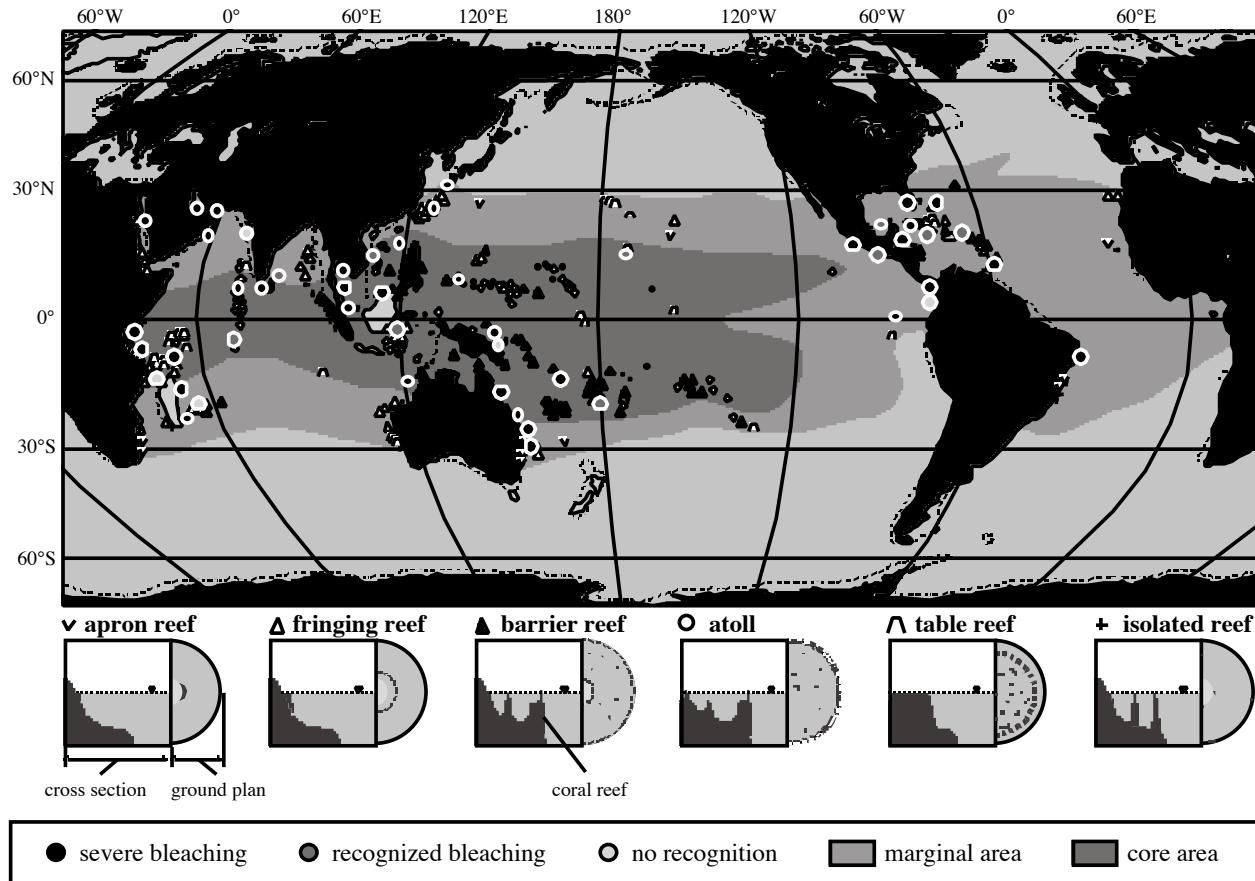

Figure 19-3: Bleaching of coral reefs reported from 1997 to 1998 (Mimura and Harasawa, 2000).

other ocean-atmosphere interactions, such as Indian Ocean dipole events, will lead to regular and prolonged sea-level depressions (10–40 cm) in the western Pacific and eastern Indian Ocean, with adverse effects on shallow reefs in their regions (see Chapter 6).

19.3.3.5. Mangrove Ecosystems

Mangrove ecosystems resemble coral reefs in that they have a narrow global distribution: They cover 11,500 km² in all of Australia, and the largest mangrove forest in the world—the Sundarbans of Bangladesh and India—covers 6,000 km² (see Section 11.2.4.1). Yet they have a rich biodiversity and a significant effect on adjacent and distant systems. Mangroves are made up of salt-adapted, intertidal evergreen trees on low-energy, sedimentary tropical shorelines, extending landward in lagoons, estuary margins, and tidal rivers (see Sections 6.4.4 and 11.2.4.1).

Mangrove ecosystems are highly vulnerable to sea-level rise induced by climate change, which will change the salinity distribution and inundate mangroves. For example, a 45-cm rise could inundate 75% of the Sundarbans (see Section 11.4.1);

a 1-m rise will completely inundate the Sundarbans (see Section 11.2.1.6). In addition, redistribution of species whose habitats will be affected by inundation may be impaired because migration, especially to the north, will be blocked by human settlements. Loss of productivity, species, and ecosystem goods and services therefore is expected. Climate change effects will be further exacerbated, and vulnerability to climate change will increase human-induced damage. For example, between 56 and 75% of different Asian mangrove forests have been lost during the 20th century because of overexploitation and replacement by aquaculture installations (see Section 11.1.3.1). Like the Sundarbans, the Port Royal mangrove wetland in Jamaica may completely collapse with a 1-m sea-level rise (see Section 17.2.4.2).

On the other hand, although mangroves are vulnerable, some may be adaptable to climate change (see Section 12.4.1.6) because they could survive in areas where vertical accretion equals sea-level rise. Because sediment flux determines mangrove response to sea-level rise and fluxes vary between regions and locations, the fate of the world's mangrove ecosystems will not be uniform (see Section 6.4.4). Yet even where accretion will offset sea-level rise, any infrastructure will limit the potential for landward migration of coastal mangrove species and habitats

(see Section 6.2). Thus, at least some if not many of the world's mangrove ecosystems are unique and threatened entities.

19.3.4. Human Systems

Some human systems also are unique and threatened by climate change. These tend to be poor and isolated communities that are tied to specific locations or ecosystems. Among the unique and threatened human systems are some small island states and indigenous communities.

19.3.4.1. Threatened Small Island States

Because of their low elevation and small size, many small island states are threatened with partial or virtually total inundation by future rises in sea level. In addition, increased intensity or frequency of cyclones could harm many of these islands. The existence or well-being of many small island states is threatened by climate change and sea-level rise over the next century and beyond.

Many small island states—especially the atoll nations of the Pacific and Indian Oceans—are among the most vulnerable to climate change, seasonal-to-interannual climate variability, and sea-level rise. Much of their critical infrastructure and many socioeconomic activities tend to be located along the coastline—in many cases at or close to present sea level (Nurse, 1992; Pernetta, 1992; Hay and Kaluwin, 1993). Coastal erosion, saline intrusion, sea flooding, and land-based pollution already are serious problems in many of these islands. Among these factors, sea-level rise will pose a serious threat to the ecosystems, economy, and, in some cases, existence of many small island states. It is estimated that 30% of known threatened plant species are endemic to such islands, and 23% of bird species found on these islands are threatened (Nurse *et al.*, 1998). Projected future climate change and sea-level rise will lead to shifts in species composition (see Chapter 17).

Many small island nations are only a few meters above present sea level. These states may face serious threat of permanent inundation from sea-level rise. Among the most vulnerable of these island states are the Marshall Islands, Kiribati, Tuvalu, Tonga, the Federated States of Micronesia, and the Cook Islands (in the Pacific Ocean); Antigua and Nevis (in the Caribbean Sea); and the Maldives (in the Indian Ocean). Small island states may face the following types of impacts from sea-level rise and climate change (Gaffin, 1997; Nurse *et al.*, 1998):

- Increased coastal erosion
- Changes in aquifer volume and water quality with increased saline intrusion
- Coral reef deterioration resulting from sea-level rise and thermal stress
- Outmigration caused by permanent inundation
- Social instability related to inter-island migration

- Loss of income resulting from negative effects on tourist industry
- Increased vulnerability of human settlement due to decrease in land area
- Loss of agriculture and vegetation.

Gaffin (1997) concludes that without planned adaptation, the vulnerabilities of small island states are as follows:

- An 80-cm sea-level rise could inundate two-thirds of the Marshall Islands and Kiribati.²
- A 90-cm sea-level rise could cause 85% of Male, the capital of the Maldives, to be inundated (Pernetta, 1989).

19.3.4.2. Indigenous Communities

Indigenous people often live in harsh climatic environments to which their culture and traditions are well adapted. Indigenous people generally have low incomes and inhabit isolated rural environments and low-lying margins of large towns and cities. Therefore, they are more exposed to social problems of economic insecurity, inadequate water supplies, and lower health standards (see Sections 12.2.5 and 15.3.2.8). These inadequacies in social safety nets indeed put them at greater risk of climate-related disasters and their effects (see Section 12.7.2.4).

For many reasons, indigenous communities are unique and threatened by climate change. First, they are more vulnerable to climate-related disasters such as storms, floods, and droughts because of inadequate structural protection measures and services, as well as to any increase in the prevalence of pests and diseases—especially vector-borne, respiratory, or otherwise infectious diseases (Woodward *et al.*, 1998; Braaf, 1999). Second, their lifestyles are tied to current climate and vegetation and wildlife. Third, changes in current climate could threaten these lifestyles and would present these peoples with difficult choices concerning their future.

Native peoples in the Mackenzie basin in Canada are an example of an indigenous community that is threatened by climate change (Cohen 1994, 1996, 1997a,b,c). The Mackenzie basin is a watershed that extends from the mid-latitudes to the subarctic in northwest Canada. Over the past 35 years, the area has been experiencing a rapid temperature increase of about 1°C per decade. The changes in temperature also are changing the landscape of the basin as permafrost melts, landslides and forest fires increase, and water levels are lowered.

For the native people in the basin, wildlife is the important natural resource; it is harvested by hunting, fishing, and trapping. It is critically important in economic terms—primarily as a source of food, income, and traditional clothing—but inseparable from the cultural importance for maintaining traditional systems

²The estimate of land loss based on a 1-m sea-level rise, resulting in 80% island losses (IPCC, 1996).

of knowledge and identity (Pinter, 1997). As noted, changes in the climate in the basin would have substantial impacts on water resources and vegetation. Changes in forest fire frequencies would lead to cumulative impacts on wildlife, including terrestrial, aquatic, and bird species. For example, because of a decrease in water availability, muskrats already have disappeared from the Peace Athabasca delta (Pinter, 1997). In this area, trapping once was a major industry, but this economic activity has now disappeared. Thus, changes in ecosystem resource bases will have direct impacts on native lifestyles in the Mackenzie basin (Cohen *et al.*, 1997a).

Some important changes are expected in native lifestyles in the Mackenzie Basin regardless of climate change. For example, an increasing number of people will seek their livelihoods in the wage economy, and migration to other areas will intensify. These changes could result in a decline in cultural values and heritage that are thousands of years old. If climate change adversely affects the lifestyle of the indigenous community, this decline could be accelerated.

19.3.5. Conclusions

There are many unique and threatened systems distributed over various regions of the world. Although they are restricted to relatively narrow geographical ranges, they can affect other entities beyond their range. The existence or functioning of some of these systems is threatened by a small temperature change; the existence or functioning of many others will be threatened by a medium to large temperature change. These effects include impacts such as loss of many species and ecosystems, disappearance of tropical glaciers, damage to coral reefs, inundation of some low-lying islands, loss of coastal wetlands, and potential harm to aboriginal societies and their cultures.

Many of these systems already are stressed by development, including pollution, habitat destruction, encroachment for expansion of human habitation, and overextraction of natural resources. The combination of climate change and societal development puts these systems at greater risk. In some cases, climate change hastens the destruction of these systems; in other cases it may result in the destruction of systems that could survive societal stresses alone (e.g., small island states and some mangrove ecosystems such as the Sundarbans).

Removing societal stresses and managing resources in a sustainable manner may help some unique and threatened systems cope better with climate change.

19.4. Distribution of Impacts

A second reason for concern is the distribution of impacts among people and across regions. The impacts of climate change will not be distributed equally. Some individuals, sectors, systems, and regions will be less affected—or may even benefit; other

individuals, sectors, systems, and regions may suffer significant losses. This pattern of relative benefits or losses is not likely to remain constant over time. It will be different with different magnitudes of climate change. Some regions may have gains only for certain changes in temperature and precipitation and not for others. As a result, some regions that may first see net benefits eventually may face losses as well as the climate continues to warm.

19.4.1. Analysis of Distributional Incidence: State of the Art

Research into the distribution of impacts of climate change is in its infancy, in large measure because this research poses several methodological challenges.

A first difficulty is synthesis—the need to reduce the complex pattern of individual impacts to a more tractable set of regional or sectoral indicators. The challenge is to identify a set of indicators that can summarize and make comparable the impacts in different regions, sectors, or systems in a meaningful way. A range of indicators and methods have been put forward. Many models use physical measures such as the number of people affected (e.g., Hoozemans *et al.*, 1993), change in net primary productivity (NPP) (White *et al.*, 1999), or the number of systems undergoing change (e.g., Alcamo *et al.*, 1995).

The most widespread numeraire, however, is economic cost (Nordhaus, 1991, 1994a; Cline, 1992; Hohmeyer and Gaertner, 1992; Titus, 1992; Downing *et al.*, 1995, 1996; Fankhauser, 1995; Tol, 1995; Mendelsohn and Neumann, 1999). This numeraire is particularly well-suited to measure market impacts—that is, impacts that are linked to market transactions and directly affect GDP (i.e., a country's national accounts). The costs of sea-level rise, for example, can be expressed as the capital cost of protection plus the economic value of land and structures at loss or at risk; agricultural impacts can be expressed as costs or benefits to producers and consumers, including the incremental costs of adaptation. Using a monetary numeraire to express nonmarket impacts such as effects on ecosystems or human health is more difficult. It is possible in principle, however. There is a broad and established literature on valuation theory and its application, including studies (mostly in a nonclimate change context) on the monetary value of lower mortality risk, ecosystems, quality of life, and so forth. However, economic valuation can be controversial and requires sophisticated analysis, which still is mostly lacking in a climate change context.

Physical metrics—such as NPP or percentage of systems affected—on the other hand, are best suited for natural systems. When they are applied to systems under human management, they suffer from being poorly linked to human welfare, the ultimate indicator of concern. Some researchers therefore recommend different numeraires for market impacts, mortality, ecosystems, quality of life, and equity (Schneider *et al.*, 2000b). They recognize, however, that final comparisons across different numeraires nonetheless are required; they regard this as the job of policymakers, however.

Persistent knowledge gaps is a second source of difficulty. Distributional analysis depends heavily on the geographical details of climate change, but these details are one of the major uncertainties in the outputs of climate change models. This is particularly true for estimates of precipitation; for example, estimates of water-sector impact can vary widely depending on the choice of GCM.³ Uncertainties continue at the level of impact analysis. Despite a growing number of country-level case studies, our knowledge of local impacts is still too uneven and incomplete for a careful, detailed comparison across regions. Furthermore, differences in assumptions often make it difficult to compare case studies across countries. Only a few studies try to provide a coherent global picture on the basis of a uniform set of assumptions. The basis of most such global impact assessments tends to be studies undertaken in developed countries—often the United States—which are then extrapolated to other regions. Such extrapolation is difficult and will be successful only if regional circumstances are carefully taken into account, including differences in geography, level of development, value systems, and adaptive capacity. Not all analyses are equally careful in undertaking this task.

There are other shortcomings that affect the quality of analysis. Although our understanding of the vulnerability of developed countries is improving—at least with respect to market impacts—information about developing countries is quite limited. Nonmarket damages, indirect effects (e.g., the effect of changed agricultural output on the food-processing industry), the link between market and nonmarket effects (e.g., how the loss of ecosystem functions will affect GDP), and the sociopolitical implications of change also are still poorly understood. Uncertainty, transient effects (the impact of a changing rather than a changed and static climate), and the influence of climate variability are other factors that deserve more attention. Because of these knowledge gaps, distributional analysis has to rely on (difficult) expert judgment and extrapolation if it is to provide a comprehensive picture.

A third problem is adaptation. There has been substantial progress in the treatment of adaptation since the SAR, but adaptation is difficult to capture adequately in an impact assessment. Adaptation will entail complex behavioral, technological, and institutional adjustments at all levels of society, and the capacity to undertake them will vary considerably (see Chapter 18). Various approaches are used to model adaptation (e.g., spatial analogs, microeconomic modeling), but they are prone to systematic errors about its effectiveness. The standard approach used in coastal impact assessment and in many agricultural models is to include in the analysis a limited number of “prominent”

³For example, Frederick and Schwarz (1999) found that climate changes estimated in the southeastern United States in the 2030s under the Canadian Climate Centre scenario result in an estimated US\$100 billion yr⁻¹ in damages. This estimate may be the result of internal model variability and does not fully account for adaptive responses or lower damages from reduced flood risks. Nonetheless, it demonstrates the high sensitivity of water resources to extreme changes in climate.

Box 19-2. The Impact of Climate Change on Coastal Zones

The impact of sea-level rise has been widely studied for many parts of the world. Although uncertainties remain, several generic conclusions can be drawn. First, impacts will not be distributed evenly. Islands and deltas are particularly vulnerable. Second, forward-looking and sustainable economic development, coupled with efficient adaptation (mostly protection of vulnerable shores), can significantly reduce the economic impact of sea-level rise. Some analysts have even found that coastal vulnerability may decrease if the rate of economic development is sufficiently high and climate change sufficiently slow. However, not all countries will be able to undertake the necessary adaptation investments without outside financial assistance, and uncertainty about sea levels (e.g., as a result of storm surges) may make it difficult to identify efficient policies. Third, coastal wetlands can cope with a relatively modest rate of sea-level rise, but not with a fast one. Additional wetlands could be lost if their migration is blocked by hard structures built to protect developed coastal areas. Fourth, most of the impact will not be through gradual sea-level rise but through extreme events such as floods and storms. This makes people without insurance or a strong social network especially vulnerable. Thus, as a whole, sea-level rise is likely to have strong negative effects on some people, even if the aggregate impact is limited. Fifth, the aggregate impact of sea-level rise could be roughly proportional to the observed rise. At a local scale, however, sea-level rise is more likely to be felt through successive crossings of thresholds.

but ultimately arbitrary adaptations. This underestimates adaptive capacity because many potentially effective adaptations are excluded (Tol *et al.*, 1998). On the other hand, approaches that are based on analogs—such as the Ricardian approach used by, for example, Mendelsohn *et al.* (1994), Mendelsohn and Dinar (1998), and Darwin (1999)—probably overestimate adaptive capacity because they neglect the cost of transition and learning. This is especially true for cases in which adaptation in developed countries today is used as a proxy for worldwide adaptation to an uncertain future climate. Only a very few studies model adaptation as an optimization process in which agents trade off the costs and benefits of different adaptation options (Fankhauser, 1995; Yohe *et al.*, 1995, 1996).

The analysis is further complicated by the strong link between adaptation and other socioeconomic trends. The world will change substantially in the future, and this will affect vulnerability to climate change. For example, a successful effort to roll back malaria (as promoted by the development community) could reduce the negative health effects of climate change. On the other hand, growing pressure on natural resources from unsustainable economic development is likely to exacerbate the impacts of

climate change on natural systems. Even without explicit adaptation, impact assessments therefore depend on the “type” of socioeconomic development expected in the future. The sensitivity of estimates to such baseline trends can be strong enough in some cases to reverse the sign (i.e., a potentially negative impact can become positive under a suitable development path, or vice versa) (Mendelsohn and Neumann, 1999).

Despite the limits in knowledge, a few general patterns emerge with regard to the distribution of climate change impacts. These patterns are derived from general principles, observations of past vulnerabilities, and limited modeling studies.

19.4.2. Distribution of Impacts by Sector

Susceptibility to climate change differs across sectors and regions. A clear example is sea-level rise, which mostly affects coastal zones (see Box 19-2). People living in the coastal zone generally will be negatively affected by sea-level rise, but the numbers of people differ by region. For example, Nicholls *et al.* (1999) found that under a sea-level rise of about 40 cm by the 2080s, assuming increased coastal protection, 55 million people would be flooded annually in south Asia; 21 million in southeast Asia, the Philippines, Indonesia, and New Guinea; 14 million in Africa; and 3 million in the rest of the world. The relative impacts in small island states also are significant (see Section 19.3). In addition, the Atlantic coast of North and Central America, the Mediterranean, and the Baltic are projected to have the greatest loss of wetlands. Inland areas face only secondary effects—which, unlike the negative primary effects, may be either negative or positive (Yohe *et al.*, 1996; Darwin and Tol, 2001).

Agriculture, to turn to another example, is a major economic sector in some countries and a small one in others. Agriculture is one of the sectors that is most susceptible to climate change, so countries with a large portion of the economy in agriculture face a larger exposure to climate change than countries with a lower share, and these shares vary widely. Whereas countries of the Organisation for Economic Cooperation and Development (OECD) generate about 2–3% of their GDP from agriculture, African countries generate 5–58% (WRI, 1998).

Activities at the margin of climatic suitability have the most to lose from climate change, if local conditions worsen, and the most to win if conditions improve. One example is subsistence farming under severe water stress—for instance, in semi-arid regions of Africa or south Asia. A decrease of precipitation, an increase in evapotranspiration, or higher interannual variability (particularly longer droughts) could tip the balance from a meager livelihood to no livelihood at all, and the unique cultures often found in marginal areas could be lost. An increase in precipitation, on the other hand, could reduce pressure on marginal areas. Numerous modeling studies of shifts in production of global agriculture—including Kane *et al.* (1992), Rosenzweig and Parry (1994), Darwin *et al.* (1995), Leemans (1997), Parry *et al.* (1999), and Darwin (1999)—have estimated

Box 19-3. The Impact of Climate Change on Agriculture

The pressures of climate change on the world’s food system are better understood than most other impacts. Research has focused on crop yields; on the basis of those insights, many studies also look at farm productivity, and a smaller number look at national and international agricultural markets.

Climate change is expected to increase yields at higher latitudes and decrease yields at lower latitudes. Changes in precipitation, however, also can affect yields and alter this general pattern locally and regionally. Studies of the economic impact of this change (in all cases, climate change associated with 2xCO₂) conclude that the aggregated global impact on the agricultural sector may be slightly negative to moderately positive, depending on underlying assumptions (e.g., Rosenzweig and Parry, 1994; Darwin, 1999; Parry *et al.*, 1999; Mendelsohn *et al.*, 2000). Most studies on which these findings are based include the positive effect of carbon fertilization but exclude the negative impact of pests, diseases, and other disturbances related to climate change (e.g., droughts, water availability). The aggregate also hides substantial regional differences. Beneficial effects are expected predominantly in the developed world; strongly negative effects are expected for populations that are poorly connected to regional and global trading systems. Regions that will get drier or already are quite hot for agriculture also will suffer, as will countries that are less well prepared to adapt (e.g., because of lack of infrastructure, capital, or education). Losses may occur even if adaptive capacity is only comparatively weak because trade patterns will shift in favor of those adapting best. Overall, climate change is likely to tip agriculture production in favor of well-to-do and well-fed regions—which either benefit, under moderate warming, or suffer less severe losses—at the expense of less-well-to-do and less well-fed regions. Some studies indicate that the number of hungry and malnourished people in the world may increase, because of climate change, by about 10% relative to the baseline (i.e., an additional 80–90 million people) later in the 21st century (e.g., Parry *et al.*, 1999).

that production in high-latitude countries is likely to increase and production in low-latitude countries is likely to decrease, even though changes in total global output of agriculture could be small. Results in the temperate zone are mixed. Low-latitude countries tend to be least developed and depend heavily on subsistence farming. Under current development trends they will continue to have a relatively high share of GDP in agriculture. Thus, the impacts of declines in agricultural output on low-latitude countries are likely to be proportionately greater than any gains in high-latitude countries (see Box 19-3).

Vulnerability to the health effects of climate change also differs across regions and within countries, and differences in adaptive capacity again are important. Box 19-4 notes that wealthier countries will be better able to cope with risks to human health than less wealthy countries. Risks also vary within countries, however. In a country such as the United States, the very young and the very old are most sensitive to heat waves and cold spells, so regions with a rapidly growing or rapidly aging population would have relatively large exposure to potential health impacts. In addition, poor people in wealthy countries may be more vulnerable to health impacts than those with average incomes in the same countries. For example, Kalkstein and Greene (1997) found that in the United States, residents of inner cities, which have a higher proportion of low-income people, are at greater risk of heat-stress mortality than others. Differences among income groups may be more pronounced in developing and transition countries because of the absence of the elaborate safety nets that developed countries have constructed in response to other, nonclimate stresses.

These observations underscore one of the critical insights in Chapter 18: Adaptive capacity differs considerably between sectors and systems. The ability to adapt to and cope with climate change impacts is a function of wealth, technology, information,

skills, infrastructure, institutions, equity, empowerment, and ability to spread risk. The poorest segments of societies are most vulnerable to climate change. Poverty determines vulnerability via several mechanisms, principally in access to resources to allow coping with extreme weather events and through marginalization from decisionmaking and social security (Kelly and Adger, 2000). Vulnerability is likely to be differentiated by gender—for example, through the “feminization of poverty” brought about by differential gender roles in natural resource management (Agarwal, 1991). If climate change increases water scarcity, women are likely to bear the labor and nutritional impacts.

The suggested distribution of vulnerability to climate change can be observed clearly in the pattern of vulnerability to natural disasters (e.g., Burton *et al.*, 1993). The poor are more vulnerable to natural disasters than the rich because they live in more hazardous places, have less protection, and have less reserves, insurance, and alternatives. Adger (1999), for instance, shows that marginalized populations within coastal communities in northern Vietnam are more susceptible to the impacts of present-day weather hazards and that, importantly, the wider policy context can exacerbate this vulnerability. In the Vietnamese case, the transition to market-based agriculture has decreased

Box 19-4. The Health Impacts of Climate Change

Global climate change will have diverse impacts on human health—some positive, most negative. Changes in the frequency and intensity of extreme heat and cold, floods and droughts, and the profile of local air pollution and aeroallergens will directly affect population health. Other effects on population health will result from the impacts of climate change on ecological and social systems. These impacts include changes in infectious disease occurrence, local food production and nutritional adequacy, and the various health consequences of population displacement and economic disruption. Health impacts will occur very unevenly around the world. In general, rich populations will be better protected against physical damage, changes in patterns of heat and cold, introduction or spread of infectious diseases, and any adverse changes in world food supplies.

The geographic range and seasonality of various vector-borne infectious diseases (spread via organisms such as mosquitoes and ticks) will change, affecting some populations that currently are at the margins of disease distribution. The proportion of the world's population living in regions of potential transmission of malaria and dengue fever, for example, will increase. In areas where the disease currently is present, the seasonal duration of transmission will increase. Decreases in transmission may occur where precipitation decreases reduce vector survival, for example.

An increased frequency of heat waves will increase the risk of death and serious illness, principally in older age groups and the urban poor. The greatest increases in thermal stress are forecast for mid- to high-latitude (temperate) cities, especially in populations with limited air conditioning. Warmer winters and fewer cold spells, because of climate change, will decrease cold-related mortality in many temperate countries. Basic research to estimate the aggregate impact of these changes has yet been limited largely to the United States and parts of Europe. Recent modeling of heat-wave impacts in 44 U.S. urban populations, allowing for acclimatization, suggests that large U.S. cities may experience, on average, several hundred extra deaths per summer. Although the impact of climate change on thermal stress-related mortality in developing country cities may be significant, there has been little research in such populations.

For each anticipated adverse health impact, there is a range of social, institutional, technological, and behavioral adaptation options that could lessen that impact. The extent to which health care systems will have the capacity to adopt them is unclear, however, particularly in developing countries. There is a basic and general need for public health infrastructure (programs, services, surveillance systems) to be strengthened and maintained. The ability of affected communities to adapt to risks to health also depends on social, political, and economic circumstances.

the access of the poor to social safety nets and facilitated the ability of rich households to overexploit mangroves, which previously provided protection from storms. Similarly, Mustafa (1998) demonstrates differentiation of flood hazards in lowland Pakistan by social group: Insecure tenure leads to greater impacts on poorer communities. See Chapter 18 for further examples. The natural disaster literature also concludes that organization, information, and preparation can help mitigate large damages at a moderate cost (e.g., Burton *et al.*, 1993). This underscores the need for adaptation, particularly in poor countries.

19.4.3. Distribution of Total Impacts

Several studies have estimated the total impact (aggregated across sectors) in different regions of the world. Table 19-4 shows aggregate, monetized impact estimates for a doubling of

atmospheric CO₂ on the current economy and population from four studies. Clearly, in all of these studies there are substantial uncertainties about the total impacts to regions and whether some regions will have net benefits or net damages at certain changes in global average temperature. Most studies, however, show the following:

- Developing countries, on the whole, are more vulnerable to climate change than developed countries.
- At low magnitudes of temperature change, damages are more likely to be mixed across regions, but at higher magnitudes virtually all regions have net damages.
- The distribution of risk may change at different changes in temperature.

Developing countries tend to be more vulnerable to climate change because their economies rely more heavily on climate-sensitive activities (particularly agriculture), and many already

Table 19-4: Indicative world impacts, by region (% of current GDP). Estimates are incomplete, and confidence in individual numbers is very low. See list of caveats in Section 19.4.1. There is a considerable range of uncertainty around estimates. Tol's (1999a) estimated standard deviations are lower bounds to real uncertainty. Figures are expressed as impacts on a society with today's economic structure, population, laws, etc. Mendelsohn *et al.* (2000) estimates denote impact on a future economy. Positive numbers denote benefits; negative numbers denote costs (Pearce *et al.*, 1996; Tol, 1999a; Mendelsohn *et al.*, 2000; Nordhaus and Boyer, 2000).

	IPCC SAR 2.5°C Warming	Mendelsohn <i>et al.</i> 1.5°C Warming	Nordhaus and Boyer 2.5°C Warming	Tol 1°C Warming ^a

operate close to environmental and climatic tolerance levels (e.g., with respect to coastal and water resources). If current development trends continue, few developing countries will have the financial, technical, and institutional capacity and knowledge base for efficient adaptation (a key reason for higher health impacts). For temperature increases of less than 2–3°C, some regions may have net benefits and some may have net damages. If temperature increases more than 2–3°C, most regions have net damages, and damages for all regions increase at higher changes in global average temperature.

19.5. Aggregate Impacts

The third reason for concern relates to the overall (i.e., worldwide or aggregate) economic and ecological implications of climate change. Numerous studies have addressed aggregate impacts, particularly in the context of integrated assessment.

19.5.1. Aggregate Analysis: An Assessment

Estimating the aggregate impact of climate change is an intricate task that requires careful professional judgment and skills. Aggregate analysis is based on the same tools as most distributional analysis and uses regional data as inputs. Consequently, it shares with distributional analysis the methodological difficulties and shortcomings discussed more fully in Section 19.4:

- Choice of an appropriate (set of) numeraire(s) in which to express impacts
- Need to overcome knowledge gaps and scientific uncertainties to provide a comprehensive picture
- Difficulties in modeling the effects of adaptation
- Difficulties in forecasting baseline developments (such as economic and population growth, technical progress).

In addition, analysts have to grapple with some issues that are generic to aggregate analysis. The most important issue is spatial and temporal comparison of impacts. Aggregating impacts requires an understanding of (or assumptions about) the relative importance of impacts in different sectors, in different regions, and at different times. Developing this understanding implicitly involves value judgments. The task is simplified if impacts can be expressed in a common metric, but even then aggregation is not possible without value judgments. The value judgments that underlie regional aggregation are discussed and made explicit in Azar and Sterner (1996), Fankhauser *et al.* (1997, 1998), and Azar (1999). Aggregation across time and the issue of discounting are discussed in more detail in TAR WGIII Chapter 7. Aggregate impact estimates can be very sensitive to the aggregation method and the choice of numeraire (see Chapter 1).

All of these factors make aggregate analysis difficult to carry out and reduce our overall confidence in aggregate results. Nevertheless, aggregate studies provide important and policy-relevant information.

19.5.2. Insights and Lessons: The Static Picture

Most impact studies assess the consequences of climate change at a particular concentration level or a particular point in time, thereby providing a static “snapshot” of an evolving, dynamic process. The SAR suggested that the aggregate impact of 2xCO₂—expressed in monetary terms—might be equivalent to 1.5–2.0% of world GDP. Estimated damages are slightly lower (relative to GDP) in developed countries but significantly higher in developing countries—particularly in small island states and other highly vulnerable countries, where impacts could be catastrophic (Pearce *et al.*, 1996). The SAR was careful, however, to point out the low quality of these numbers and the many shortcomings of the underlying studies.

Since publication of the SAR, our understanding of aggregate impacts has improved, but it remains limited. Some sectors and impacts have received more analytical attention than others and as a result are better understood. Agricultural and coastal impacts in particular are now well studied (see Boxes 19-2 and 19-3). Knowledge about the health impacts of climate change also is growing (see Box 19-4). Several attempts have been made to identify other nonmarket impacts, such as changes in aquatic and terrestrial ecological systems and ecosystem services, but a clear and consistent quantification has not yet emerged.

Table 19-4 contains a summary of results from aggregate studies that use money as their numeraire. The numerical results as such remain speculative, but they can provide insights on signs, orders of magnitude, and patterns of vulnerability. Results are difficult to compare because different studies assume different climate scenarios, make different assumptions about adaptation, use different regional disaggregation, and include different impacts. The estimates by Nordhaus and Boyer (2000), for example, are more negative than others because they factor in the possibility of catastrophic impact. The estimates by Mendelsohn *et al.* (2000), on the other hand, are driven by optimistic assumptions about adaptive capacity and baseline development trends, which result in mostly beneficial impacts.

Standard deviations rarely are reported, but they are likely to be several times larger than the “best guess.” They are larger for developing countries, where results generally are derived through extrapolation rather than direct estimation. This is illustrated by the standard deviations estimated by Tol (2001b), also reproduced in Table 19-4. These estimates probably still underestimate the true uncertainty—for example, because they exclude omitted impacts and severe climate change scenarios. Note that the aggregation can mask large standard deviations in estimates of damages to individual sectors (Rothman, 2000).

An alternative indicator of climate change impact (excluding ecosystems) is the number of people affected. Few studies directly calculate this figure, but it is possible to compare the population of regions experiencing negative impacts with that of positively affected regions. Such calculations suggest that a majority of people may be negatively affected already at average global warming of 1–2°C. This may be true even if the

net aggregate monetary impact is positive because developed economies, many of which could have positive impacts, contribute the majority of global production but account for a smaller fraction of world population. The quality of estimates of affected population is still poor, however. They are essentially “back-of-the envelope” extensions of monetary models, and the qualifications outlined in that context also apply here. In addition, they do not consider the distribution of positive and negative effects within countries.

On the whole, our confidence in the numerical results of aggregate studies remains low. Nevertheless, a few generic patterns and trends are emerging in which we have more confidence:

- Market impacts are estimated to be lower than initially thought and in some cases are estimated to be positive, at least in developed countries. The downward adjustment is largely a result of the effect of adaptation, which is more fully (although far from perfectly) captured in the latest estimates. Efficient adaptation reduces the net costs of climate change because the cost of such measures is lower than the concomitant reduction in impacts. However, impact uncertainty and lack of capacity may make efficient and error-free adaptation difficult.
- Nonmarket impacts are likely to be pronounced, and many (but not all) of the effects that have not yet been quantified could be negative. In particular, there is concern about the impact on human health and mortality. Although few studies have taken adequate account of adaptation, the literature suggests substantial negative health impacts in developing countries, mainly because of insufficient basic health care (e.g., Martens *et al.*, 1997). There also is concern about the impact on water resources (e.g., Arnell, 1999; Frederick and Schwarz, 1999) and ecosystems (e.g., Markham, 1996; White *et al.*, 1999).
- “Horizontal” interlinkages such as the interplay between different impact categories (e.g., water supply and agriculture), the effect of stress factors that are not related to climate, adaptation, and exogenous development trends are crucial determinants of impact but have not been fully considered in many studies.
- Estimates of global impact are sensitive to the way numbers are aggregated. Because the most severe impacts are expected in developing countries, aggregate impacts are more severe and thus more weight is assigned to developing countries. Using a simple summing of impacts, some studies estimate small net positive impacts at a few degrees of warming; others estimate small net negative impacts. Net aggregate benefits do not preclude the possibility that a majority of people will be negatively affected—some of them severely so.

Overall, the current generation of aggregate estimates may underestimate the true cost of climate change because they tend to ignore extreme weather events, underestimate the compounding effect of multiple stresses, and ignore the costs of transition and learning. However, studies also may have overlooked

positive impacts of climate change. Our current understanding of (future) adaptive capacity, particularly in developing countries, is too limited, and the treatment of adaptation in current studies is too varied, to allow a firm conclusion about the direction of the estimation bias.

19.5.3. Insights and Lessons: Vulnerability over Time

One of the main challenges of impact assessments is to move from the static analysis of certain benchmarks to a dynamic representation of impacts as a function of shifting climatic parameters, adaptation measures, and exogenous trends such as economic and population growth. Little progress has been made in this respect, and our understanding of the time path that aggregate impacts will follow under different warming and development scenarios still is extremely limited. Among the few explicitly dynamic analyses are Sohngen and Mendelsohn (1999) and Yohe *et al.* (1996).

Some information about impacts over time is available for individual sectors. Scenarios derived from IAMs can provide comprehensive emissions, concentrations, and climate change estimates that can be linked to impact models. Table 19-5 summarizes estimates of global ecosystem impacts that were derived from such a model (IMAGE 2.1—Leemans *et al.*, 1998; Swart *et al.*, 1998). The metric used is percentage change. The example illustrates the clearly nonlinear dynamics of nonmarket impacts with different pathways for positive (escalating) and negative (saturating) impacts. The impact levels in this model evolve gradually, and there are impacts even at low levels of climate change. Although this finding is consistent with observed change (see Section 19.2), it is sensitive to the choice of metric. White *et al.* (1999), for example, found that carbon storage in terrestrial vegetation would expand under moderate warming because increases in productivity are enough to offset reductions elsewhere. They show that as higher GHG concentrations and magnitudes of climate change are reached, carbon storage eventually will decline.

Little is known about the shape of the aggregate impact function. Dynamic functions remain highly speculative at this point because the underlying models provide only a very rough reflection of real-world complexities. Figure 19-4 provides examples from three studies. Although some analysts still work with relatively smooth impact functions (e.g., Nordhaus and Boyer, 2000), there is growing recognition (e.g., Mendelsohn and Schlesinger, 1997; Tol, 2001c) that climate change dynamics in fact might be more complex and may not follow a monotonic path. Generic patterns that are emerging include the following:

- Moderate climate change may have positive and negative effects, with most positive effects occurring in the market sector of developed countries. For higher levels of warming, impacts are likely to become predominantly negative. However, the overall pattern is complex, estimates remain uncertain, and the possibility of highly deleterious outcomes cannot be excluded (medium confidence).

Table 19-5: Aggregate impact of climate change on ecosystems (Swart et al., 1998). See also list of caveats in Section 19.4.1.

Impact Indicator	Scenario					
	0.5°C	1.0°C	1.5°C	2.0°C	2.5°C	3.0°C
Temperate cereals, area experiencing						
– Yield decrease ^a	12	16	18	20	20	22
– Yield increase ^a	2	3	4	8	12	15
Maize, land area experiencing						
– Yield decrease ^a	13	18	22	26	29	33
– Yield increase ^a	2	4	6	9	13	17
Change in natural vegetation ^b	11	19	26	32	37	43
Endangered nature reserves ^c	9	17	24	32	37	42

^a Yield decrease and increase are percentage area with at least 10% change in potential rainfed yield. Reference area is current crop area.

^b Change in natural vegetation is percentage of land area that shifts from one vegetation type to another. Reference area is global land area.

^c Endangered nature reserves are percentage of reserves, where original vegetation disappears, so that conservation objectives cannot be met. Reference is total reserve number.

- Impacts in different sectors may unfold along different paths. Coastal impacts, for example, are expected to grow continuously over time, more or less in proportion to the rise in sea level. The prospects for agriculture, by contrast, are more complex. Whereas some models predict aggregate damages already for moderate warming, many studies suggest that under some (but not all) scenarios the impact curve might be hump-shaped, with short-term (aggregate) benefits under modest climate change turning into losses under more substantial change (e.g., Mendelsohn and Schlesinger, 1997) (low confidence).

Aggregating intertemporal impacts into a single indicator is extremely difficult, perhaps elusive. The marginal damages caused by 1 t of CO₂ emissions in the near future were estimated in the SAR at US\$5–125 t⁻¹ C. Most estimates are in the lower part of that range; higher estimates occur only through the combination of high vulnerability with a low discount rate (see Pearce et al., 1996). Plambeck and Hope (1996), Eyre et al. (1997), and Tol (1999a) have since reassessed the marginal costs of GHG emissions. Performing extensive sensitivity and uncertainty analyses, they arrive at essentially the same range of numbers as Pearce et al. (1996). In the complex dynamics that determine marginal damage costs, the more optimistic estimates of market damages used in recent studies are balanced out by other factors such as higher nonmarket impacts and a better capture of uncertainties. Overall, the SAR assessment still is a good reflection of our understanding of marginal damage costs; our confidence in marginal damage numbers remains very low.

19.5.4. Sensitivity of Aggregate Estimates

At a time when the quality of numerical results still is low, a key benefit of aggregate impact analysis lies in the insights it

provides regarding the sensitivity of impacts. Sensitivity analysis offers critical information about attributes of the damage function that are likely to be most influential for the

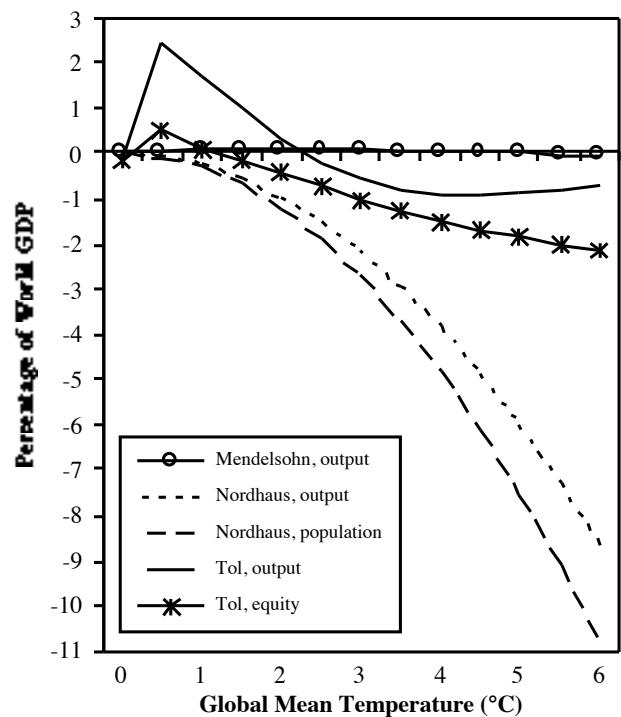

Figure 19-4: Monetary impacts as a function of level of climate change (measured as percentage of global GDP). Although there is confidence that higher magnitudes and rates of increase in global mean temperature will lead to increasing damages, there is uncertainty about whether aggregate damages are positive or negative at relatively low increases in global mean temperature.

choice of policy and, by implication, where additional climate change impacts research is most needed.

19.5.4.1. Composition of Impact Function

Most aggregate analysis is based on IAMs (see Chapter 2). Impact functions used in IAMs vary greatly with respect to the level of modeling sophistication, the degree of regional aggregation, the choice of numeraire, and other characteristics (see Tol and Fankhauser, 1998). Many models have used monetary terms (e.g., U.S. dollars) to measure impacts. Spatially detailed models (e.g., Alcamo *et al.*, 1998) pay some attention to unique ecosystems. Disruptive climate changes have received little attention, except for a survey of expert opinions (Nordhaus, 1994b) and analytical work (e.g., Gjerde *et al.*, 1999). Some climate change impact studies restrict themselves to sectors and countries that are relatively well studied (e.g., Mendelsohn and Neumann, 1999). Others try to be comprehensive, despite the additional uncertainties (e.g., Hohmeyer and Gaertner, 1992). Some studies rely on an aggregate description of all climate change impacts for the world as a whole (e.g., Nordhaus, 1994a). Other studies disaggregate impacts with substantial spatial and regional detail (e.g., Alcamo *et al.*, 1998). The aggregate approaches tend to point out implications for efficiency and in practice often ignore equity (see Tol, 2001a, for an exception). The detailed approaches tend to identify distributional issues,

but working out the equity implications typically is left to the reader.

19.5.4.2. Shape of Damage Function

Most impact studies still look at the equilibrium effect of one particular level of GHG concentration, usually $2\times\text{CO}_2$. Full analysis, however, requires impacts to be expressed as a function of change in GHG concentrations. With so little information to estimate this function, studies have to rely on sensitivity analyses. Different damage functions can lead to profoundly different policy recommendations. Compare, for example, the profile of impacts under a linear and a cubic damage function (see Figure 19-5). Relative to the linear specification, a cubic function implies low near-term impacts but rapidly increasing impacts further in the future. Using conventional discounting, this means that early emissions under a cubic damage function will cause less damage over their atmospheric lifetime, compared to a scenario with linear damages. The marginal damage caused by emissions further in the future, on the other hand, is much higher if we assume a cubic damage function (Peck and Teisberg, 1994).

Some studies explore the implications of more nonlinear impact functions. For instance, Manne and Richels (1995) use a “hockey-stick” function that suddenly turns upward at arbitrarily chosen thresholds. Such studies are designed to reflect relatively small impacts before $2\times\text{CO}_2$ and rapidly worsening impacts beyond $2\times\text{CO}_2$. In this analysis, it is economically efficient to stabilize CO_2 concentrations, but the desired level of stabilization depends on the shape of the hockey stick and the location of its kink. Other analyses, which rely on more linear impact functions, have difficulty justifying concentration stabilization at any level.

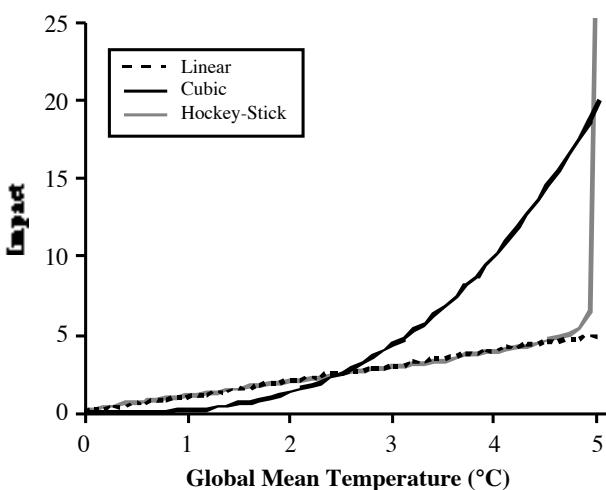

Figure 19-5: Aggregate impact of climate change as a function of global mean temperature. Displayed are hypothetical examples of a linear function, which assumes that impacts are proportional to temperature change since preindustrial times; a cubic function, which assumes that impacts are proportional to temperature change to the power of three; and a hockey-stick function, which assumes that impacts are approximately proportional to temperature change until a critical threshold is approached. Aggregate damage functions used in integrated assessments are mostly illustrative. They should be regarded as “placeholders” that will be replaced by more accurate functional forms as our knowledge of impact dynamics improves.

19.5.4.3. Rate of Change

Although most impact studies focus on the level of climate change, the rate of climate change generally is believed to be an important determinant, in many instances because it affects the time that is available for adaptation. Again, the paucity of underlying impact studies forces integrated assessors to use exploratory modeling. Under most “business-as-usual” scenarios, the rate of climate change is greater in the short run than in the long run because emissions increase faster in the short run; this is even more pronounced in emission reduction policy scenarios. Indeed, in considering the rate of change, tolerable window and safe-landing analyses (Alcamo and Kreileman, 1996; Toth *et al.*, 1997; Petschel-Held *et al.*, 1999) often find the rate of change to be the binding constraint in the first half of the 21st century.

19.5.4.4. Discount Rate and Time Horizon

Aggregate models suggest that the most severe impacts of climate change will occur further in the future. The chance of large-scale discontinuities (thermohaline circulation, West Antarctic ice sheet) also is higher in the future. The outcome of policy

analysis therefore is sensitive to the weight afforded to events occurring in the remote future. In other words, estimates are sensitive to the choice of time horizon (Cline, 1992; Azar and Sterner, 1996; Hasselmann *et al.*, 1997) and the discount rate (i.e., the value of future consumption relative to today's value). The literature on discounting is reviewed in Portney and Weyant (1999) and in TAR WGIII Chapter 7. Numerical analysis (e.g., Tol, 1999a) has shown that estimates of marginal damage (i.e., the additional damage caused by an extra ton of emissions) can vary by as much as a factor of 10 for different (and reasonable) assumptions about the discount rate. This makes the discount rate the second-most important parameter for marginal damage. The most important parameter is the degree of cooperation in reducing emissions (Nordhaus and Yang, 1996; Tol, 1999b).

19.5.4.5. Welfare Criteria

Comparison of impacts (i.e., the relative weight assigned to impacts in different regions and at different times) is one of the most sensitive aspects of aggregate analysis. With the exception of the discount rate, little explicit attention is paid to this aspect of climate change impacts, although studies differ considerably in their implicit assumptions. Fankhauser *et al.* (1997) and Azar (1999) are among the few studies that make their aggregation assumptions explicit. They find that, in general, the higher the concerns about the distribution of the impacts of climate change, the more severe the aggregate impacts. Fankhauser's (1995) estimate of the annual global damage of $2\times\text{CO}_2$, for instance, is based on the implicit assumption that people are neutral with respect to distribution (that is, losses to the poor can be compensated by equal gains to the rich) and risk (that is, a 1:1,000,000 chance of losing \$1 million is equivalent to losing \$1 with certainty). Replacing these assumptions with standard risk aversion or mild inequity aversion, the global damage estimate increases by about one-third (Fankhauser *et al.*, 1997). Marginal impacts are more sensitive. For the same changes in assumptions, Tol (1999a) finds a three-fold increase in the marginal damage estimate. The sensitivity of aggregate impact estimates is further illustrated in Figure 19-4.

19.5.4.6. The Treatment of Uncertainty

Sensitivity analysis is the standard approach to deal with impact uncertainty. Some studies, however, have gone one step further and explicitly model uncertainty as a hedging problem. The premise underlying these models is that today's policymakers are not required to make once-and-for-all decisions binding their successors over the next century. There will be opportunities for mid-course adjustments. Climate negotiations are best viewed as an ongoing process of "act, then learn." Today's decisionmakers, in this view, must aim at evolving an acceptable hedging strategy that balances the risks of premature actions against those of waiting too long.

The first step, then, is to determine the sensitivity of today's decisions to major uncertainties in the greenhouse debate. How

important is it to be able to predict impacts for the second half of this century? Or to know what energy demands will be in 30 years and identify the technologies that will be in place to meet those demands? An exhaustive analysis of these questions has yet to be undertaken, but considerable insight can be gleaned from an Energy Modeling Forum study conducted several years ago (EMF, 1997). In the study, seven modeling teams addressed a key consideration in climate policymaking: concerns about events with low probability but high consequences.

The study assumed uncertainty would not be resolved until 2020. Two parameters were varied: the mean temperature sensitivity factor and the cost of damages associated with climate change and variability. The unfavorable high-consequence scenario was defined as the top 5% of each of these two distributions. Two surveys of expert opinion were used for choosing the distribution of these variables (for climate sensitivity, see Morgan and Keith, 1995; for damages, see Nordhaus, 1994a).

The analysis showed that the degree of hedging depends on the stakes, the odds, and nonimpact parameters such as society's attitude toward risk and the cost of greenhouse insurance. Also critical is the timing of the resolution of key uncertainties. This underscores the importance of scientific research.

19.6. Extreme and Irreversible Effects

19.6.1. The Irregular Face of Climate Change

Natura non facit saltus—nature does not take jumps. Modern science has thoroughly shattered this tenet of the Aristotelian school of thought. Long-term observations and experimental insights have demonstrated convincingly that smooth, or *regular*, behavior is an exception rather than a rule. Available records of climate variability, for example, reveal sudden fluctuations of key variables at all time scales. Large, abrupt climate changes evident in Greenland ice-core records (known as Dansgaard-Oeschger oscillations—Dansgaard *et al.*, 1993) and episodic, massive discharges of icebergs into the North Atlantic (known as Heinrich events—Bond *et al.*, 1992) are obvious examples of *irregular* behavior as a result of weak external forcing. Ecosystems also display discontinuous responses to changing ambient conditions, such as changes in disturbance regimes (Holling, 1992a; Peterson *et al.*, 1998) and species extinctions (Pounds *et al.*, 1999). Irreversible changes in ecosystems are triggered by disturbances (e.g., Gill, 1998), pests (e.g., Holling, 1992b), and shifts in species distributions (Huntley *et al.*, 1997). Irregular behavior is accepted as a major aspect of the dynamics of complex systems (Berry, 1978; Schuster, 1988; Wiggins, 1996; Badini and Politi, 1997).

A quantitative entity behaves "irregularly" when its dynamics are discontinuous, nondifferentiable, unbounded, wildly varying, or otherwise ill-defined. Such behavior often is termed *singular*, particularly in catastrophe theory (Saunders, 1982), and illustrates how smooth variations of driving forces can cause abrupt and drastic system responses. The occurrence, magnitude, and timing

of singularities are relatively difficult to predict, which is why they often are called “surprises” in the literature.

It is important to emphasize that singular behavior is not restricted to natural systems. There has been speculation, for example, about possible destabilization of food markets, public health systems, and multilateral political agreements on resource use, but solid evidence rarely has been provided (e.g., Döös, 1994; Hsu, 1998). Rigorous scientific analysis of certain classes of singular socioeconomic phenomena is emerging (Bunde and Schellnhuber, 2000), but huge cognitive gaps remain in this field.

Singularities have large consequences for climate change vulnerability assessments. Unfortunately, most of the vulnerability assessment literature still is focusing on a smooth transition from what is assumed to be an equilibrium climate toward another equilibrium climate (often $1x\text{CO}_2$ to $2x\text{CO}_2$). This means that most impact assessments still implicitly assume that climate change basically is a “well-behaved” process. Until recently, only a few authors have emphasized the importance of discontinuous, irreversible, and extreme events to the climate problem (e.g., Lempert *et al.*, 1994; Nordhaus, 1994a; Schellnhuber, 1997); concerns about the impacts of these events and their consequences for society now are becoming much more common. Singularities could lead to rapid, large, and unexpected impacts on local, regional, and global scales. Anticipating and adapting to such events and their impacts would be much more difficult than responding to smooth change, even if these responses must be made in the face of uncertainty. Furthermore, singularities considerably complicate the search for optimal emissions reduction strategies that are based on, for example, benefit-cost analysis or tolerable emissions strategies that are based on, as another example, the precautionary principle.

This section reviews and synthesizes relevant available information on the impacts of singular behavior of (components of) the climate system or singular impacts of climate change and draws conclusions about the consequences for vulnerability assessments. Because no generally accepted framework to assess singularities of climate change exists, an illustrative typology of singularities is discussed first. The different characteristics of each class in this typology justify why insights from this section contribute to two separate reasons for concern: extreme weather events and large-scale singularities.

19.6.2. Characteristics of Singularities

The causes of singularities are diverse, but most can be grouped in the categories of *nonlinearity*, *complexity*, and *stochasticity*. Choices about how to assess singular climate impacts depend strongly on the factors generating such behavior. The first two categories arise in a largely *deterministic* context, so their incidence can be assessed with proper models. The latter is probabilistic, however, rendering its incidence basically unpredictable. Only statistical properties can be analyzed.

Predictability (and consequently adaptability) is directly related to the *stochastic* nature of the underlying dynamics.

The first, and most obvious, class of singularities is caused by strongly nonlinear or discontinuous functional relationships. A conspicuous case is the critical threshold, where responses to a continuous change in a driving variable bring about sudden and severe impacts, such as extinction events. Changes in mean climate can increase the likelihood of crossing these thresholds. Even one of the simplest physical thresholds in the climate system—the melting point of ice—could induce singular impacts. For example, thawing of permafrost regions would be induced by only a few degrees of warming (Pavlov, 1997) and would severely affect soil and slope stability, with disastrous effects on Arctic infrastructure such as oil pipelines (see Section 16.2.5 and SAR WGII Section 11.5.3). Section 19.3 extensively illustrates the occurrence of critical thresholds that are relevant for bleaching of coral reefs (a temperature threshold) and coastal mangroves (a sea-level rise threshold).

Complexity itself is a second potential cause for singular behavior in many systems. Complex systems, of course, are composed of many elements that interact in many different ways. Anomalies in driving forces of these systems generally distort interactions between constituents of the system. Positive feedback loops then can easily push the systems into a singular response. (Note that complexity is by no means synonymous with nonlinearity!)

Complex interactions and feedbacks gradually have become a focal point of global and climate change investigations: Several illustrative studies, for example, deal with the interplay between atmosphere, oceans, cryosphere, and vegetation cover that brought about the rapid transition in the mid-Holocene from a “green” Sahara to a desert (Brovkin *et al.*, 1998; Ganopolski *et al.*, 1998; Claussen *et al.*, 1999), with the mutual amplification of regional climate modification and unsustainable use of tropical forests as mediated by fire (Cochrane, 1999; Goldammer, 1999; Nepstad *et al.*, 1999) and with the dramatic disruptions possibly inflicted on Southern Ocean food webs and ecological services by krill depletion resulting from dwindling sea-ice cover (see Brierly and Reid, 1999; see also Section 16.2.3).

The third category, stochasticity, captures a class of singularities that are triggered by exceptional events. In the climate context, these are, by definition, extreme weather events such as cyclones and heavy rains (see Table 3-10). Their occurrence is governed by a generally well-behaved statistical distribution. The irregular character of extreme events stems mainly from the fact that, although they reside in the far tails of this distribution, they nonetheless occur from time to time. Therefore, they could affect downstream systems by surprise and trigger effects that are vastly disproportional to their strength. Climate change also could lead, however, to changes in probability distributions for extreme events. Such changes actually could cause serious problems because the risk and

consequences of these transitions are difficult to quantify and identify in advance. The impacts caused by these events have not yet been explored, although they should constitute an essential aspect of any impact and adaptation assessment.

The impacts of extreme event consequences of stochastic climate variability, however, have begun to attract researchers' attention in a related context. As noted in Chapter 18, changes in mean climate can increase the likelihood that distributed weather will cross thresholds where the consequences and impacts are severe and extreme. This variant of stochastic singularity therefore can change in frequency even if the probability of extreme weather events, measured against the mean, is unaffected by long-term trends.

There also is a fourth type that generally arises from a combination of all other singularity categories. This type—sometimes referred to as “imaginable surprises” (Schneider *et al.*, 1998; see also Chapter 1)—represents conceivable global or regional disruptions of the operational mode of the Earth system. Such *macro-discontinuities* may cause damages to natural and human systems that exceed the negative impacts of “ordinary” disasters by several orders of magnitudes.

Responses to climate change can alter their character from singular to regular—and vice versa—as they cascade down the causal chain: *geophysical perturbations*, *environmental impacts*, *sectoral and socioeconomic impacts*, and *societal responses*. Only the last three are climate change effects in the proper sense, but the first is important because it translates highly averaged indicators of climate change into the actual trigger acting at the relevant scale. Most singular geophysical perturbations create singular impacts—which may, in turn, activate singular responses. One therefore might assume that singularities tend to be preserved down such a cascade. Singular events also can arise further down the causal chain. Purely regular geophysical forcing, for example, can cause singular impacts, and singular socioeconomic responses may result from regular impacts.

Harmful impacts of climate change generally can be alleviated by adaptation or exacerbated by mismanagement (see, e.g., West and Dowlatabadi, 1999; Schneider *et al.*, 2000a; see also Chapter 18). Climate-triggered singular phenomena can generate substantial impacts because their predictability and manageability are low. Such impacts would be considerably reduced if they could be “regularized” by appropriate measures. For example, an ingenious array of seawalls and dikes could transform an extreme storm surge into a mundane inundation that could be controlled by routine contingency procedures. So too could a long-term policy of retreat from the sea. However, inappropriate flood control structures could wreak havoc, particularly because they foster a false sense of security and actually inspire further coastal development.

In summary, singularities tend to produce singularities, as a rule; regularities may turn into singularities under specific conditions, and singularities can be regularized by autonomous ecological processes or judicious societal measures. Defining

the propagation of singular events in the causal cascade or opportunities to convert them into regular events remains a major research challenge.

19.6.3. Impacts of Climate Change Singularities

This subsection sketches the most evident singularities discussed in the context of climate change and reviews the pertinent literature on their potential impacts.

19.6.3.1. Extreme Weather Events

That the occurrence of weather events is essentially stochastic is a well-established fact (e.g., Lorenz, 1982; Somerville, 1987). Most climatic impacts arise from extreme weather events or from climatic variables exceeding some critical level and thereby affecting the performance or behavior of a biological or physical system (e.g., Downing *et al.*, 1999). The same holds for the impacts of climate change (see Chapters 1, 2, and 3, especially Table 3-9; Pittock and Jones, 2000).

For many important climate impacts, we are interested in the effects of specific extreme events or threshold magnitudes that have design or performance implications. To help in zoning and locating developments or in developing design criteria for the capacities of spillways and drainage structures, the heights of levee banks, and/or the strengths of buildings, for example, planners and engineers routinely use estimated “return periods” (the average time between events) at particular locations for events of particular magnitudes. Such event magnitudes include flood levels (Hansen, 1987; Handmer *et al.*, 1999) and storm-surge heights (Middleton and Thompson, 1986; Hubbert and McInnes, 1999). Return period estimates normally are based on recent instrumental records, sometimes augmented by estimates from other locations, or statistical or physically based modeling (Middleton and Thompson, 1986; Hansen, 1987; Beer *et al.*, 1993; National Research Council, 1994; Pearce and Kennedy, 1994; Zhao *et al.*, 1997; Abbs, 1999). The assumption usually is made that these statistics, based on past events, are applicable to the future—but climate change means that this often will not be the case.

Thus, a central problem in planning for or adapting to climate change and estimating the impacts of climate change is how these statistics of extreme events are likely to change. Similar problems arise in nonengineering applications such as assessing the economic performance or viability of particular enterprises that are affected by weather—for example, farming (Hall *et al.*, 1998; Kenny *et al.*, 1999; Jones, 2000)—or health effects (Patz *et al.*, 1998; McMichael and Kovats, 2000; see also Chapter 9).

Relatively rapid changes in the magnitude and frequency of specified extreme events arise because extremes lie in the low-frequency tails of frequency distributions, which change rapidly with shifts in the means. Moreover, there also can be changes

in the shape of frequency distributions, which may add to or subtract from the rate of change of extremes in particular circumstances (Mearns *et al.*, 1984; Wigley, 1985, 1988; Hennessy and Pittock, 1995; Schreider *et al.*, 1997). Such changes in the shape of frequency distributions require special attention. Evidence suggests that they are particularly important for changes in extreme rainfall (Fowler and Hennessy, 1995; Gregory and Mitchell, 1995; Walsh and Pittock, 1998), possibly in the intensities of tropical cyclones (Knutson *et al.*, 1998; Walsh and Ryan, 2000), and in ENSO behavior (Dilley and Heyman, 1995; Bouma *et al.*, 1997; Bouma, 1999; Timmermann *et al.*, 1999; Fedorov and Philander, 2000). Return periods can shorten, however, even if none of these higher moment effects emerge; simply moving mean precipitation higher, for example, could make the 100-year flood a 25-year flood.

It is noteworthy that the central role in impact assessments of the occurrence of extreme weather events gives rise to multiple sources of uncertainty in relation to climate change. The stochastic nature of the occurrence of extremes and the limited historical record on which to base the frequency distribution for such events give rise, even in a stationary climate, to a major uncertainty. Beyond that, any estimate of a change in the frequency distribution under a changing climate introduces new uncertainties. Additional uncertainties relate to our limited understanding of the impacted systems and their relevant thresholds, as well as the possible effects of adaptation, or societal change, in changing these thresholds. If this were not complicated enough, many impacts of weather extremes arise from sequences of extremes of the same or opposite sign—such as sequences of droughts and floods affecting agriculture, settlements, pests, and pathogens (e.g., Epstein, 2000) or multiple droughts affecting the economic viability of farmers (e.g., Voortman, 1998).

Planned adaptation to climate change therefore faces particular difficulty in this environment because projections of changes in the frequency of extreme events and threshold exceedence require a multi-decadal to century-long projected (or “recent” observed) data series, or multiple ensemble predictions (which is one way of generating improved statistics). Thus, it is difficult to base planned adaptation on the record of the recent past, even if there is evidence of a climate change trend in the average data. Planned adaptation therefore must rely on model predictions of changes in the occurrence of extreme and threshold events (e.g., see Pittock *et al.*, 1999), with all their attendant uncertainties. Real-life adaptation therefore will most likely be less optimal (more costly or less effective) than if more precise information on future changes in such thresholds and extremes were available.

Nonetheless, planned adaptation will most likely proceed in response to changes in the perceived relative frequency of extreme events. Properly done, it can have immediate benefit by reducing vulnerability to current climate as well as future benefit in reducing exposure to future climate change. As suggested above, however, there are many ways to respond inappropriately if care is not taken. In short, changes in extremes and in the frequency of exceeding impacts thresholds are a vital

feature of vulnerability to climate change that is likely to increase rapidly in importance because the frequency and magnitude of such events will increase as global mean temperature rises.

19.6.3.2. Large-Scale Singularities

Singularities that occur in complex systems with multiple thresholds can be assessed with appropriate models. In real systems, however, there always are stochastic elements that influence the behavior of these systems, which are difficult to model. The runaway greenhouse effect, for example, consists of a series of positive feedback loops that result from systemic interactions or can be triggered by stochastic events (Woodwell *et al.*, 1998). Table 19-6 lists examples of such singularities that are triggered by different causes. All of these examples have regional or global consequences. The systemic insights in their behavior generally are based on different simulation approaches. Although local examples (e.g., species extinction) also are abundant in the scientific literature, they are ignored here because climate change does not (yet) seem to be the sole cause, and the processes involved generally are not modeled systematically.

19.6.3.2.1. Nonlinear response of North Atlantic thermohaline circulation

Many model studies (reviewed in Weaver *et al.*, 1993; Rahmstorf *et al.*, 1996) have analyzed the nonlinear response of the worldwide ocean circulation—the so-called conveyor belt. This system transports heat and influences regional climate patterns. One component of this system is the current in the Atlantic Ocean. Warm surface currents flow northward. Heat release and evaporation from the ocean surface lowers the temperature and increases the density and salinity of the water. In the North Atlantic, this denser water sinks at the Labrador and Greenland convection sites and flows back south as deepwater. This so-called North Atlantic THC could slow down or even shut down under climate change (see TAR WGI Chapters 7 and 9).

The paleoclimatic record shows clear evidence of rapid climatic fluctuations in the North Atlantic region (with possible connections to other regions) during the last glaciation and in the early Holocene (see TAR WGI Section 2.4.3). At least some of these events—notably the Younger Dryas event, when postglacial warming was interrupted by a sudden return to colder conditions within a few decades about 11,000 years ago—are thought to be caused by changes in the stability of North Atlantic waters. These changes, which are recorded in the central Greenland ice cores and elsewhere, were accompanied by large changes in pollen and other records of flora and fauna in western Europe, indicating that they had widespread effects on European regional climate and ecosystems (Ammann, 2000; Ammann *et al.*, 2000). The likely cause for these fluctuations is changes in the stability of the THC brought about by an influx of freshwater from melting icebergs and/or ice caps (see TAR WGI Section 7.3.7). As discussed in WGI, enhanced greenhouse

Table 19-6: Examples of different singular events and their impacts.

Singularity	Causal Process	Impacts	Reference
Nonlinear response of thermohaline circulation (THC)	– Changes in thermal and freshwater forcing could result in complete shutdown of North Atlantic THC or regional shutdown in the Labrador and Greenland Seas. In the Southern Ocean, formation of Antarctic bottomwater could shut down. Such events are found in the paleoclimatic record, so they are plausible.	– Consequences for marine ecosystems and fisheries could be severe. Complete shutdown would lead to a stagnant deep ocean, with reducing deepwater oxygen levels and carbon uptake, affecting marine ecosystems. Such a shutdown also would represent a major change in heat budget and climate of northwestern Europe.	WGI TAR Chapters 2.4, 7, and 9; see Section 19.6.4.2.1
Disintegration of West Antarctic Ice Sheet (WAIS), with subsequent large sea-level rise	– WAIS may be vulnerable to climate change because it is grounded below sea level. Its disintegration could raise global sea level by 4–6 m. Disintegration could be initiated irreversibly in the 21st century, although it may take much longer to complete.	– Considerable and historically rapid sea-level rise would widely exceed adaptive capacity of most coastal structures and ecosystems.	WGI TAR Chapters 7 and 11; see Section 19.6.4.2.2; Oppenheimer, 1998
Runaway carbon dynamics	– Climate change could reduce the efficiency of current oceanic and biospheric carbon sinks. Under some conditions, the biosphere could even become a source. – Gas hydrate reservoirs also may be destabilized, releasing large amounts of methane to the atmosphere. – These processes would generate a positive feedback, accelerating buildup of atmospheric GHG concentrations.	– Rapid, largely uncontrollable increases in atmospheric carbon concentrations and subsequent climate change would increase all impact levels and strongly limit adaptation possibilities.	WGI TAR Chapter 3; Smith and Shugart, 1993; Sarmiento <i>et al.</i> , 1998; Woodwell <i>et al.</i> , 1998; Bains <i>et al.</i> , 1999; Joos <i>et al.</i> , 1999; Katz <i>et al.</i> , 1999; Norris and Rohl, 1999; Walker <i>et al.</i> 1999; White <i>et al.</i> , 1999
Transformation of continental monsoons	– Increased GHGs could intensify Asian summer monsoon. Sulfate aerosols partially compensate this effect, although dampening is dependent on regional patterns of aerosol forcing. Some studies find intensification of the monsoon to be accompanied by increase in interseasonal precipitation variability.	– Major changes in intensity and spatial and temporal variability would have severe impacts on food production and flood and drought occurrences in Asia.	TAR WGI Sections 9.3.6.2 and 9.3.5.2.2; TAR WGII Section 11.5.1; Lal <i>et al.</i> , 1995; Mudur, 1995; Meehl and Washington, 1996; Bhaskaran and Mitchell, 1998
Qualitative modification of crucial climate-system patterns such as ENSO, NAO, AAO, and AO	– ENSO could shift toward a more El Niño-like mean state under increased GHGs, with eastward shift of precipitation. Also, ENSO's variability could increase. – There is a growing attempt to investigate changes in other major atmospheric regimes [NAO, Arctic Oscillation (AO), and Antarctic Oscillation (AAO)]. Several studies show positive trend in NAO and AO indices with increasing GHGs.	– Changing ENSO-related precipitation patterns could lead to changed drought and flood patterns and changed distribution of tropical cyclones. – A positive NAO/AO phase is thought to be correlated with increased storminess over western Europe.	TAR WGI Sections 7.7.3 and 9.3.5.2; Corti <i>et al.</i> , 1999; Fyfe <i>et al.</i> , 1999; Shindell <i>et al.</i> , 1999; Timmermann <i>et al.</i> , 1999

Table 19-6 (continued)

Singularity	Causal Process	Impacts	Reference
Rearrangement of biome distribution as a result of rising CO ₂ concentrations and climate change	– Many studies show large redistribution of vegetation patterns. Some simulate rapid dieback of tropical forests and other biomes; others depict more gradual shifts. More frequent fire could accelerate ecosystem changes.	– All models initially simulate an increase in biospheric carbon uptake, which levels out later. Only a few models simulate carbon release.	White <i>et al.</i> , 1999; Cramer <i>et al.</i> , 2000
Destabilization of international order by environmental refugees and emergence of conflicts as a result of multiple climate change impacts	– Climate change—alone or in combination with other environmental pressures—may exacerbate resource scarcities in developing countries. These effects are thought to be highly nonlinear, with potential to exceed critical thresholds along each branch of the causal chain.	– This could have severe social effects, which, in turn, may cause several types of conflict, including scarcity disputes between countries, clashes between ethnic groups, and civil strife and insurgency, each with potentially serious repercussions for the security interests of the developed world.	Homer-Dixon, 1991; Myers, 1993; Schellnhuber and Sprinz, 1995; Biermann <i>et al.</i> , 1998; Homer-Dixon and Blitt, 1998

warming could produce similar changes in stability in the North Atlantic because of warming and freshening of North Atlantic surface waters.

The current operation of THC is self-sustaining within limits that are defined by specific thresholds. If these thresholds were exceeded, two responses would be possible: shutdown of a regional component of the system or complete shutdown of the THC. Both responses have been simulated. A complete shutdown was simulated by Manabe and Stouffer (1993) for a quadrupling of atmospheric CO₂ and by Rahmstorf and Ganopolski (1999) for a transient peak in CO₂ content. These studies suggest that the threat of such complete shutdown increases beyond a global mean annual warming of 4–5°C, but this is still speculative. It took several centuries until the circulation was shut down completely in both studies. A regional shutdown in the Labrador Sea (while the second major Atlantic convection site in the Greenland Sea continued to operate) was simulated by Wood *et al.* (1999). Simulated regional shutdown can occur early in the 21st century and can happen rapidly—in less than a decade. Simulations by Manabe and Stouffer (1993) and Hirst (1999) show further the possibility of a shutdown of the formation of Antarctic bottomwater, which is the second major deepwater source of the world ocean.

These simulations clearly identify possible instability for the THC. Determining appropriate threshold values, however, requires analysis of many scenarios with different forcings and sensitivity studies of important model parameters. Stocker and Schmittner (1997), for example, have shown that the THC is sensitive not only to the final level of atmospheric CO₂ concentration but also to the rate of change. Rahmstorf and Ganopolski (1999) show that uncertainties in the hydrological cycle are a prime reason for uncertainty in forecasting, whether a

threshold is crossed or not (see Figure 19-6). Further parameters are climate sensitivity (high values increase the likelihood of a circulation change) and the preindustrial rate of Atlantic overturning (an already weak circulation is more liable to break down) (e.g., Schneider and Thompson, 2000). These simulations suggest that global warming over the next 100 years could lead to a sudden breakdown of the THC decades to centuries later, which would lead irrevocably to major effects on future generations.

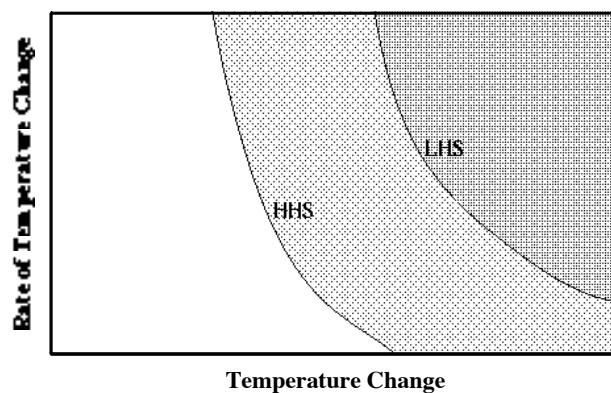

Figure 19-6: Stability of North Atlantic thermohaline circulation (THC) computed with the CLIMBER model (Petoukhov *et al.*, 2000). Degree of shading indicates probability of THC collapse. Light shading denotes low probability; dark shading denotes high probability. The higher the hydrological sensitivity (HHS = high hydrological sensitivity, LHS = low hydrological sensitivity), the faster the rate of temperature increase, or the greater the magnitude of temperature increase, the more likely that the North Atlantic THC becomes unstable.

The possible impacts of these circulation changes have not yet been studied systematically. Complete shutdown of the THC would represent a major change in the heat budget of the northern hemisphere because this circulation currently warms northwestern Europe by 5–10°C (Manabe and Stouffer, 1988; Rahmstorf and Ganopolski, 1999). Consequently, shutdown would lead to sudden reversal of the warming trend in this region. The impacts of a regional shutdown would be much smaller but probably still serious. For the European climate, loss of the Greenland Sea branch probably would have a much stronger effect than loss of the Labrador Sea branch because the northward extent of the warm North Atlantic current depends mainly on the former. In either case, the consequences of circulation changes for marine ecosystems and fisheries could be severe (see Section 6.3). Shutdown of the major deepwater sources in the North Atlantic and Southern Ocean would lead to an almost stagnant deep ocean, with as-yet unexplored consequences (e.g., for deepwater oxygen levels, carbon uptake, and marine ecosystems).

Neither the probability and timing of a major ocean circulation change nor its impacts can be predicted with confidence yet, but such an event presents a plausible, non-negligible risk. The change would be largely irreversible on a time scale of centuries, the onset could be relatively sudden, and the damage potential could be very high.

19.6.3.2.2. Disintegration of West Antarctic ice sheet

The WAIS contains 3.8 million km³ of ice, which, if released to the ocean, would raise global sea level by 4–6 m. The WAIS has been the subject of attention since analysis of paleodata (Hughes, 1973) and ice sheet models (Weertman, 1974) predicted that such a marine-grounded ice sheet is inherently unstable.

Analysis of ice sediments indicates that in the past 1.3 million years, the WAIS has collapsed at least once (Scherer *et al.*, 1998). It was inferred from marine sediments that the WAIS is still dynamic. Since the last glacial maximum, the grounding line (i.e., the boundary between the floating ice shelves and the grounded ice) has retreated considerably (Hughes, 1998), and this process continues. It probably reflects dynamics that were set in motion in the early Holocene (Conway *et al.*, 1999). This has important implications because it points toward the long equilibration time scales involved in WAIS dynamics.

Fast-flowing ice streams, which feed the shelves from the interior, dominate the discharge of the WAIS (see TAR WGI Section 11.5). These ice flows are constrained at various boundaries. Whereas early studies emphasized the role of ice-shelf boundaries in such ice flow, more recent work points to the importance of different boundaries (i.e., the ice-stream bed, the lateral margins, and the inland end—Anandakrishnan *et al.*, 1998; Bell *et al.*, 1998; Joughin *et al.*, 1999; Payne, 1999). With respect to the time scales of an eventual WAIS disintegration, this distinction is crucial because the ice shelves respond to changes in climate within centuries, whereas the conditions at the ice-stream

margins and beds have response times on the order of millennia (e.g., McAyeal, 1992). Whether proper incorporation of ice-stream dynamics into ice-sheet models generally eliminates the presumed instability cannot be conclusively resolved. McAyeal (1992), for example, incorporated ice-stream dynamics and deformable bed conditions explicitly into his ice-sheet model and showed that under periodic climate and sea-level forcing (100,000-year cycles), the WAIS collapsed and regrew sporadically throughout a period of 1 million years.

Even if accelerated loss of grounded ice were unlikely to occur over the 21st century, changes in ice dynamics could result in increased outflow of ice into the ice shelves and trigger a grounding-line retreat. An in-water temperature of a few degrees Celsius could cause the demise of the WAIS ice shelves in a few centuries and float its marine-based parts over a period of 1,000–2,000 years (Warner and Budd, 1998). This would produce a sea-level rise of 2–3 m. Huybrechts and de Wolde (1999) evaluate a climate change scenario that stabilizes GHG concentrations at four times the present value in 2150. They show that melting of the WAIS would contribute to 1-m sea-level rise by 2500—a rate of rise that would be sustained at 2 mm yr⁻¹ for centuries thereafter. The response of the Greenland ice sheet contributed to several meters of sea-level rise by 3000. Even under this stabilization scenario, melting of the Greenland ice sheet would be irreversible. Both studies, however, simply assume no change in ocean circulation and an immediate warming of water in the sub-ice-shelf cavity with a warming climate. Both assumptions still await full validation.

Global warming projected for the 21st century could set in motion an irreversible melting of the West Antarctic and Greenland ice sheets, implying sustained sea-level rise and irreversible losses. The impacts of complete disintegration of the WAIS and subsequent sea-level rise by 4–6 m, however, have not been fully explored. As summarized by Oppenheimer (1998), the disintegration time scales predicted by models vary widely, between 400–500 years (Thomas *et al.*, 1979) and 1,600–2,400 years (McAyeal, 1992). These time scales correspond to a mean contribution to sea level of 10–15 and 2.5 mm yr⁻¹, respectively. Whereas an estimate in the lower range is approximately equal to the present-day rate of sea-level rise, a value in the middle to high range lies outside human experience and would widely exceed the adaptive capacity of most coastal structures and ecosystems (see Sections 19.3 and 6.5).

19.6.4. Climate Protection in an Irregular World

The predictability and manageability of singular phenomena is low. Their impacts can be sudden, large, and irreversible on a time scale of centuries. Regularizing such impacts would be an appropriate response, but this would require much better understanding of the statistics and characteristics of the complex processes involved. The presence of singularities therefore makes analytic and political treatment of the climate change problem particularly difficult.

Little is known, in quantitative terms, about the potential damages that could be inflicted by singularities on ecosystems and market sectors across the globe. This deficit has two main reasons (see also Moss and Schneider, 2000). First, extensive research on the causes, mechanisms, and impacts of singular events in the context of climate change is just getting started. Second, mechanistic and probabilistic analysis of complex nonlinear systems is more demanding—by orders of magnitude—than investigation of simple linear ones.

The knowledge base for assessing consequences of singularities will probably be broadened considerably over the next 5–10 years. Further advances in simulation modeling soon will allow better projections of future climate variability down to modified extreme events statistics (CLIVAR, 1998), as well as better translations of those projections into impacts on natural and societal systems (e.g., Weyant *et al.*, 1996; Alcamo *et al.*, 1998; Rotmans and Dowlatabadi, 1998). Earth system analysis, as supported by the big international research programs—World Climate Research Programme (WCRP), International Geosphere-Biosphere Programme (IGBP), and International Human Dimensions Programme (IHDP)—will bring about more complete understanding of macro-singularities within the responses of the Earth system under pertinent forcing (Schellnhuber, 1999). A major source of information and comprehension, in this context, will be evidence provided by paleorecords (IGBP, 1998). These scientific efforts should assist the decisionmaking process by creating a clearer picture of the future. Unfortunately, creating plausible projections is always tricky in practice (Sarewitz *et al.*, 2000).

A major challenge is to make responsible use of available information regarding the likelihood and the consequences of conceivable singular events. Responsibility here means the obligation of decisionmakers to make the “right” decision, taking into account the diverse societal values and wide ranges of individual interests that are at stake and that may be mutually contradictory. Thus, the standard challenge is to develop proper policies under uncertainty (i.e., neither ignorance nor omniscience) to achieve the objectives of the UNFCCC and to satisfy affected stakeholders as well as possible.

Abroad and intensive discourse on the ethical aspects of singular responses to climate change (e.g., Markandya and Halsnaes, 2000; Munasinghe, 2000; Toth, 2000) is rediscovering many of the arguments put forward in traditional moral philosophy and risk policy. Ethical and procedural aspects of this type have been examined in various other contexts before, where certain concepts (such as human rights) act as a constraint on economic activity (emphasizing utilitarian goals), even when the cost-benefit ratio is unfavorable (e.g., the review of the agricultural situation by Aiken, 1986).

One of the crucial questions is how to deal with high-consequence impacts that *may* wipe out entire systems or cultures. Such non-impossible “nightmare” or “doomsday” scenarios could result from the speculative but consistent concatenation of individually possible causal relationships (e.g., Schellnhuber and

Yohe, 1997). A vexing question is whether the lack of credible scientific evidence for such a scenario provides justification to ignore its possibility completely. Some argue that such effects have to be avoided by all means, irrespective of the economic burdens involved. Others argue that the uncertainties involved do not provide enough support for extensive measures and their economic costs. Within the climate-change framework, however, many incalculable risks could be reduced considerably by more sensible measures. The debate on the “legitimacy” of the different perspectives is impossible to resolve, however (Jasanoff, 1990).

The vague evidence provided by the present state of research supports the notion that even relatively small changes in mean climate could lead to large changes in the occurrence of stochastic extreme events. Furthermore, it suggests that large-scale discontinuities are unlikely below a 2°C warming but relatively plausible for a sustained warming of 8–10°C. The relatively small set of investigations discussed above lead to the conclusion that a warming range of 4–5°C seems to represent a critical disturbance regime where macro-discontinuities may start to emerge. This temperature threshold appears to be sensitive to the rate of change at which this level is reached.

19.7. Limitations of Methods and Directions for Future Research

This section discusses the strengths and limitations of the analytic approaches used to address the reasons for concern, mainly with regard to whether they can, with the confidence levels given, indicate the severity of impact or risk as a function of increase in global mean temperature. This discussion identifies key uncertainties inherent in each method and offers directions for future research that could improve our confidence in the results produced with each approach.

The organization of this section parallels that of the previous sections of this chapter. The strengths, limitations, uncertainties, and directions for each approach are discussed in the same order in which they were discussed in the preceding sections. However, integrated assessment frameworks are considered separately from aggregate approaches. Last is a discussion of integration across methods and reasons for concern.

19.7.1. Observations

Advantages: Because observations are based on observed effects rather than models, they can be used to indicate whether climate change is causing impacts and whether impacts lead to positive, negative, or indeterminate outcomes. They also can be used to validate hypotheses and models that formalize hypotheses on cause and effect.

Disadvantages: The problem with relying on observations to determine the severity of impacts or risk from climate change is that there has been only 0.7°C of mean global warming over

the past century (although some regions have experienced much more warming). Because many impact thresholds may not be crossed until greater magnitudes or rates of warming are reached, it is not clear how to interpret an observed effect of warming or a group of such observations. Such observed impacts to date often will be of only minor consequence, even though they may tend to confirm our understanding of impact processes. Moreover, lack of observed impacts may be simply because climate change has not yet reached critical thresholds for such effects. Finally, attribution of causality is very difficult with observed effects or groups of effects. One must be able to demonstrate that a regional change in climate is a significant cause of an observed effect and that the regional change in climate is linked to global climate change.

Uncertainties: Uncertainties include the magnitude of climate change that has occurred, the extent to which impacts can be attributed to climate change that has occurred, and whether the relationship between climate change and possible impacts is linear or nonlinear and continuous or discontinuous.

Research Needs: For climate change impact detection to advance, there is a need for continued, improved, and augmented data collection and further development of analytical techniques. Geographical diversity is needed to balance the current bias of study locations in North America and Europe; more observation studies are needed in developing countries, with emphasis on those where physical, biological, and socioeconomic systems have higher vulnerability to climate change (see Chapter 18).

Because climate and impact systems are linked over a range of temporal scales, longer time series of data allow better understanding of the relative magnitudes of short- and long-term responses (Duarte *et al.*, 1992; McGowan *et al.*, 1999). Large-amplitude temporal changes usually involve large spatial dimensions, so broad-scale spatial/temporal studies are necessary as well. Satellite measurements of the Earth's surface provide a very useful monitoring capability for ocean, ecosystem, and land-cover changes. For example, satellite measurements of the Earth's surface offer the potential for aggregation of observed impacts with regard to broad-scale ecological responses such as vegetative responses to increasing lengths of growing seasons (e.g., Myneni *et al.*, 1997), complemented by meteorological and vegetation data (e.g., Schwartz, 1998).

For ecosystem impacts, continuing observations are needed at sites where studies already have been conducted, at long-term ecological research sites (e.g., Chapin *et al.*, 1995), and in protected areas. Programs that provide continued long-term monitoring of marine and terrestrial environments also are important (Duarte *et al.*, 1992; Southward *et al.*, 1995). Large-scale spatial/temporal ecosystem studies are necessary because effects from local changes cannot be extrapolated to large areas without evidence (McGowan *et al.*, 1999; Parmesan *et al.*, 1999).

Definition of indicator species or systems is a useful element of detection studies (e.g., Beebee, 1995; Nehring, 1998; Cannell *et al.*, 1999). Coupled with monitoring programs, such data may

then provide a consistent set of evidence with which to study past, present, and future impacts of climate changes.

A further critical research need is to strengthen analytical tools for understanding and evaluating observed climate change impacts. Robust meta-analyses of studies that present good quality, multivariate data from a diversity of settings around the world will help to define further the global coherence among impacts now observed. Care also must be taken to ensure that the sample of studies is representative across time and space, is not biased in its reporting, and uses appropriate statistical tests. Also needed is development of methods to analyze differential effects of climate across a range or sector. Individual and grouped studies need to address possible correlations with competing explanations in a methodologically rigorous manner.

Also needed are refinements in the fingerprint approach (e.g., Epstein *et al.*, 1998), including more precise definition of expected changes and quantitative measurement techniques, similar to that used in detection of climate changes (see TAR WGI Chapter 12). For climate, fingerprint elements include warming in the mid-troposphere in the southern hemisphere, a disproportionate rise in nighttime and winter temperatures, and statistical increases in extreme weather events in many locations. These aspects of climate change and climate variability have implications for ecological, hydrological, and human systems that may be used to define a clear and robust multidimensional "expected impact signal" to be tested in a range of observations. A more refined and robust fingerprint approach may aid in the study of difficult-to-detect, partially causal climate effects on socioeconomic systems such as agriculture and health.

19.7.2. Studies of Unique and Threatened Systems

Assessments of unique and threatened systems tend to be based on studies of particular exposure units such as coral reefs, small islands, and individual species.

Advantages: These studies contain richness of detail and involve many researchers, often from developing and transition countries. In contrast to aggregate studies, studies of exposure units can be used, at least in principle, to analyze distributional effects by focusing on impacts on particular systems, species, regions, or demographic groups.

Disadvantages: One of the main disadvantages is that exposure-unit studies often are not carried out in a consistent manner. Exposure-unit studies often examine related sectors in isolation and do not examine linkages or integration among sectors and regions; for example, studies of the effects of climate change on ecosystems or individual species often are conducted without examining the potential effects of societal development on such systems. Local processes and forces (e.g., urbanization, local air pollution) often can be more important than global ones at the local scale, complicating the task of measuring the influence of global climate change at the local scale.

Another key disadvantage is incompleteness of coverage. For example, in spite of many and extensive country studies, there still are many gaps in coverage in terms of countries, regions within countries, and unique and important potential impacts that have not been assessed. The choice of exposure units may not necessarily cover the most vulnerable systems. Topics such as impacts on biodiversity or unique ecosystems often are not covered. There also has been little attention to impacts on poor and disadvantaged members of society. Even where particular critical exposure units have been covered, there may be just a single study. Drawing conclusions with high confidence on the basis of one study may be inappropriate.

Uncertainties: Uncertainties include the likely magnitude of climate change at the spatial resolution required by the study of the particular unique and threatened system, masking of global change effects by nonclimate factors, the degree of linearity/nonlinearity in the relationship between stimulus and response, and the degree to which results from individual studies can be extrapolated or aggregated.

Research Needs: It would be desirable to have more studies of individual systems, according to some set of priorities concerning the likely immediacy of the impacts. Additional work on standardizing methods and reporting of results also would be extremely useful. It also would be useful to devote more effort to integration of results from existing studies. Again, it would be especially useful to increase monitoring of changes in organisms, species, and systems that have limited range now or are near their limits and to try to separate out or consider other causal mechanisms such as local air pollution, loss of habitat, and competition from invading pests and weeds.

19.7.3. Distributional Impacts

Advantages: Distributional impact studies draw attention to likely heterogeneity in impacts among different regions and social and economic groups. They also help to identify and assess the situation of the “most vulnerable” people and systems. Thus, such studies bring equity considerations to center stage.

Disadvantages: Distributional impact studies require regional climate change projections and impact projections at the regional to local scale, where GCMs may not be very accurate. They also require projections of demographics and socioeconomic structure over a long time horizon.

Uncertainties: Research into the distribution of impacts of climate change is recent (see Section 19.4). There are some findings on which there is virtual unanimity. Some findings are broad conclusions—such as that more resource-constrained regions are likely to suffer more negative impacts, as are people whose geographic location exposes them to the greatest hazards from climate change. (Such people often live in regions with marginal climate for food growing or in highly exposed coastal zones.) Others are more specific but to date have been more conclusive with regard to the direction of different impacts

among regions, rather than the magnitudes. For example, we know that impacts in developing low-latitude countries are more negative—in part because those countries tend to be operating at or above optimum temperatures already—and, in some cases, in regions where rainfall will decrease, leading to water stress. There also is limited capacity for adaptation in these areas. In some mid-latitude developed countries, agriculture would benefit initially from warmer conditions and longer growing seasons. Beyond such sweeping statements, uncertainties are vast. Resource constraints and (climatic) marginality are multidimensional and complex phenomena. Currently, it is not known which components of resource constraints or climatic marginality are more important or which components may compensate for others or may have synergistic effects. There are suggestions in other literature, but these have not been systematically applied to the impacts of climate change, conceptually or empirically.

In sum, there is virtual consensus about the broad patterns. There is much less knowledge about the details, although that situation is slowly improving.

Research Needs: Development of appropriate indicators of differences in regional impacts and ways of comparing them across regions and socioeconomic groups would be extremely useful. Improved methods for characterizing baseline demographics and socioeconomic conditions in the absence of climate change or climate change-motivated policies also would be useful. There is a need to quantify regional differences and to develop estimates of the cost of inequity in monetary or other terms (e.g., effect on poverty rates and trade, social and political instability, and conflict). More accurate projections of regional climate change would increase confidence in predictions of regional climate change impacts.

19.7.4. Aggregate Approaches

Advantages: Aggregate analyses synthesize climate change impacts in an internally consistent manner, using relatively comprehensive global indicators or metrics. These often are expressed in U.S. dollars (e.g., Tol, 2001b) or other common metrics such as changes in vegetation cover (Alcamo *et al.*, 1998). This enables direct comparisons of impacts among sector systems and regions and with other environmental problems and emission control costs. Some aggregate analyses have assessed differences in relative impacts in developed and developing regions of the world and have shown that regional differences in impacts may be substantial.

Disadvantages: Aggregate analyses lack richness of detail. Partly this is inherent because aggregation explicitly seeks to synthesize complex information. Partly this is because aggregate analyses tend to rely on reduced-form models. Condensing the diverse pattern of impacts into a small number of damage indicators is difficult. Some metrics may not accurately capture the value of certain impacts; for example, nonmarket impacts such as mortality and loss of species diversity or cultural heritage

often are not well captured in monetization approaches, and change in vegetation cover may not clearly indicate threats to biodiversity. Other complicating issues concern comparison of impacts across time (impact today and several generations from now) and between regions (e.g., impact in developing and developed countries), as well as how much importance to assign to different effects. In addition, many aggregate studies examine a static world rather than a dynamic one and do not consider the effects of changes in extreme events or large-scale discontinuities. The aggregation process is not possible without value judgments, and different ethical views imply different aggregate measures across socioeconomic groupings and generations (see Azar and Sterner, 1996; Fankhauser *et al.*, 1997). Choice of discount rates can affect valuation of damages. In addition, general shortcomings that affect all reasons for concern are particularly prominent in aggregate analysis (e.g., accounting for baseline development, changes in variability and extreme events, and costs and benefits of adaptation).

Uncertainties: Uncertainties include whether all climate change impacts (positive and negative) are included, the implications of various aggregation and valuation methods, and implicit or explicit assumptions of methods, including possible mis-specifications of nonlinearities and interaction effects.

Research Needs: The next generation of aggregate estimates will have to account better for baseline developments, transient effects, climate variations, and multiple stresses. Further progress also is still needed in the treatment of adaptation. A broader set of primary studies on impacts in developing countries and nonmarket sectors would reduce the need for difficult extrapolation. More work also is needed on the ethical underpinnings of aggregation and on alternative aggregation schemes. Work on reflecting information from the other reasons for concern into the aggregate approach is underway, but proceeding slowly.

19.7.5. Integrated Assessment Frameworks

Advantages: Integrated assessment frameworks or models provide a means of structuring the enormous amount of and often conflicting data available from disaggregated studies. They offer internally consistent and globally comprehensive analysis of impacts; provide “vertical integration” (i.e., cover the entire “causal chain” from socioeconomic activities giving rise to GHG emissions to concentration, climate, impacts, and adaptations); provide “horizontal integration” (i.e., account for interlinkages between different impact categories, adaptations, and exogenous factors such as economic development and population growth); and allow for consistent treatment of uncertainties. IAMs have been used primarily for benefit-cost and inverse (or threshold) analyses. The latter have the advantage of being directly related to Article 2 because they define impacts that may be considered “dangerous” (through specification of thresholds related to, e.g., harm to unique and threatened systems or the probability of large-scale discontinuities).

Disadvantages: The main disadvantages with most IAMs are those associated with aggregate approaches: reliance on a single or a limited number of universal measures of impacts. These may not adequately measure impacts in meaningful ways. This is partly because IAMs rely on reduced-form equations to represent the complexities of more detailed models. Their usefulness is highly dependent on how well they are able to capture the complexities of more disaggregated approaches. Some of the IAMs used for benefit-cost analyses have considered large-scale irregularities (e.g., Gjerde *et al.*, 1999), but inclusion of such outcomes is preliminary. Few have accounted for loss of or substantial harm to unique and threatened systems. Although inverse (or threshold) approaches allow researchers to overcome these problems, the disadvantages of this kind of analysis include the difficulty of explicitly specifying thresholds and combining them within and across sectors and regions.

Uncertainties: Uncertainties are the same as those for the aggregate approach or for unique and threatened systems, depending on the structure and objectives of the model. This also would include the effects of different assumptions, methods, and value choices.

Research Needs: Among the biggest challenges facing integrated assessment modelers (see Weyant *et al.*, 1996) are developing a credible way to represent and value the impacts of climate change; a credible way to handle low-probability but potentially catastrophic events; a credible way to incorporate changes in extreme weather events; and realistic representations of changes in socioeconomic and institutional conditions, particularly in developing countries. In addition, they must decide how to allow explicitly for effects of different value choices, systems, and assumptions; how to quantify uncertainties; and how to credibly incorporate planned adaptation, including costs and limitations.

19.7.6. Extreme Events

Advantages: Extreme events are recognized as major contributors to the impacts of climate variability now and to potential impacts of climate change in the future. Thus, realistic climate change impact assessments must take them into account even though they may change in complex ways—such as in frequency, magnitude, location, and sequences (e.g., increased variability may lead to more frequent floods and droughts). Better understanding of changes in extreme events and adaptation measures for coping with them also will help in coping with present variability.

Disadvantages: Extreme events are more difficult to model and characterize than average climates. Changes in extreme events will be complex and uncertain, in part because extremes occur in a chaotic manner even in the present climate. Large data series are needed to characterize their occurrence because, by definition, they are rare events. This means that long time scale model simulations are needed to develop relevant statistics from long time slices or multiple realizations. Extreme events

need to be considered in terms of probabilities or risks of occurrence rather than predictions. This chaotic element adds to other sources of uncertainty. It means that engineering or other design standards based on climatology that normally use long data series of observations will need a synthetic data set that simulates potential changes in future climate. It also makes adaptation to changes in extremes more difficult because planned adaptation must rely on necessarily uncertain projections into the future from theory and thus requires greater faith in the science before the information will be acted on.

Uncertainties and Research Needs: Better knowledge of the behavior of extremes will require long or multiple simulations at finer spatial and temporal scales, to capture the scale, intensity, and frequency of the events. Some types of extreme events (e.g., hail and extreme wind bursts) are poorly simulated at present; others, such as ENSO and tropical cyclones, are extremely complex and only now are beginning to be better simulated. Arguments for changes in their behavior are still often largely theoretical, qualitative, or circumstantial, rather than well based in verified models. Moreover, much more work is needed on how they will affect natural and human systems and how much of the recent trend to greater damages from extreme events is related to changes in exposure (e.g., greater populations, larger investments, more insurance cover, or greater reporting) rather than changes in the number and intensity of those extremes. More work is needed on how best to adapt to changes in extreme events, especially on how planners and decisionmakers can best take information on projected changes in extremes into consideration. This may be done best by focusing on projected change in the risk of exceeding prescribed natural, engineering, or socioeconomic impacts thresholds.

19.7.7. Large-Scale Singular Events

Advantages: Consideration of strongly nonlinear or even disruptive effects accompanying climate change is a critical component of the “dangerous interference” debate. The basic idea is to corroborate any non-negligible probability for high-consequence impacts that may be triggered by human climate perturbations. The political process to avoid high-consequence impacts may be facilitated by the global scope of such effects (e.g., disintegration of the WAIS generating a planetary sea-level rise of approximately 5 m). Inclusion of extreme events in the analysis helps, in general, to pursue all other reasons for concern in a realistic way because irregular impacts may dominate impacts on unique and threatened systems, distributional impacts, and aggregate impacts.

Disadvantages: This is an emerging area of research, facing several serious challenges because of the complexity of nonlinear interactions to be considered. The prevailing lack of knowledge is reflected in use of the term “surprises” for disruptive events. The potentials for climate change-induced transformations of extreme events regimes and for large-scale discontinuities in the Earth system are still highly uncertain. The search for irregularities might turn out to be futile and distract scientific

resources from other important topics, such as the distributional aspects of regular climate change impacts.

Uncertainties and Research Needs: By definition, uncertainties are most severe in this realm of impact research. At present, there is no way of estimating the probabilities of certain disruptive events or assigning confidence levels to those probabilities. As a consequence, a strong research program should be launched that combines the best paleoclimate observations with the strongest simulation models representing full and intermediate complexity.

19.7.8. Looking across Analytic Approaches

Looking across the different analytic approaches (implicitly, the different reasons for concern), it is clear that to a great extent they complement and in many respects do not overlap each other. Combining these approaches into an integrated framework is the ambition of IAMs, at least in principle. However, this process is just starting. Because observed evidence has not been incorporated in the other analytic approaches, impacts to unique and threatened systems have not been accounted for in aggregate and IAM approaches, they are difficult to sum, and large-scale irregular impacts have only begun to be addressed, it does not appear to be feasible yet to combine these approaches into a comprehensive analytic approach. Thus, those who are seeking to implement climate policies must currently do their own integration of information from the alternative lines of inquiry.

19.8. Conclusions

This chapter focuses on certain reasons for concern with regard to what might be considered a “dangerous” climate change (reported as increases in global mean temperature; see Section 19.1.2). Each reason for concern can be used by itself or in combination with other reasons for concern to examine different aspects of vulnerability to climate change. We offer no judgment about how to use some or all of these reasons for concern to determine what is a dangerous level of climate change. The reasons for concern are as follows:

- 1) The relationship between global mean temperature increase and damage to or irreparable loss of unique and threatened systems
- 2) The relationship between global mean temperature increase and the distribution of impacts
- 3) The relationship between global mean temperature increase and globally aggregated impacts
- 4) The relationship between global mean temperature increase and the probability of extreme weather events
- 5) The relationship between greenhouse concentrations and the probability of large-scale singular events.

In addition, we address what observed effects of climate change tell us with regard to Article 2 of the UNFCCC. We

review the state of knowledge with regard to what observations and each reason for concern tell us about climate change impacts.

19.8.1. Observations

Based on a review of the literature of observations of climate change impacts, as reflected in other TAR chapters, we conclude:

- Statistically significant associations between trends in regional climate and impacts have been documented in ~10 physical processes and ~450 biological species, in terrestrial and marine environments on all continents. Although the presence of multiple factors (e.g., land-use change, pollution, biotic invasion) makes attribution of observed impacts to regional climate change difficult, more than 90% (~99% physical, ~80% biophysical) of the changes documented worldwide are consistent with how physical and biological processes are known to respond to climate. Based on expert judgment, we have high confidence that the overall patterns and processes of observations reveal a widespread and coherent impact of 20th-century climate changes on many physical and biological systems.
- Signals of regional climate change impacts may be clearer in physical and biological systems than in socioeconomic systems, which also are simultaneously undergoing many complex changes that are not related to climate, such as population growth and urbanization. There are preliminary indications that some social and economic systems have been affected in part by 20th-century regional climate changes (e.g., increased damages from flooding and droughts in some locations). It generally is difficult to separate climate change effects from coincident or alternative explanations for such observed regional impacts.

There is preliminary evidence that unique and threatened systems are beginning to be affected by regional climate change and that some systems have been affected by recent increases in extreme climate events in some areas. Many high-latitude and high-altitude systems are displaying the effects of regional climate change. It is difficult to define observed impacts at aggregate levels, and evidence of large-scale singular events occurring as a result of recent climate change is lacking.

19.8.2. What does Each Reason for Concern Indicate?

Looking across these different reasons for concern, what can we conclude about what change in global average temperature is “dangerous”? A few general caveats apply:

- In spite of many studies on climate change impacts, there is still substantial uncertainty about how effective adaptation will be (and could be) in ameliorating negative effects of climate change and taking advantage of positive effects.

- The effect of changes in baseline conditions, such as economic growth and development of new technologies, that could reduce vulnerability has not been adequately considered in most impact studies.
- Most impact studies assess the effects of a stable climate, so our understanding of what rates of change may be dangerous is limited.

It does not appear to be possible—or perhaps even appropriate—to combine the different reasons for concern into a unified reason for concern that has meaning and is credible. However, we can review the relationship between impacts and temperature over the 21st century for each reason for concern and draw some preliminary conclusions about what change may be dangerous for each reason for concern. *Note that the following findings do not incorporate the costs of limiting climate change to these levels. Also note that there is substantial uncertainty regarding the temperatures mentioned below. These magnitudes of change in global mean temperature should be taken as an approximate indicator of when various categories of impacts might happen; they are not intended to define absolute thresholds.*

For simplification, we group different levels of global mean temperature increase into “small,” “medium,” and “large.” “Small” denotes a global mean temperature increase of up to approximately 2°C;⁴ “medium” denotes a global mean temperature increase of approximately 2–3°C; and “large” denotes a global mean temperature increase of more than approximately 3°C. In addition, changes in global mean temperature do not describe all relevant aspects of climate-change impacts, such as rates and patterns of change and changes in precipitation, extreme climate events, or lagged (or latent) effects such as rising sea levels.

19.8.2.1. Unique and Threatened Systems

Tropical glaciers, coral reefs, mangroves, biodiversity “hot spots,” and ecotones are examples of unique and threatened entities that are confined to narrow geographical ranges and are very sensitive to climate change. However, their degradation or loss could affect regions outside their range. There is medium confidence that many of these unique and threatened systems will be affected by a small temperature increase. For example, coral reefs will bleach and glaciers will recede; at higher magnitudes of temperature increase, other and more numerous unique and threatened systems would become adversely affected.

19.8.2.2. Distributional Impacts

The impact of climate change will not be evenly distributed among the peoples of the world. There is high confidence that

⁴A 2°C warming from 1990 to 2100 would be a magnitude of warming greater than any that human civilization has ever experienced. Thus, “small” does not necessarily mean negligible.

developing countries tend to be more vulnerable to climate change than developed countries, and there is medium confidence that climate change would exacerbate income inequalities between and within countries. There also is medium confidence that a small temperature increase would have net negative impacts on market sectors in many developing countries and net positive impacts on market sectors in many developed countries. However, there is high confidence that with medium to high increases in temperature, net positive impacts would start to decline and eventually turn negative, and negative impacts would be exacerbated. Estimates of distributional effects are uncertain because of aggregation and comparison methods, assumptions about climate variability, adaptation, levels of development, and other factors. In addition, impacts are likely to vary between and within countries. Thus, not all developing or developed countries will necessarily have benefits or damages in unison.

19.8.2.3. Aggregate Impacts

With a small temperature increase, there is medium confidence that aggregate market sector impacts would amount to plus or minus a few percent of world GDP; there is low confidence that aggregate nonmarket impacts would be negative. Some

studies find a potential for small net positive market impacts under a small to medium temperature increase. However, given the uncertainties about aggregate estimates, the possibility of negative effects cannot be excluded. In addition, most people in the world would be negatively affected by a small to medium temperature increase. Most studies of aggregate impacts find that there are net damages at the global scale beyond a medium temperature increase and that damages increase from there with further temperature increases. The important qualifications raised regarding distributional analysis also apply to aggregate analysis. By its nature, aggregate analysis masks potentially serious equity differences. Estimates of aggregate impacts are controversial because they treat gains for some as cancelling out losses for others and because weights that are used to aggregate over individuals are necessarily subjective.

19.8.2.4. Extreme Climate Effects

The frequency and magnitude of many extreme climate events increase even with a small temperature increase and will become greater at higher temperatures (high confidence). Extreme events include, for example, floods, soil moisture deficits, tropical and other storms, anomalous temperatures, and fires. The impacts of extreme events often are large locally and

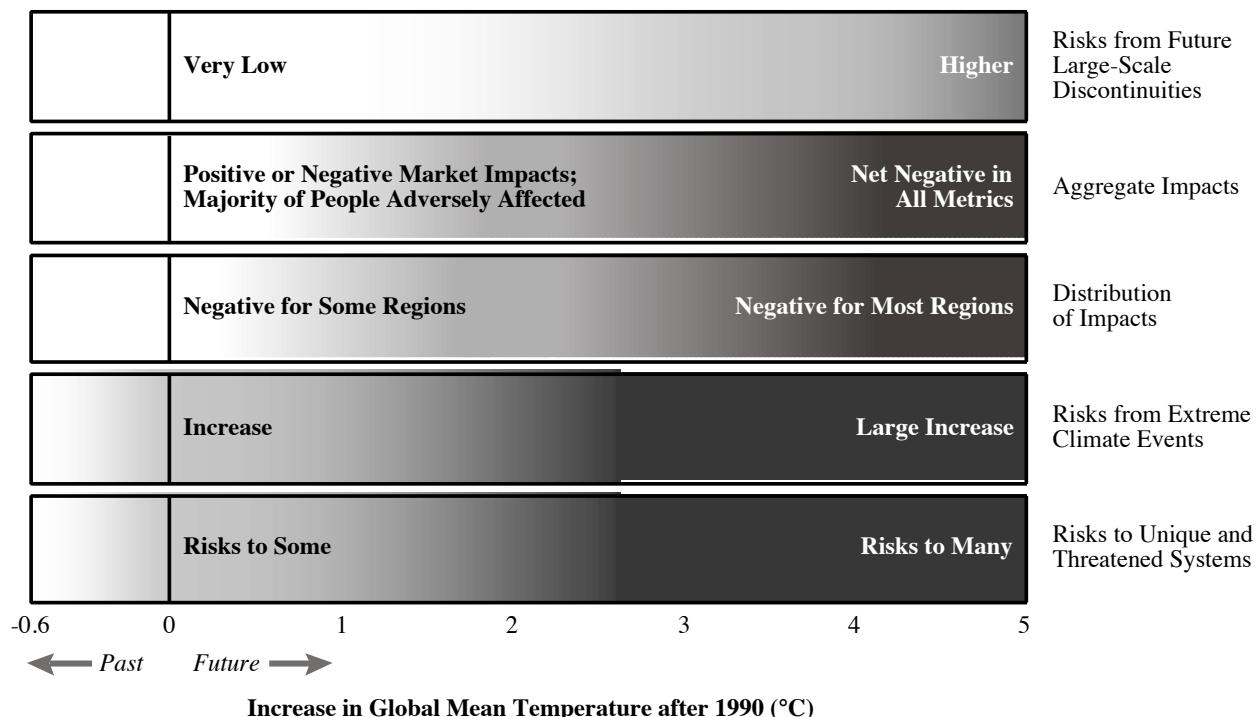

Figure 19-7: Impacts of or risks from climate change, by reason for concern. Each row corresponds to a reason for concern; shades correspond to severity of impact or risk. White means no or virtually neutral impact or risk, light gray means somewhat negative impacts or low risks, and dark gray means more negative impacts or higher risks. Global average temperatures in the 20th century increased by 0.6°C and led to some impacts. Impacts are plotted against increases in global mean temperature after 1990. This figure addresses only how impacts or risks change as thresholds of increase in global mean temperature are crossed, not how impacts or risks change at different rates of change in climate. Temperatures should be taken as approximate indications of impacts, not as absolute thresholds.
